(see Fig. 1) the head was sharply retracted, greatly resembling opisthotonos. The forearms were firmly flexed upon the arms while the hands were clenched, the fists coming in close contact either with the clavicles or chin. The thorax was arched forward, bending the ribs acutely almost to the point of breaking. The abdomen was slightly bulging and extraordinarily tense to the touch, giving the sensation of overstretched leather. The lower extremities were bent angularly and the feet either overlapped each other or were strongly flexed. Now and then a partial relaxation of the muscular contraction was observed (see Fig. 2) during which time the head straightened and the lower parts of the legs assumed a more natural position. Handling of the baby invariably increased the spasm, the muscular contracture often reaching extreme intensity, so much so that when the infant was put in reclining posture upon the palm of a hand it lay there still and rigid like a log of wood, for minutes at a time showing not a sign of muscular activity. However, notwithstanding this extreme hypertonicity of the entire body musculature the baby was able to urse without the slightest difficulty; in fact it evinced a desire to drink everlastingly. This symptom alone was amply sufficient to eliminate genuine tetanus or eclampsia, and it could readily be differentiated from tetany by the spasm in tetanism being almost continuous; by occurring in infants under three or four months of age, and by the peculiar general muscular contracture. Furthermore, the "triad of tetany" was absent. In tetanism the contracture ceases almost entirely during profound

Archives of Pediatrics, August, 1910.

sleep, in which state, by the way, these babies very rarely are. As a rule they are half awake, crying and tossing for something to appease their voracious appetite. The tetanic spasm is not fatal *per se*, though being reduced to so low a vitality the infants suffering from it ordinarily succumb to the accompanying gastrointestinal derangement or complications. This is especially true with babies treated in hospitals, where "hospitalism" or, in other words, lack of motherly, affectionate attention and exposure to germ-laden hospital-ward-air greatly contributes to the high mortality. With motherly care and strict supervision of the feeding quite a number of these infants recover completely, the spasm subsiding gradually with the improvement in their general health. The child under consideration made a perfect recovery (see Fig. 3). Finding that her mother's milk averaged about 5 per cent. of fat, I restricted the breast feeding to five minutes' nursing, at three to four hours' intervals, immediately to be followed by a two-ounce highly diluted malt soup feeding. The baby received also daily two intestinal irrigations of one drachm of sodium bicarbonate to

Fig. 3—The same child as shown in Figs. 1 and 2 three months later.

one quart of hot water. During the first week lavage was resorted to once a day. In the beginning I also administered ten drops of fresh infusion of digitalis t.i.d., hesitating to give strychnine owing to the muscular hypertonicity. The baby was kept very warm and, weather permitting, as much as possible outdoors. The mother's breasts were emptied regularly after each nursing by means of a breast pump and fats and sweets were eliminated from her usual diet. After a standstill of about ten days the child began to gain in weight, the gain becoming gradually more pronounced from week to week, so that at five months she weighed over eleven pounds. The general management of the case was, of course, slowly changed according to indications. It is self-understood that every case calls for special therapeutic measures. Bottle-fed babies should be put on suitable breast milk, or, if this is not obtainable, on properly diluted malt soup. In view of its tendency to develop gradually and to subside on prompt treatment, tetanism offers ample opportunities for its prevention in its early stages.

JUXTA-EPIPHYSEAL FRACTURE OF THE UPPER END OF THE HUMERUS.

A NEW POSTURAL TREATMENT.

By FRED H. ALBEE, M. D.,

NEW YORK.

ASSISTANT PROFESSOR (HEAD OF DEPARTMENT) OF ORTHOPEDIC SURGERY CORNELL MEDICAL COLLEGE; ADJUNCT PROFESSOR OF ORTHOPEDIC SURGERY, POST-GRADUATE HOSPITAL AND MEDICAL SCHOOL; PROFESSOR OF ORTHOPEDIC SURGERY, UNIVERSITY OF VERMONT; ETC.

The following is a report supplemental to one which appeared in the *Post-Graduate*, June, 1908:

Epiphyseal disjunction of the upper end of the

Fig. 1.—Case 4, before reduction. Note the three fragments. This plane does not show the marked forward tilting of the fragments which existed.

humerus is an accident of youth and occurs from birth to the twentieth year. It is generally conceded to be the most common of epiphyseal fractures. The most frequent period is from the tenth to the eighteenth year, and one authority states that it never occurs under the sixth year. In the writer's experience with a large number of fractures, separation at the epiphyseal cartilage has occurred in all bones rarely under ten years. The upper epiphysis of the humerus comprises the head and both of the tuberosities. It originates in three ossification centers, the head and the two tuberosities, which unite to form the epiphysis at an indefinite period. The union with the shaft takes place at about twenty Thus these fractures are situated between the anatomical and surgical necks and may be confused with a fracture of either. In some cases the dis-

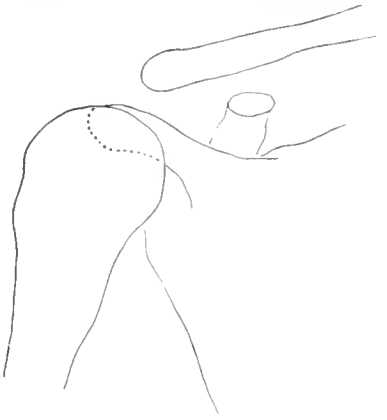

Fig. 2.—Case 4, after union. From a skiagram taken at the end of six weeks, after firm union had taken place.

placement does not occur until a few days after the injury. The diagnosis is usually made by palpation, which reveals the normal convexity of the shoulder, due to the presence of the humeral head in the glenoid cavity, thus distinguishing it from a

dislocation. The upper end of the lower fragment, somewhat rounded in its contour, can usually be felt under the coracoid process. The crepitus is of a softer quality than in cases of ordinary fractures, *i.e.* cartilaginous. Localized pain and swell-

Fig. 3.—Case 4, showing the dressing and position.

ing are present. A wrinkling of the skin, caused by the hooking of the upper end of the lower fragment into the subcutaneous tissues, is very characteristic. Abduction is especially limited and muscular spasm interferes with all motions. A high injury near the joint in a young individual, showing displacement forward and inward of the shaft, is very suggestive of epiphyseal disjunction.

This is the most difficult fracture of the humerus to treat by conventional methods, *i.e.* such as the plaster-of-Paris shoulder cap, the triangular axillary splint and Bardenheuer's extension method, there being a strong tendency always to a recurrence of the displacement. It is frequently impossible to hold the upper fragment in position without an open operation and wiring. One of the best known textbooks on fractures states that where there is much displacement the epiphysis of the humerus may have to be removed. These difficulties are due in the writer's opinion to the following causes: First, because of the position taken by the upper fragment, when complete disjunction has occurred, namely, the fractured end of this fragment is strongly rolled upward and forward and fixed in that position by the combined pull of the tuberosity muscles, and the counter impingement of the greater tuberosity against the acromion process, thus preventing further elevation. In old fractures remaining unreduced for any length of time, contractures of these muscles and the surrounding soft tissues are added to the already mentioned fixation forces. Codman in his paper on subdeltoid bursitis in the *Boston Medical and Surgical Journal*, May 31, 1906, was the first to publish the anatomical observation, that when the arm is rotated inward and elevated to the horizontal position the greater tuberosity impinges on the acromion process and prevents further elevation of the humerus on the scapula, and that rotation outward of the arm is necessary to allow further elevation on the scapula. This being true, it will be seen that it is not necessary to elevate the long fragment above a horizontal plane when attempting to adjust it in alignment with a position which the capital fragment takes by unopposed muscular pull.

Second, because there is no efficient method of reducing and holding the displaced upper fragment in alignment with the shaft, when the latter is persistently and invariably fixed to the side of the thorax. Splints fail because of the spherical contour of the fragment and the thickness of the overlying soft parts. Extension fails because of its inefficiency to overcome the antagonistic pull of the tuberosity muscles, chiefly from the fact that none of the arm muscles have their origin or insertion on this fragment and therefore presents the same mechanical condition as when a cylinder or sphere is placed between two tense cords. Simultaneous traction on the ends of these cords does not rotate the object between them. Again, when the short fragment remains rotated upward the upper end of the long fragment comes into apposition with the slippery side of the head of the humerus and therefore presents a small chance of union and a strong propensity to slipping and dislocation.

The following are illustrative cases:

Case I.—A. O., a young man, sixteen years of age, was seen by the writer May 25, and the following history was obtained: Past history negative. Fell from a tree April 13, 1906, striking on the left shoulder. The father claimed that he procured the best surgical talent obtainable and that the boy, in the two weeks following the injury, was etherized three times for the purpose of replacing fragments. A plaster-of-Paris shoulder cap with an auxiliary pad was used each time as a retaining apparatus. The reduction seemed satisfactory each time, but displacement had always recurred when the shoulder cap was removed. A physical examination at the time the writer saw him revealed that practically all motion between the humerus and scapula was absent. The injured arm was about one inch short. The shoulder was still considerably swollen. A

Fig. 4.—Case 7, Dr. Hawley's second case. This shows the tilted up position of the capital fragment.

sharp prominence could be felt directly under the skin, just to the outer side of the coracoid process, which was apparently the upper end of the lower fragment. The skin was dimpled and somewhat fixed over this prominence. No crepitus could be

elicited. A skiagram was taken which showed an epiphyseal fracture with much overlapping of the fragments. The upper end of the lower fragment was displaced upward and in front of the head. On account of the malunion and the above described

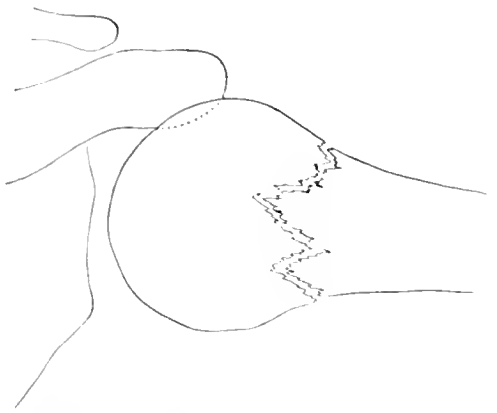

FIG. 5.—Case 7, Dr. Hawley's second case. From a skiagram taken, under the direction of Dr. Hawley, after the arm had been elevated anteriorly to a right angle with the trunk; it demonstrates the efficiency of that position in securing alignment in these cases.

difficulties of treatment, an open operation was decided upon. The fracture was exposed by a large U-shaped incision with its apex about 1½ inches above the insertion of the deltoid muscle. The skin, fasciae, and deltoid muscle were turned upward *en masse*. The *x*-ray findings were verified. The fragments were so firmly united in their faulty position that some difficulty was experienced in accomplishing a separation. The fractured surface of the head was found rotated strongly upward and forward, and firmly fixed in this position apparently by the pull of the tuberosity muscle upward, the contracture of muscles and soft tissues, and the counter impingement of the greater tuberosity against the acromion process. After the removal of a few spicules of bone the fragments were brought into good apposition by strongly elevating the arm forward and slightly outward, so as to come into alignment with the upper fragment. They were then firmly wired with silver wire. But upon attempting to bring the arm to the side, the head would not rotate downward, and the wire began to cut through. It was decided to fix the arm in this position anteriorly elevated to horizontal plane with the humerus rotated inward. The deltoid muscle was approximated by interrupted chromic catgut No. 1 sutures through its substance and its fascia which had purposely been left adherent. The shoulder and arm were then incorporated, with the elbow flexed to a right angle, in a plaster-of-Paris spica from the wrist to the umbilicus. The best technique for applying this cast to a patient under an anesthetic is to have the patient's head and shoulders pulled beyond the head of the operating table and that part of the body supported by an orderly sitting on a stool, with his foot on the round of the stool and his knee in the interscapular space. The thorax is best padded with complete sheets of cotton wadding. Traction is produced by an assistant pulling upward as the cast is applied. If the patient is not anesthetized for any reason he can be seated in upright position on a stool. Two old people not reported at this time have been treated in this way with very satisfactory results. The convalescence of the above case was uneventful. The patient was kept in bed one week. During this time the weight of the arm and the cast was taken from his chest by suspending the same to a pole placed longitudinally over the bed. This suspension, however, has not been necessary in any of the succeeding cases. The cast was removed at the end of three weeks and massage and passive motion were instituted. At the end of nine weeks the motions were practically normal. He was presented at the New York Academy of Medicine in February, 1908. The patient stated at that time that he considered the injured arm as good as the other. April 26, 1910, just four years after the operation, this young man came to the writer, complaining of a sensitive swelling the size of a walnut on the outer side of his shoulder. An *x*-ray examination was made which showed that the silver wire had dropped out of the humerus and was apparently located in an abscess which it had produced in subcutaneous tissues. On May 6, 1910, under ether, an incision was made over the fluctuating swelling and the wire and about four drams of thick pus were evacuated. The convalescence was uneventful. The function of the shoulder was not affected and the arm remained as good as the other. However, the fact that an abscess occurred about this wire four years after it had been placed there, and also the fact that the wire had dropped through and out of the bone, of its own weight, has, with other similar experiences induced the writer to practically never use metal plates or wire for immobilizing bone. Absorbable material, such as coarse kangaroo tendon, or large chromicized catgut, holds quite as well and quite as long as metal wire, because of the very early occurrence of absorption of bone about the metal. When direct splint action is needed such as a Lane plate, autotransplantation of live plates of bone has been practiced with the greatest of success, especially in long standing cases of pseudoarthrosis. Where live bone is used there is the opposite of absorption, viz., proliferation of bone is stimulated in the recipient bone as well as from the bone graft itself. However, as will be seen from the remaining cases herein reported, operations and retaining internal splints and sutures are rarely needed when the above described holding position is used.

The first mention which I am able to find of the use of abduction in the reduction of this type of fracture was by E. M. Moore of Rochester, N. Y., in 1874. He described his success in replacing the fragments by abduction, but emphasized his great difficulty in retaining the reposition when he brought the arm down to the side of the thorax for fixation in the old conventional way. He apparently always fixed the arm to the side. He also stated that some of his cases finally came to an excision of the head, on account of his inability to hold the fragments. In 1902 and 1908 Beck and Whitman, both of this city, respectively, described successful results from fixing the arm in a position of lateral abduction.

CASE II.—The next case which came under my care was a muscular young man of eighteen years. Previous history negative. While playing football, November 2, 1907, the patient dove for the ball, striking the ground on his left shoulder with a good deal of force. A severe injury resulted and the patient was taken to a nearby hospital, where attempts to reduce the shoulder were made, and a plaster-of-Paris shoulder cap with axillary pad was applied. The diagnosis at the time of reduction was dislocation. After six weeks the young man's family finally became anxious about the unsatis-

factory progress of the arm and the writer was consulted. The physical examination was almost precisely that of my first case. The upper end of the lower fragment, however, was not as near the skin. The arm was 1¼ inches short. The fracture was approached by the same route as the former case. The fragments were separated by means of a chisel. The bone ends were freshened as slightly as seemed wise for fear of destroying the epiphyseal cartilage. The fragments were then brought into apposition by the method described above. From my experience in the first case I felt perfectly safe in relying upon the position of anterior elevation to hold the fragments without aid from a metal suture. The wound was closed and a plaster-of-Paris spica was applied as before. The plaster was removed at the end of two and one-half weeks and massage with passive motion begun. This patient, within three months after the operation, in competition won a position on a college swimming squad. Also a few months later he played third base on a semi-professional baseball nine. He has continued to the present time as active in athletics as formerly, especially in basketball, swimming, and baseball.

Case III.—For the third case I am indebted to Dr. H. Winnett Orr, Lincoln, Neb. A young man, sixteen years of age, who had fallen from a scaffold in the barn, striking on his head and shoulder, with the arm thrown out to catch himself, was brought to Dr. Orr, June 26, 1908. A diagnosis of fracture of the upper end of the humerus was made. The next day an *x*-ray examination was made and it was determined that an epiphyseal separation of the upper end of the humerus had occurred. Dr. Orr, having read a few days before a report of the writer's first two cases, put the arm and shoulder up in a plaster-of-Paris spica in the position I have just described. A slight modification of extending the plaster over the hand was made. The patient was discharged from the hospital July 16, 1908. The arm was continued in the same dressing for four weeks, following which it was gradually lowered and passive motion was begun. At the end of eight weeks he was practically well, and Dr. Orr stated May 14, 1909, that while a difference can be noticed in the two arms, nevertheless for all practical purposes the injured arm is just as good as the other. He does general farm work and plays baseball as well as ever.

Case IV.—A boy, seven years old, fell two weeks before being seen by the writer at the Hospital for the Ruptured and Crippled. The parents stated that the boy was playing on the table and fell, striking his shoulder on the stove. The boy was seen by the family physician and the arm was put up in a plaster-of-Paris shoulder cap. An anesthetic was used. The family became skeptical about the progress of the arm and came to the hospital, May 12, 1909. A skiagram and a fluoroscopic examination were made, and a high fracture of the surgical neck was found, with marked displacement forward. The displacement was overcome and the arm was put in the anterior elevated position in a plaster spica from the umbilicus to the wrist. At the end of four weeks the plaster was removed and a skiagram was taken, which showed the fragments in perfect position. The patient was seen again at the end of five and one-half weeks, when very slight limitation of motion was found and the boy could do almost everything with that arm that he could with the other. There was no shortening.

Case V.—For this case I am indebted to Dr. J. M. Berry of Troy, N. Y., who has written me about his success in treating several difficult cases by the above described method. This case was that of a boy, sixteen years old, who sustained an epiphyseal fracture of the shoulder. It was put up under an anesthetic by Dr. Berry in the elevated anterior position. The case was reported in full in the *Albany Medical Journal* of March, 1911. An excellent functional result was obtained.

For the following nine cases I am greatly indebted to G. W. Hawley of Bridgeport, Conn.:

Case VI.—January 10, 1910, M. S., fifty-six years of age, a stationary engineer, while on his way to work slipped on the icy pavement and fell, striking left arm. After rising to his feet he found his left arm very painful and useless. Examination a few hours later showed evidences of contusion about the upper arm and shoulder, with marked bowing of the anterior surface of the arm in its upper third. False motion and crepitus were present at a point about 6 inches below the upper end of the humerus. At this point the ends of the fractured bone could be distinctly felt. The upper fragment was held in a position of moderate flexion and adduction, and could not be easily forced downward into alignment with the lower fragment. The effort was then made to bring the lower fragment into line with the upper, and it was found that this was possible only when the arm was raised forward and upward to the horizontal plane. It was observed that as the lower fragment was elevated the upper fragment was also carried upward until it became fixed by the head of the bone locking under the acromion process when the lower fragment readily came into alignment with it. Fixation of the arm in this position was maintained after the method of Albee for juxtaepiphyseal fracture of the upper end of the humerus by a plaster-of-paris dressing extending from the wrist to the umbilicus over the shoulder. The following day, radiographs were taken showing oblique fracture of the humerus about 6 inches from its upper end, with the fragments in satisfactory position. At the end of the fifth week the dressings were removed and massage with moderate motion was instituted. At the end of the tenth week examination revealed an apparently perfect functional and architectural result.

Case VII.—J. J., twenty-five years of age, fell from a second story window December 7, 1910. He was admitted to St. Vincent Hospital with the diagnosis of dislocation of the right shoulder and fracture of the right radius. Examination revealed a Colles fracture and an apparent upward and backward dislocation of the head of the humerus. A radiograph taken at once and examined in the wet disclosed a high fracture of the anatomical neck with the head in the glenoid fossa and the end of the shaft displaced upward, fully 1½ inches. The axes of the two fragments were at an angle of 90 degrees. The arm was then abducted slowly with strong traction, and a second radiograph taken and developed at once. This showed the two fragments in such good apposition that the line of fracture was difficult to make out. The fracture of the radius was then reduced and the shoulder was immobilized in Albee's position, the plaster being carried down to include the wrist. The fixation was removed at the end of the fourth week. Good union and in good position. Massage and passive motion. Practically normal function at seventh week.

Case VIII.—J. G., eighteen years of age, sustained a spiral fracture of the middle and upper thirds of the right humerus while playing ball, May 30, 1911. Examination showed a marked tendency for the upper fragment to draw upward and inward. Accurate alignment only obtained by drawing lower fragment upward and inward into line with upper fragment. Immobilization with plaster-of-paris in Albee's position, inward rotation, abduction, and flexion to 60 degrees. Radiograph gave satisfactory position. Perfect functional result.

Case IX.—G. D., five years of age, sustained an oblique fracture of the surgical neck of the left humerus, and a fracture of the middle one-third of the left femur, as the result of being run over by a wagon May 9, 1911. A radiograph of the shoulder with the arm rotated outward disclosed considerable overriding and angulation. With a shoulder sling and the arm placed in Albee's position under strong traction, plaster-of-paris was applied. On account of a similar strong tendency of the upper fragment of the femur to flex the thigh was immobilized in hyperflexion. The plaster was removed at the end of the third week. Final architectural and functional results perfect.

Case X.—T. G., eight years of age, was struck by an automobile and received a dislocation of the head of the left humerus with a fracture of the surgical neck. After radiographic examination and under ether the head of the humerus was easily reduced and the shoulder was immobilized in Albee's position. Recovery and full functional restoration.

Case XI.—M. B., twenty-six years of age. Oblique fracture left humerus, upper and middle one-third, sustained by a fall on sidewalk when intoxicated, May 15, 1911. Had previously, three years before, broken same arm. Arm immobilized in Albee's position, flexion to about 60 degrees. Radiograph showed slight overriding. Result excellent. Union delayed.

Case XII.—G. O'B., sixteen years old. Fracture surgical neck right humerus from fall from a shed, June 7, 1911. Marked tendency of upper fragment to flexion and adduction. Reduction and immobilization in Albee's position. Final appearance and function, normal August 1, 1911.

Case XIII.—M. B., forty-seven years of age. Fracture middle one-third left humerus; tripped and fell against a porch post. Some tendency of upper fragment to flexion. Alignment not satisfactory with arm at side. Immobilization in Albee's position because of better alignment, more secure fixation, and more comfort to patient. Excellent result.

Case XIV (Dr. Hawley's last case).—J. C., fifty-six years of age. Spontaneous fracture middle one-third left humerus. Carcinoma metastases of the bones from mammary cancer of six years' standing. During the night, while pulling up the bed covering, felt arm snap. Disclaims using any unusual force or sudden movement. An untreated scirrhus growth of right breast, firmly adherent to chest wall. Radiographic examination shows mottled areas of osteoporosis of shaft of humerus with nearly transverse fracture. Immobilization in Albee's position in 60 degrees flexion. At present in fixation.

Case XV.—An old woman, seventy years old. Fracture of high surgical neck of humerus. Was put up by the writer in the dispensary of the Hospital for the Ruptured and Crippled, without an anesthetic. On account of the weakness of the patient the plaster over the thorax was extended downward, so as to get its bearing on the pelvis. The functional results were excellent.

Case XVI.—D. T., a laborer, sixteen years of age, was admitted to the Muhlenberg Hospital, Plainfield, N. J., April 10, 1911. He had fallen April 6 from a bicycle and sustained an epiphyseal fracture of the upper end of the right humerus. The writer was called in consultation on April 11 by Dr. W. H. Murray. An x-ray examination confirmed the diagnosis, also, that the upper fragment was tilted upward and forward. The arm was put up, under ether, by the method herein described in a plaster-of-paris cast. The convalescence has been uneventful and very satisfactory. Final result excellent.

In view of the cases herein reported, the clinical observation of a considerably additional number, and the careful examination of a large number of radiograms taken both before and after treatment, in the writer's opinion the following are some of the advantages which may be claimed for this method of treatment:

1. This posture relaxes the prehensile or most of the strongest muscles of the shoulder and arm, namely, the pectoralis major, the biceps, the supraspinatus, the coracobrachialis, the strongest part of the deltoid, and the subscapularis muscles.

2. The lower fragment is controlled accurately and held very securely.

3. As in the case of a subtrochanteric fracture of the femur the capital fragment cannot be controlled on account of its shortness and the pull of the trochanteric muscles, therefore the lower fragment is placed in alignment with it in strong flexion and abduction. This treatment of the femur has for a long time been accepted, the same mechanical reasons holding here—that is, the long fragment of the humerus is placed in alignment with the position the short one mechanically takes on account of the pull of the tuberosity muscles.

4. If limitation of motion at the shoulder occurs this relation of humerus to scapula is the one of selection, both because it is a position of usefulness and because it permits the scapulothoracic muscles to functionate the most efficiently.

5. From the experience of Drs. Orr, Berry, Hawley, and the writer it is a more comfortable position than the classical position of fixation to the side of thorax.

6. The distal fragments can be controlled and the overriding prevented much better than in any other position.

7. The arm can be held and traction applied very easily while the plaster-of-paris cast is being applied.

125 West Fifty-eighth Street.

Carcinoma of the Cervix and Pregnancy.—E. Pisani reports a case of carcinoma of the cervix uteri in which pregnancy occurred. When labor pains began a cesarean section was performed and twins were delivered alive, after which the uterine body and ovaries were removed. The author considers that in such cases, in which the cancer is so diffused that cure is impossible, it is necessary to operate in the interests of the fetus. If there is a possibility of curing the mother by operation this should be done early, disregarding the interests of the fetus, whether it is viable or not. One should not await labor, nor should one induce it so as to operate by hysterectomy after or during the puerperium. The pregnancy should not be permitted to go to term. The best method of operation at any period of pregnancy is the abdominal one. —*Rendiconti della Societa Toscana di Ostetricia e Ginecologia.*

RECENT INVESTIGATIONS ON THE DISORDERS OF GROWTH.

THE phenomena of aberrant growth comprise one of the most interesting groups of clinical manifestations, nevertheless one which has not been adequately explored. The spontaneous character of growth, like that of life itself, has apparently diverted attention from the slight disturbances of the former function, while the exaggerated forms of arrested development alone have been deemed worthy of careful study. The minor degrees of defective development have been regarded as falling within the limits of normal variation, and for this reason the definite factors in their causation have been largely overlooked.

In the evolution of the undersized body heredity plays an important rôle. One need only mention the instances of stunted growth occurring in the offspring of the insane, the syphilitic, the tuberculous, the alcoholic, and the underfed. An undersized body is frequently the unmistakable index of a vitiated ancestral stock. The relentless struggle against the odds of overcrowding and other unhygienic conditions, operating through many generations, stamps its unmistakable seal upon an entire race or tribe. In addition to these inherited tendencies may be mentioned the effects of a vicious hygiene during infancy an dearly childhood, particularly an insufficient or inappropriate diet and a lack of fresh air, both of which are important factors inhibiting a normal development.

Former studies along this line have been conducted chiefly with reference to the phenomena of loss or gain in weight, while scant attention has been paid to the effect of malnutrition or of disease upon the normal increment in length. In a recent investigation W. Freund (*Jahrbuch für Kinderheilkunde*, Vol. 70, No. XXI) took up this phase of the subject and discovered a number of interesting facts. He found that temporary disturbances of nutrition resulting in loss of weight, as well as the acute infectious diseases, have no effect upon the increment in bodily length, but that long continued nutritional defects and chronic infections, such as tuberculosis, have a decided influence in the inhibition of the normal increase in stature. The effect of these conditions in causing loss of weight, however, is much more pronounced. Similarly, W. Birk (*Berliner klinische Wochenschrift*, 1911, No. 27) found that the cessation of growth accompanying malnutrition in the very young infant does not in any way compromise subsequent development, provided the nutritional defect is removed. In other words, the energy of growth in the young is an extraordinary one and is not impaired by temporary though total inhibition. In the older child this energy is still less vulnerable, and even the severest form of malnutrition cannot entirely check the process of growth.

This topic naturally leads to the discussion of the significance of infantilism, a subject to which considerable attention has been paid within recent years. This term was first used by Lasègue to denominate the persistence of the physical and mental characteristics of the child, and following him French clinicians have devoted to this subject considerable attention and have written extensively about it. They have recognized two forms of infantilism, that of Brissaud, or the myxedematous type resulting from thyroid insufficiency, and the type of Lorain which may be the result of any one of a great many causes. These are tuberculosis, syphilis, chronic malaria, and other infections; chronic drug intoxications; and cardiovascular affections such as mitral stenosis and underdevelopment of the arterial system (anangioplasia).

The tendency of modern writers is to broaden the conception of the term infantilism. It is no longer regarded as signifying a mere persistence of infantile characteristics, but is rather defined as a retardation of development. The disease begins chiefly in infancy and during intrauterine life, but may begin even after the age of puberty. It may be the result of various toxic or organic conditions as in the type of Lorain. On the other hand there is a group of cases which cannot be assigned to any discoverable cause and it is to this group that the term "essential infantilism" has been applied. The most important variety of this group has been described by Hastings Gilford under the name "ateleiosis." This is a retardation of development that may begin at any age, and results in the persistence of the physical characteristics that exist at the age of onset. If it begins in early childhood, the disease is easily recognized by the persistence of the short stature, large head, the features, and the intelligence characteristic of the young child. In the extreme cases the sexual organs remain infantile throughout life, and the individual retains the infantile characteristics. In those cases in which the sexual organs develop the facial traits of the mature individual may develop though the other characteristics of infantilism persist. Gilford (*British Journal of Diseases of Children*, July, 1911) believes that ateleiosis may be explained as a mutation, since it occurs spontaneously and is occasionally transmitted by heredity. On the other hand, symptomatic infantilism is a continuous variation or fluctuation and is not inherited.

The most comprehensive conception of infantilism is that which has been elaborated by the German clinicians. They regard it as a retardation of development that does not affect equally all parts of the body and that may manifest itself chiefly in a retardation of development of the nervous system, or of the cardiovascular system, or of the sexual or-

gans, etc. Tandler of Vienna was the first to point out the clinical types of partial infantilism, such as cryptorchism, while a host of German gynecologists have written voluminously on the rôle of infantilism in their particular specialty. Chief among these may be mentioned Hegar who has pointed out the close relationship between underdevelopment of the ovaries and the infantile type of uterus. In a recent monograph Paul Mathes deals largely with this phase of the subject. He believes that the term infantilism signifies not merely a retardation in organic development but also, and sometimes solely, a retardation or arrest in functional development. Therefore he regards the conditions of asthenia universalis congenita as a manifestation of infantilism, visceroptosis, scoliosis, flatfoot, etc., being included in this category.

Thus the term infantilism is one whose connotation has broadened beyond the definition given to it originally by the French observers. The increasing knowledge of the ductless glands has added a number of important factors in the etiology of infantilism. To the cases due to thyroid insufficiency have been added those caused by defective secretion of the suprarenals. Bramwell has described a form caused by pancreatic insufficiency, and lately Jameson Evans (*Birmingham Medical Review*, January 15, 1912) has pointed out the relation between some cases of infantilism and hypopituitarism. The type of intestinal infantilism described by Herter has been accepted by many other observers as a definite clinical entity. Not to omit mention of the form of infantilism associated with the "lymphatic-chloratic diathesis" described many years ago by Paltauf, one may conclude that the term infantilism has acquired a comprehensive connotation. It includes a most heterogeneous group of cases which have little in common except the retardation of development, which in turn may vary within wide limits and affect almost any part of the body.

THE VENEREAL PROBLEM IN THE ARMY AND NAVY.

THE venereal problem is insistent in all lands and in all classes of society, and particularly so in the aggregations of healthy, lusty young men which chiefly make up armies and navies. It is necessarily the object of those in authority to keep the physique and staying powers of soldiers and sailors at the highest possible standard. The sole *raison d'etre* of armies and navies is to be able to strike hard, and in order to do this its individual members must be constitutionally and physically efficient. Venereal diseases have been always the bane of both services and the despair of army and navy medical officers. The prostitute is generally recognized as the main means of dissemination of venereal diseases among soldiers and sailors, and therefore the logical way to counteract the evil effects of these infections would seem to be to exercise sanitary supervision and control over diseased women of the streets. However, this is no easy matter, for the views and prejudices of many must be taken into account ere steps of this character can be taken. Prostitution in this country is regarded from a different standpoint as regards its legal and municipal aspect from that of the majority of other civilized countries. In America the old theory of the English law is followed, that prostitution is merely a matter with which the police should deal as a nuisance. In Anglo-Saxon communities the question is not looked squarely in the face, facts are blinked at, and the consequence is that outward appearances alone are considered; decency is thereby preserved, but the sore is festering, and indeed the effects of this prudish conduct are becoming so obvious that social reformers everywhere are clamoring for a general movement calculated to cleanse our Augean stables. The labor will be one worthy of Hercules, but much can be accomplished by concerted endeavors.

In the *Military Surgeon*, March, 1912, Lieut-Col. J. R. Kean, Medical Corps, U. S. Army, has a long article in which he discusses the subject from the service officer's outlook. The article teems with figures and carries conviction. According to the author, the venereal records of the American Army for the latter half of the nineteenth century were far better than those of the British Army at home stations for the same period, and might have been favorably compared with those of any of the armies of Europe. But while these have been steadily improved the American Army has retrograded, until at the present time it maintains, and for longer than ten years has maintained, a shameful preeminence in this respect over the army at home of any of the great powers. Kean is of the opinion that the cause which tended most potently to this deplorable result was the granting of discharges to all soldiers who had served through the Spanish War. The places of most of the trained professional soldiers were taken by recruits. But by 1902 these should have become seasoned soldiers and the venereal rates for the home army should have approximately reverted to normal. Then the canteen was abolished and the soldier was driven outside the limits of the post, where he found fiery drinks and the lowest type of prostitutes.

A close study of British Army venereal statistics and comparison with those of our army statistics is made, for, as Kean truly remarks, these statistics are of the utmost importance on account of the close kinship of race, temperament, laws, and customs of the two nations, the similarity of ethical standards, and the susceptibility of both peoples to be moved by sentimental and emotional propaganda, especially when carried on in the name of morality. Statistics, then, seem to show that, while the British Contagious Disease Act certainly exerted a considerable amount of influence in controlling venereal diseases in the British Army, especially in the control of secondary syphilis, this beneficent action was to a great extent educational. In India Lord Kitchener waged a vigorous campaign against venereal disease in the Indian Army. He caused to be promulgated new cantonment rules with a view of controlling such diseases, and, needless to state, had the rules enforced with iron hand. The outcome has been most satisfactory. Of the European armies, the Russian Army has the best record for low venereal rates. The system is, as is everything Russian, of a beaureaucratic and paternal nature, which probably would not com-

lend itself wholly to the liberty-loving American and Briton. Prostitution in Germany is not forbidden by law, but it is subject to very strict rules and ordinances.

In this country and in Great Britain there are two parties who hold views diametrically opposed on the question. One party believes in regulating prostitution and the other does not.

So far as the army and navy are concerned, the question of controlling venereal disease therein resolves itself into the question of controlling prostitution. Lord Kitchener's policy with this end in view has been eminently successful among the British troops in India. There is no reason to doubt that similar measures would be equally effective in American army posts, at any rate in the Philippines. Kean advances a scheme for the American Army, one of the chief features of which is the recommendation that athletics and wholesome amusements should be encouraged. He also advises the education of the soldier in sexual matters and moral standards, the promotion of total abstinence, and methods of venereal prophylaxis for those who cannot be persuaded to practise continence. The methods for the navy at shore stations should be, of course, identical with those of the army. When afloat the crew should be carefully instructed in sexual hygiene and in the danger of promiscuous incontinence; the men on return from shore leave should be questioned as to exposure, and if this be admitted, methodical cleaning and disinfection should be ordered. Col. Kean states that the navy, like the army, suffers at present from the failure of the highest military authority to adopt a clear cut, systematic policy, vigorously enforced. He thinks that this is the most valuable lesson which can be learned from Lord Kitchener's administration in India.

False Amaurotic Idiocy.

Amaurotic family idiocy is now recognized as one of a considerable number of forms of mental defect associated with a definite material substratum. It by no means follows, however, that a similar association could not arise upon some other kind of soil, or that the amaurosis and idiocy could not be combined in the same subject by merely fortuitous association. In hereditary syphilis there might be a combination of mental defect with retinochoroiditis, both due to the transmitted dyscrasia. At a recent session of the Gesellschaft für Natur und Heilkunde, Dresden, Schob exhibited a patient with both idiocy and amaurosis in which it had been necessary to consider both the Tay-Sachs disease and syphilis before arriving at the conclusion that the association of the two conditions was probably due to neither of these affections. The patient was a girl aged 12, daughter of an imbecile mother, and of Christian ancestry. These two facts alone should serve to exclude the familial affection, for the latter is confined to the children of sound parents and seemingly occurs in Hebrews only. There is no mention of other children in the family. The patient was in every way normal at birth, and only upon beginning her school studies was mental inferiority apparent. At about this period epilepsy developed, and this and the mental state became progressively aggravated. The sight had failed within two years and at present the child showed a high grade of idiocy with atrophy of both retina and optic nerve. The serodiagnostic tests for syphilis were inconclusive, but all the evidences obtainable from the cerebrospinal fluid spoke against this affection. Some rapidly progressive process was evidently at work in the nervous centers, but to assume that it could only have been syphilis is much too narrow a view. The Tay-Sachs disease seems to be easily excluded. On the other hand the association of the intracranial and intraocular mischief could not have been accidental. The case was evidently of the border line type, suggesting that a number of toxic substances may be able to cause diffuse nerve lesions in predisposed individuals, and for the present it may be styled false amaurotic idiocy.

Chemotherapy of Pneumonia.

It is evident that ethylhydrocuprein, the quinine-like synthetic which is able to prevent and cure artificial pneumococcus sepsis in mice is not to be successful in pneumonia in mankind. There is nothing remarkable in this discrepancy for Hiss's leucocyte extract was also able to antagonize various kinds of mouse sepis and very good results were also claimed for it in human pneumonia; yet we no longer hear reports about it.. It is evident from a very recent discussion before the Berlin Medical Society (*Münchener med. Wochenschrift*, March 26) that the earliest reports as to the use of ethylhydrocuprein in man have led to disappointment. Morgenroth had given samples of it to numerous clinicians and one of the latter, A. Fraenkel, had tested it in twenty-one cases, in which there occurred a mortality of four, or about 19 per cent., which considering the mild nature of most of the cases was fairly high. Three double pneumonias and a deliriant case comprised the fatalities. Morgenroth then announced that further work with mice had shown the importance of the new synthetic against certain strains of pneumococcus. Fraenkel also stated that the remedy was by no means free from drawbacks, as several patients developed amblyopia. Meyer believed that the autolysis toxins formed at the crisis would antagonize a merely bacteriotropic therapy.

News of the Week.

Decrease in Infant Deaths.—The Department of Health of New York City announces that during the week ending April 20 there were 251 deaths of infants under one year of age as compared with 334 for the corresponding week of 1911. From January 1 to April 20 there were in New York City 357 less deaths under one year of age than during the same period of 1911. The decrease in deaths from diarrheal diseases during this time was 220. The department ascribes this decrease in part to the work of the infants' milk stations, of which the department at present maintains fifty-one, and in part to the campaign of education which has been carried on for the last two or three years.

Plague in Venezuela.—The State Department has received warning from the American Legation at Caracas, Venezuela, of an outbreak of bubonic plague there.

Charges of Concealment of an Epidemic of Meningitis.—From San Antonio, Texas, comes the report of a mild epidemic of cerebrospinal men-

nights with 20 deaths [illegible] of the conditions, the wife of an army officer [illegible] testing against the lack of proper quarantine regulations, states that most of the cases have originated in the schools which, nevertheless, are allowed to remain in session, that the Board of Health does not allow cases of the disease to be reported, and that little is done in the way of prevention, the excuse being that publicity might cause a panic. The city is a great center for the tourist travel of the Southwest, and the writer thinks that active measures should speedily be taken to protect those who are now kept in ignorance. The army post has been placed under effective quarantine, but the townspeople are apparently unaware of the existence of an epidemic.

Human Embryos.—The Department of Anatomy of Cornell Medical College announces that it would be glad to receive human embryos from any physician who may obtain such material. The embryos are to be used in a study of normal and abnormal development, and specimens will be duly credited to the persons contributing them. On notification to Prof. Charles R. Stockard, Department of Anatomy, Cornell University Medical College, a messenger will be sent for the specimen, which should be kept until called for in a moist cloth or placed in formalin.

Echoes of the "Titanic" Disaster.—The Daughters of Jacob of New York have decided to dedicate the entire hospital ward in their home to the memory of Mrs. Isidor Straus, one of their number, who lost her life when the *Titanic* sank. The ward will be known as the "Ida Straus Ward of the Home of the Daughters of Jacob."

At St. Vincent's Hospital, New York, a committee has been formed for the purpose of raising funds for the endowment of a pathological laboratory for the hospital in memory of Dr. William Francis O'Loughlin, surgeon on the *Titanic*. He was well known at St. Vincent's to which he had sent many patients in his capacity of physician in the service of the White Star Line for forty years.

Charitable Gifts.—By the will of the late Lewis S. Wolff of Rumson, N. J., Mt. Sinai Hospital and the Montefiore Home, New York, each receive $2,000, and the General Memorial Hospital $1,500.

In Honor of Koch.—The German Emperor recently ordered in recognition of the thirtieth anniversary of the announcement of the discovery of the *B. tuberculosis*, that the Royal Institute for the Study of Infectious Diseases in Berlin shall henceforth bear the name of Robert Koch. Prof. Koch worked at the institute for over twenty years. The Emperor says: "Prof. Koch by his discovery opened the combat against the greatest scourge of mankind, which has since been conducted with unprecedented success and has made suffering humanity his eternal debtor."

Dr. D. Bryson Delavan of this city has removed from 1 East 33d street to 40 East 41st street.

Dr. James W. Holland, professor of medical chemistry and toxicology in Jefferson Medical College, has resigned his chair and also the office of dean, positions that he has held for more than twenty years.

Suit for a Five Dollar Fee.—A physician of Albany has brought suit against Governor Dix's military secretary for $5, a fee for treating the Governor's butler. The doctor claims that the defendant summoned him to attend the butler and agreed to pay his fee. This last is denied by the defendant, who says that the suit should have been brought against the butler himself. Just how much it will cost the doctor to collect that $5 is uncertain.

Civil Service Examination.—The United States Civil Service Commission announces an examination to be held on June 5, 1912, to secure eligibles from which to make certification to fill two or more vacancies in the position of medical interne, Government Hospital of the Insane, Washington, D. C., at $600 per annum, with maintenance. Promotion is regular for satisfactory service. Applicants must be over twenty years and unmarried. Women will be admitted to the examination, although at present there are no vacancies for women. Further particulars may be obtained from the United States Civil Service Commission, Washington, D. C.

To Study Malaria.—The Tulane University School of Tropical Medicine has sent out a commission, under the leadership of Prof. Charles C. Bass, for the purpose of studying malaria, and of completing some experiments undertaken by Prof. Bass for which a large clinical material is necessary. The headquarters of the commission will be at Ancon, Panama, where Col. Gorgas has placed at their disposal all the facilities of the Canal Commission's hospitals and laboratories.

Sterilization.—The Louisiana State Medical Society recently adopted resolutions urging the enactment of a law to provide for the sterilization of criminals, male and female.

Appendicitis Prevalent.—Seven students at Cornell University operated on for appendicitis within three days is the record made at the Cornell Infirmary recently.

Diphtheria Closes School.—Seton Hall College at South Orange, N. J., has been closed on account of a small epidemic of diphtheria. One death and four cases in the infirmary was the report up to April 27, with a dozen students under observation. The rest have been sent to their homes.

Smallpox.—Several cases of smallpox in a mild form have been reported to the State Board of Health of New York from Whitney Point, Broome County.

The Johns Hopkins Hospital in Baltimore reports that during one week in April 132 patients were admitted to the institution, breaking all records. The largest number received in any one day was thirty-two.

Common Towel Passes.—The Massachusetts State Board of Health has issued regulations making it unlawful after June 1, 1912, to provide a common towel in any public building, hotel, theater, school, etc., or in any railroad station or car, or steam or ferry boat.

Preventorium Dedicated.—The Nathan Straus Preventorium for Children at Farmingdale, N. J., was dedicated on April 25, being the first of its kind in the country. Among the speakers at the exercises were Governor Woodrow Wilson, Dr. Abraham Jacobi, Borough President George McAneny of New York, and Mayor Imlay of Farmingdale. The buildings provide accommodations for over 500 children. In the temporary quarters 350 children have been cared for.

Sanatorium Burns.—The St. Louis County Tuberculosis Sanatorium situated at Midway, Minn., housing forty patients, was burned on April 21.

Bronx Maternity Hospital.—Some of the residents of the Borough of the Bronx, N. Y., have

started a campaign to obtain funds for the establishment of a free maternity hospital in the congested tenement house district in that borough. It is planned to develop the present dispensary maintained on Bathgate avenue into a first-class maternity hospital.

The Bronx Hospital Dispensary was formally opened on Saturday, April 20. Dr. A. Jacobi, who is one of the consultants of the Bronx Hospital and Dispensary, made the opening address. Speeches were also delivered by Dr. S. S. Goldwater, superintendent of the Mt. Sinai Hospital, and Anthony J. Griffin, Senator of the district.

American Proctologic Society.—The fourteenth annual meeting of this association will be held in the Hotel Chalfonte, Atlantic City, N. J., on June 3 and 4, 1912, under the presidency of Dr. John L. Jelks of Memphis, Tenn. Dr. Louis H. Adler of 1610 Arch street, Philadelphia, is the secretary of the society.

Michigan State Health Officers.—A meeting of the health officers of Michigan will be held at Ann Arbor on May 22 and 23.

Ohio State Medical Society.—The annual meeting of this association will be held in Dayton on May 8 and 9. A very interesting program has been prepared by the president, Dr. Horace Bonner.

Louisiana State Medical Association.—It has been found necessary to postpone the annual meeting of this society which was scheduled for April 23 and 24, because of the floods and high water throughout Louisiana.

Southwest Missouri Medical Society.—The annual meeting will be held at Springfield on May 8 and 9. Dr. H. S. Hill of Springfield is the secretary of the society.

Nebraska State Medical Association.—Arrangements have been completed for the meeting which will be held at Lincoln on May 9 and 10, under the presidency of Dr. Nesbit of Tecumseh.

Utah State Medical Society.—The next meeting of this society is announced for October 1 and 2, at Ogden.

Mississippi State Medical Association.—At the annual meeting held on April 9 to 11 at Jackson, the following officers were elected: *President*, Dr. S. W. Glass, Dublin; *Vice-Presidents*, Dr. J. C. Walker, Houlka; Dr. W. W. Parks, Louisville; Dr. E. C. Parker, Gulfport; *Secretary*, Dr. E. F. Howard, Vicksburg; *Treasurer*, Dr. L. B. Sparkman.

South Carolina Medical Society.—The sixty-fourth annual meeting was held in Columbia recently, the following officers being elected: *President*, Dr. Charles M. Reese, Charleston; *Vice-Presidents*, Dr. A. B. Knowlton, Columbia; Dr. D. M. Michaux, Dillon, and Dr. C. P. Aimer, Charleston; *Secretary-Treasurer*, Dr. E. V. Hines, Seneca. The next meeting will be held at Rock Hill in April, 1913. The association has endorsed the plan to erect a monument in memory of the late Dr. J. Marion Sims, the State Legislature having offered to appropriate $5,000 on condition that the Medical Association raise a like sum.

Second District (N. C.) Medical Society.—The following officers were elected at the annual meeting held in Williamstown on April 12: *President*, Dr. W. E. Warren, Williamston; *Vice-President*, Dr. E. M. Long, Hamilton; *Secretary-Treasurer*, Dr. K. P. B. Bonner, Morehead City.

Marengo County (Ala.) Medical Society.—At the annual meeting held on April 18 at Demopolis, the following officers were elected: *President*, Dr. J. B. Whitfield, Demopolis; *Vice-President*, Dr. A. B. Stone, Linden; *Treasurer*, Dr. E. B. Bailey, Demopolis; *Secretary*, W. H. Abernathy, Old Spring Hill.

Lewis and Clark Medical Association.—At a meeting of this association held in Helena, Mont., on April 10, officers were elected as follows: *President*, Dr. Rudolph Horsky; *Vice-President*, Dr. T. D. Tuttle; *Secretary-Treasurer*, Dr. B. V. McCabe. Dr. B. C. Brooke was elected a delegate to the Montana State Medical Society which will meet in Helena on May 8 and 9.

LaSalle-Frio Counties (Texas) Medical Society.—A meeting of the physicians of these counties was held in Cotulla on April 11, and a reorganization of this society was effected with the following officers: *President*, Dr. Glen Bartlett, Cotulla; *Vice-President*, Dr. Hock, Pearsall; *Secretary-Treasurer*, Dr. Graham, Cotulla.

Montgomery County (Md.) Medical Society.—At the annual meeting held in Rockville on April 18, the following officers were elected for the ensuing year: *President*, Dr. Frederick N. Henderson, Rockville; *Vice-President*, Dr. Charles H. Nourse, Darnestown; *Secretary-Treasurer*, Dr. John L. Lewis, Bethesda.

Tolland County (Conn.) Medical Society.—The one hundred and twentieth annual meeting was held in Rockville on April 16, when the officers for the ensuing year were elected, as follows: *President*, Dr. John P. Hanley, Stafford Springs; *Vice-President*, Dr. Wright B. Bean, Rockville; Secretary-Treasurer, Dr. E. P. Flint, Rockville.

Plymouth District (Mass.) Medical Society.—At the annual meeting held in Brockton on April 18, the following officers were elected: *President*, Dr. W. B. Brown, Plymouth; *Vice-President*, Dr. E. P. Linfield, Avon; *Secretary-Treasurer*, Dr. Alfred C. Smith, Brockton.

Windham County (Conn.) Medical Association.—The one hundred and nineteenth annual meeting of this society was held in Willimantic on April 18, officers being elected as follows: *President*, Dr. E. F. Perry, Putnam; *Vice-President*, Dr. Clarence E. Simonds, Willimantic; *Secretary-Treasurer*, Dr. W. S. P. Keating, Willimantic.

Georgia State Medical Society.—The following officers were elected at the annual convention held in Augusta: *President*, Dr. W. W. Pilcher, Warrentown; *Vice-Presidents*, Dr. J. W. Palmer, Ailey, and Dr. T. H. Hall, Macon; *Secretary-Treasurer*, Dr. W. C. Lyles.

Obituary Notes.—Dr. Rawley W. Martin of Lynchburg, Va., a graduate of the Bellevue Hospital Medical College, New York, in 1858, a member of the American Medical Association and the Virginia State and Campbell County Medical Societies, and president of the Virginia State Board of Health, died at his home after a brief illness of pneumonia on April 20, aged 77 years. Dr. Martin was a member of the Confederate Army, and at the battle of Gettysburg led the Fifty-third Virginia infantry in Pickett's charge.

Dr. Francis Bacon of New Haven, Conn., a graduate of the Yale University Medical School in 1853, a surgeon in the Connecticut Volunteers, and later Medical Director of the Army of the Potomac during the Civil War, an expert on yellow fever, having served during the epidemic in Galveston, Texas, in 1852, professor of surgery at Yale from 1866 to 1877, and a member of the Con-

necticut State and New Haven County Medical Societies, died at his home after a long illness on April 20, aged 80 years.

Dr. DANIEL K. PEARSONS of Chicago died on April 27 at the age of 92 years. He was born in Bradford, Vt., and was graduated from the Vermont Medical School at Woodstock in the early '40s. He had before that tried to work his way through Dartmouth College and at the end of a year was nearly ruined in health by overwork and a starvation diet of corn-bread, potatoes, and bacon. It was the recollection of these hardships that turned his mind in later years toward helping impecunious colleges and students. He went to Chicago to practise and later to Wisconsin. When about 40 years old he began to invest his small savings in Michigan timber lands and later in Chicago real estate, and in twenty years had accumulated a fortune of several million dollars. He then began to give his money away to struggling colleges throughout the West, from Chicago to Walla Walla, and in the South. By strenuous efforts in this line he succeeded in giving away over six millions and died, as he wished, in comparative poverty, with only about $30,000.

Dr. J. EVERETT LUSCOMBE of Fitchburg, Mass., a graduate of the Boston University School of Medicine in 1885, and a member of the Worcester Medical Association, died at his home on April 11, aged 67 years.

Dr. JOHN W. PECK of Amoret, Mo., a graduate of the Bellevue Hospital Medical College in 1865, died at the home of his son on April 9, aged 70 years.

Dr. SAMUEL FRY, formerly of Washington, D. C., a graduate of the George Washington University, Department of Medicine, Washington in 1902, and a member of the Medical Association of the District of Columbia and the American Medical Association, died at his home in New Orleans on April 9, after a long illness, aged 41 years.

Dr. HENRY C. HOLLOWELL, city physician of Quincy, Mass., a graduate of the Hahnemann Medical College and Hospital of Philadelphia in 1887, and a veteran of the Civil War, died at his home on April 13, aged 64 years.

Dr. LOUIS NELSON, assistant instructor in pharmacology in the Harvard University Medical School, Boston, died in the Eliot Hospital, Cambridge, on April 15, from intestinal infection with the "gas" bacillus contracted during the course of experimental work, at the age of 34 years.

Dr. ARNATT READING GULICK of Perth Amboy, N. J., a graduate of the Bellevue Hospital Medical College, N. Y., in 1888, died in the Queen City Hospital, New Brunswick, of pneumonia on April 25, aged 48 years.

Dr. EDWIN ROSENTHAL died of apoplexy at Philadelphia on April 22, at the age of 54 years. He was graduated from the Philadelphia College of Pharmacy, and in 1880 from Jefferson Medical College. He was assistant demonstrator of chemistry in his alma mater for a number of years. He was a member of the medical staff of Mt. Sinai Hospital. He was a member of the Philadelphia County Medical Society, the Medical Society of the State of Pennsylvania and of the American Medical Association. He was one of the first in this country to use tuberculin, and also diphtheria antitoxin.

Dr. TALBERT SLENEAU of Port Huron, Michigan, a graduate of the University of Michigan, Department of Medicine and Surgery, Ann Arbor, in 1883, and a member of the American Medical Association and the Michigan State and St. Clair County Medical Societies, died at his home after a long illness on April 21, aged 66 years.

Dr. ARTHUR JACKSON BREWE of Philadelphia, a graduate of the Jefferson Medical College in 1905, was among those lost with the *Titantic* on April 15.

Dr. MARTIN J. LUNN of Chicago, Ill., a graduate of the College of Physicians and Surgeons of Chicago in 1902, and a member of the Illinois State and Cook County Medical Societies, died at his home after a long illness on April 19, aged 42 years.

Dr. WILLIAM R. MOOD of Summerton, S. C., a graduate of the Vanderbilt University Medical Department, Nashville, Tenn., in 1888, and a member of the American Medical Association and the South Carolina State and Clarendon County Medical Societies, died at his home suddenly on April 21, aged 48 years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

LISTER'S WILL—SPIRITUALISM AND ITS MATERIAL OBLIGATIONS—ANGINA ABDOMINIS—IMMUNITY—OBITUARY.

LONDON, April 12, 1912.

THE will of Lord Lister (made in 1908) has been proved, the gross value of his estate being £66,166. He bequeathed £10,000 each to the Royal Society, King Edward's Hospital Fund, King's College Hospital, and University College Hospital, and states he does not wish his name to be in any way associated with these sums in future. He gives £20,000 to the Lister Institute of Preventive Medicine. His scientific manuscripts and sketches to Miss Godlee and Hugh Lister to arrange and then present to the Royal College of Surgeons. His orders, medals, decorations, etc., to the University of Edinburgh, expressly declaring his intention that the authorities for the time being are at perfect liberty to dispose of all or any part at any time or in any manner (*e. g.* by having medals melted down or diplomas or other writings destroyed) that may seem to them desirable. There are legacies to relatives and executors, and annuities to faithful servants, and the residue to his nephews and nieces equally.

The Harveian Society's annual oration this year was delivered by Dr. Claye Shaw, who took for his subject the "Material Obligations of Spiritualism and Allied Phenomena." I cannot say that he shed any great light on the way in which the topic has been regarded, but perhaps that is hardly to be expected. At any rate, he displayed some courage in tackling a number of obscure but continually disputed matters. At the outset he referrred to universal belief in the existence of a spiritual power or mysterious agency of a controlling kind and the material way in which this belief has been exploited. As to the ghost theory, he dwelt on the necessity of its physical obligations, concluding that is is impossible to accept the common notion, which is simple superstition. Spirit rappings and messages from the dead cannot be, and pretenses that there have been such things must be classed as impostures. Telepathy was then discussed and pronounced equally impossible. Next the relation of spiritual force to dead matter was considered. Any

such force could only have relations with living matter, and the upholders of "the occult" were altogether illogical inasmuch as they profess to be able to control what they regard as the higher spiritual essence through the lower, admitting it to be the baser, material. It was not a tenable hypothesis that the lower could control that which made it and by which it is ruled, and must therefore be higher. The ideas which have been put forward by spiritualists were always and in all respects material, and have never brought forth anything but absurd trivialities. The orator suggested a theory of his own that the eccentric projection of ideas was mainly responsible for the common notion of the externality of force. As to hypnotism and suggestion, they had no connection with a special force and might be practised by anybody anywhere.

The word angina has become so closely associated with the chest that we do not always think it necessary to add pectoris to signify the old English "breast pang." It has, however, been applied by Bacelli and some other continental writers to paroxysms of pain in the abdomen, and it seems possible that we may follow the example with our usual indifference to accuracy of nomenclature. Under the term angina abdominis, Sir L. Brunton and Dr. E. W. Williams read at the Medical Section (R. S. M.) an account of a case of severe seizures of pain on making any exertion, which reminded them forcibly of angina pectoris, only the pain was confined to the region of the umbilicus in every attack. The patient was a man of 68 with a history of glycosuria extending over 25 years and treated by Pavy and others. In August last pains which had troubled him at times for the previous 18 months, and were attributed to flatulence, became so severe that he consulted Dr. Williams and, with his advice, Sir L. Brunton. The attacks came on suddenly after exertion, as walking or playing billiards, and in other respects resembled angina pectoris. So trinitrine was tried and that at once cut short the paroxysms just as it does the pectoral attacks. The patient's sister had suffered for seven years in the same way and she took some of her brother's medicine, which proved equally efficacious in her case. Some of the foreign cures were said to have shown symptoms of tabes, so Dr. Williams examined the kneejerks and pupils. He found the sister's kneejerks normal, but the pupillary reflexes sluggish and contracted more than they should be. The brother's kneejerks were abnormally active, the pupils a good deal contracted and almost insensible to a bright light.

Dr. P. Weber remarked that a good deal had been written on the subject abroad and various names proposed for it, one being "dyspravia intermittens angiosclerotica intestinalis," or if the stomach was believed at fault, "gastrica." Surely this looks more like an attempt at description than a name. In some reports it is distinctly stated there was general arterial sclerosis with high abdominal blood pressure; in others the pain came on with desire to defecate, but only mucus passed. He mentioned one case with arterial sclerosis and high blood pressure relieved by nitrites. He had heard of diuretine being prescribed for such a condition, and a hip bath relieving.

Dr. Crookshank had such a case, which had been thought to be due to intestinal obstruction, and was relieved when the bowels acted. But later the patient died and at the postmortem they found extensive arteriosclerosis of the celiac axis with necrosis of the pancreas. This might have been due to the obliteration of the pancreatic artery, perhaps beginning as an "intermittent claudication," and he suggested that name as preferable to angina abdominis.

Dr. F. Taylor (President), asked if the condition might not be linked up with other paroxysmal abdominal pains such as we sometimes see at the beginning of diabetic coma. He did not like the word angina for it, as that meant more than pain—a suffocating pain.

In *The Bedrock*, a new scientific quarterly, Dr. A. M. Gossage gives its readers some remarks on immunity, warning them not too accept too readily some plausible ideas about it, such as that races develop it in proportion as they come in contact with diseases. Thus the comparative immunity from measles results from direct transfer from mother to child. If the mother had never had measles she could not convey a degree of immunity to her offspring. The immunity is individual, not racial. In malaria, of which he recognizes several kinds, the natives of West Africa or of India suffer less than visitors from Europe, and it might be thought that whites are more susceptible than colored races. But it is possible that adult blacks have acquired immunity through previous attacks from residing in the locality, and that there would be no difference between the two races at birth. This hypothesis would explain why white settlers who do not die become "salted," as it is called, after long residence in malarial districts. So, too, it accounts for the fact that colored children suffer and die from malaria. Indeed, it has been found that in some districts they suffer more than white children.

The death took place on the 5th inst. of Sir James Jenkins, Inspector-General of Hospitals and Fleets and Honorary Surgeon to the King, at the age of 93. He graduated M.D. at Glasgow University in 1839, entered the navy 1841, became full surgeon in 1854, staff surgeon in 1863, department inspector in 1872, and inspector-general in 1878. He was in charge of the naval brigade in the Crimea until the capture of Sebastopol. He was present at Kinburn, and landed to attend the wounded. He received the Crimean and the Turkish medals and the Legion of Honor. He was in the China War from 1857 to 1861, and awarded the medal with two clasps. He was made C.B. in 1867 and K.C.B. in 1887.

The death occurred on the 2d inst. of Dr. Angus Fraser, consulting physician to the Aberdeen Royal Infirmary, of which he had been a student as well as at the university there, graduating M.A. in 1858 and M.D., C.M., with honors in 1862. In 1902 the university conferred upon him the honorary degree of LL.D. He had filled various offices in the university, as assessor in the court and representative in the General Medical Council. So in the Royal Infirmary, from the resident offices upward to the consulting physiciancy and lectureship on clinical medicine.

Dr. J. Dixon Mann, Professor of Forensic Medicine at Manchester University and physician to Salford Royal Hospital, died on the 6th inst. He was a member of the General Medical Council and examiner in medical jurisprudence for the Oxford and the London Universities. He graduated M.D. at St. Andrew's in 1880 and was elected F.R.C.P. ten years later. His textbook of forensic medicine and toxicology reached a fourth edition. He con-

tributed to Quain's Dictionary, the Encyclopedia, *Brain*, and other journals valuable articles. He had been president of the Medical, the Pathological, and other societies in Manchester.

Dr. George Reed, a former physician of the Royal Salford Hospital, has also died this week, at the age of 78. He qualified in 1858 and took M.D., St. Andrew's, in 1862.

William H. Folker, F.R.C.S., consulting surgeon to the North Staffordshire Infirmary, died March 26 at the age of 85. He qualified in 1851. He contributed surgical papers to the journals and societies.

Dr. Charles James Wills, late medical officer H. B. M. Telegraph Department in Persia, author of the "Land of the Lion and the Sun" and other works on modern Persia, died at Hove on March 24, aged 69. He qualified in 1864 and graduated at Aberdeen, M.D., 1866; M.D., 1867.

Dr. John Morison, consulting physician to the St. Albans and Mid-Herts Hospital, died on the 1st inst. He took M.R.C.S., England, and M.D., Edinburgh, in 1865, and D.P.H., Cantab., 1875. He held the M. O. H. and other appointments. He was deeply interested in natural history and contributed many papers to the transactions of the county society devoted to that subject, of which he had been president.

Dr. P. R. J. B. Minns died on the 31st ult., aged 71, at Thetford, where he settled in 1862 and practised until 1910, when he retired. He was M.D., St. Andrew's, 1862; for several years physician to the local hospital, and a member of the Town Council.

OUR CANADIAN LETTER.

(From Our Regular Correspondent.)

SMALLPOX IN CANADA AND NEGLECT OF VACCINATION—BILL INTRODUCED INTO ONTARIO LEGISLATURE TO PROVIDE FOR THE EFFICIENT VACCINATION OF SCHOOL CHILDREN—NEW PUBLIC HEALTH ACT FOR ONTARIO—DECREASE OF CONTAGIOUS DISEASES IN ONTARIO—ANNUAL REPORT OF BRITISH COLUMBIA BOARD OF HEALTH—REPORT OF MEDICAL OFFICER OF HEALTH OF MONTREAL—MEETING OF THE CANADIAN HOSPITAL ASSOCIATION IN TORONTO—HOSPITAL BUILDING IN TORONTO—VENTILATION OF SCHOOLS—PROPOSED AMENDMENT OF MEDICAL ACT OF QUEBEC IN ORDER TO ADMIT BONE SETTERS TO THE PRACTICE OF MEDICINE—TORONTO MEDICAL GRADUATE AT BELLEVUE—MEETING OF THE ONTARIO MEDICAL ASSOCIATION IN TORONTO.

MONTREAL, April 23, 1912.

As regards smallpox in Canada, the situation shows no improvement, but rather matters in this direction appear to be going from bad to worse. The disease exists in many parts of the Dominion, and in certain districts, notably in the province of Quebec, is remarkably prevalent. Furthermore, reports now at hand seem to indicate that the malady is becoming epidemic and the type virulent. In British Columbia three hundred cases or so have been reported during the year. In Ontario a considerable number of cases have been reported during each recent month. As mentioned in a former letter, much of the prevalence and spread of smallpox is attributed to neglect of vaccination. In connection with this question of vaccination, a great deal of dissatisfaction has been aroused among the anti-vaccinationists by a bill recently brought forward by the Hon. J. W. Hanna, in Ontario. This bill contains two very important changes from the former Ontario "Vaccination Act." Sections 16 and 17 have been omitted, or rather replaced by one section. Section 16 in the previous act provided that it should be lawful for school trustees to enforce the production of a certificate of vaccination before allowing children to attend school. Section 17 provided that where it was thought necessary by the medical officer of health, owing to the presence of smallpox, he might require a certificate of vaccination from pupils attending high schools, colleges and universities. In the section which replaces these sections the provision for vaccination has been made uniform, the government taking the view that no distinction should be made between private and public schools, and that the health authorities, in preference to the Board of Education, should exercise medical control over pupils of schools, seeing that to them falls the duty of enforcing the health laws. Thus the vaccination of children has been taken away from school trustees and placed in the hands of the health authorities, where it obviously belongs.

A new public health act for Ontario has been introduced into the Legislature by the Hon. W. J. Hanna, doubtless stimulated by the suggestions of Dr. McCullough, the Secretary to the Board of Health of Ontario. This bill provides that the Province be divided into ten districts, with a great deal of the power concentrated in the headquarters of the Board of Health, Parliament Building, Toronto. District health officers, who are to be paid an annual salary not exceeding $2,500, with $1,000 for expenses, are to be created; local boards are to be reduced in number; compulsory notification of tuberculous diseases is provided for, better inspection of meat is demanded, and altogether many excellent reforms are recommended.

The February returns of the Provincial Board of Health of Ontario show a reduction of nearly 60 per cent. in the number of contagious diseases over the corresponding month of the previous year. The total number of cases was 719, with 130 deaths, compared with 1766 cases and 224 deaths in February, 1911. The reduction in the number of cases of scarlet fever was from 610 to 108; of diphtheria, 213 to 176. Few cases of typhoid fever occurred, a gratifying change from the records of 1911. Dr. Fagan, of British Columbia, issued recently the annual report of the British Columbia Board of Health. He points to the menace of infectious disease, owing to the large immigration and to the position of the province on the seacoast. He also makes certain recommendations with regard to the sanitation of the city of Victoria, and refers in particular to the evils existing in the logging, railway, and mining camps in the vicinity.

A report has just been presented to the Board of Control of Montreal by Dr. Laberge, medical officer of health of the city, in which he shows that out of a total of 59,688 children examined by the municipal health authorities during the past year, 27,349, or almost 50 per cent., were in an unhealthy condition. Of this number, 19,843 were suffering from mouth affections, defective and decayed teeth and gum affections. Two thousand, one hundred and forty children were found to be unvaccinated.

The sixth annual meeting of the Canadian Hospital Association was held in Toronto on April 4, 5, and 6, last, under the presidency of Dr. H. A. Boyce.

Kingston, Ont. The program was lengthy and many papers of much interest were read. Dr. Bruce Smith conducted a round table conference and question drawer, and stated in the course of his remarks that the hand picking process in the running of hospitals has got to cease. This is to say, that it must cease in Ontario, as the new Public Health Act, which will shortly become law in that province, provides that any hospital refusing to accept cases of tuberculosis for treatment will not receive a grant from the government. In a paper on the administration of the smaller hospitals, Miss M. M. Carson, of Brantford, made a plea for the more considerate treatment of nurses and employees of hospitals. Dr. E. H. Young, of Kingston, Ont., read a paper on the hospitalization of asylums, and Dr. C. K. Clarke, discussing this paper, said that the general public has felt a great horror of the insane, and until they got over that horror the hospitalization of asylums will be checked. According to the speaker, the curse of the whole service in the asylums for the insane in Ontario has been politics, and until politics are eliminated from the service it will continue backward. Miss Amy Armour, of New York City, contributed a paper on hospital housekeeping, in which she demonstrated the necessity for expert dietitians and for training nurses to be expert dietitians. She urged strongly the need for more and better food for nurses, the universally poor food served to nurses being, in her opinion, one of the reasons for the decreasing number of pupils available. The relation of the hospital to the public was discussed by Dr. Helen MacMurchy, who drew attention to the efforts through hospitals to establish a race of healers and to advance medicine. Miss Brent, superintendent of the Hospital for Sick Children, Toronto, discussing the question of hospital treatment of babies, said that babies do better in their homes than in hospital, and the policy of those responsible for the management of the Sick Children's Hospital in Toronto, was to send the babies home as quickly as possible and have the district nurses follow them up and educate the mothers as to the proper food for babies. If the babies require further treatment at any time they are brought back to the hospital, but returned to their homes at the earliest opportunity. More district nurses, according to Miss Brent, are needed in Toronto. Perhaps the most interesting statement made at the meeting was that by Dr. Hurd, president of the American Hospital Association, who declared that the Canadian meeting was better attended and the papers of a higher standard than those contributed to the American meeting. Dr. Hurd also stated that in his opinion the standard of nurses is lowering. The better class of girls will not train because the strain is too great. Unless the hours on duty are shortened and better food is served, the standard will continue to lower. At present, said Dr. Hurd, many of the nurses who graduate from hospitals are no higher in standard than those who receive their diplomas from a school of correspondence, that has a course of only a few weeks. The officers elected were: President, Miss M. J. Morton, Collingwood; vice-presidents, Dr. Donald Robertson, of Ottawa; Dr. H. A. Boyce, of Kingston; Miss Rogers, of Niagara Falls; Dr. Lincoln, of Calgary; Dr. G. H. Young, of Kingston; secretary, Dr. J. N. G. Brown, Toronto; treasurer, Miss Matheson, Toronto.

Hospital building in Toronto proceeds apace, and soon instead of being regarded as a city in which the hospital accommodation was inadequate and not commensurate with the size and wealth of the chief city of the English speaking provinces, Toronto will be looked upon almost as a model so far as hospital buildings and equipment are concerned. A new site for the Toronto Hospital for the Insane has been chosen. The pathological building of the magnificent general hospital now in course of erection in Toronto is open. A new wing of St. Michael's Hospital was opened on March 19. It contains eleven public wards, 28 semi-private and 16 private wards. A fine isolation hospital is to be built, the Western Hospital is being enlarged, and last but not least, the splendid Hospital for Sick Children, the best built and equipped in the world, and whose erection and upkeep were largely due to the generosity and public spirit of J. Rose Robertson, proprietor of the *Evening Telegram,* is to be considerably added to. The addition is to consist of an out-patient department, infectious department, and pathological department. The top floor of the existing building will be used for operating purposes, and will be provided with new equipment. The alterations will cost about $250,000. Dr. A. B. Le Mesurier, of the staff of the Children's Hospital, Toronto, and a medical graduate of Toronto University, has passed the competitive examination for house surgeon at Bellevue Hospital, New York, at the head of the list.

A proposal to amend the Medical Act of the Province of Quebec in order that bone setters might be allowed to practise was defeated on February 29, by a vote of 32 to 23. The Ontario Medical Association will hold its annual meeting in Toronto on May 21 to 23. The chief feature of the program will be a symposium on headaches, a symposium on exophthalmic goiter, and an illustrated lecture on experimental medicine by Professor Alexis Carell, of the Rockefeller Institute.

Two Cases of Precocious Cerebrospinal Syphilis, One Occurring after Salvarsan, the Other with Post-Mortem Findings. A. Myerson.

Chronic Duodenal Ulcer.—H. S. Rowen states that the usual history of a case of this condition is that of a young male adult who develops symptoms of stomach trouble, marked by bitter, sour, acid belching and regurgitation and pain coming on at from two to three hours after meals and relieved by taking food. These spells gradually begin to recur at closer and closer intervals. Vomiting is almost unknown, and hemorrhage may be disregarded in the early diagnosis and considered as a late complication. Physical examination is practically negative.

Diagnosis of Solitary or Inactive Kidney or Blocked Ureter.—E. Garceau states that if one can totally, effectually, and continuously plug one ureter with an appropriate catheter, at the same time laying another catheter in the bladder, one will be sure of collecting the total output of urine from the kidney in whose ureter the catheter has been placed; at the same time, if urine is drawn from the vesical catheter one will know that a kidney discharging

urine exists on the opposite side; if no urine is drawn with the vesical catheter one will know that one of the following conditions is to be reckoned with: (1) solitary kidney; (2) blocked ureter, from stone, kink, obliterative disease, etc.; (3) a kidney inactive and non-secreting from previous disease. Having determined the absence of urine on the suspected side, it remains to make a differential diagnosis. If the patient has never had any symptoms whatever on the side in question the probability is that the condition is one of absent kidney, especially if no ureteral orifice can be found in a smooth bladder. Blocked ureter may be of the acute or the chronic variety. The acute form is usually due to stone. Here the fulminating symptoms, colic, local tenderness and general disturbance, leave no doubt as to the diagnosis. In the chronic form, also usually due to stone, the *x*-ray will be of assistance; also a history of previous pain in the kidney together with other localizing symptoms. A kidney inactive and non-secreting is diagnosed by the previous history. If the patient has had renal pain, if there has been a tumor, and especially if there has been abundant pyuria in former times, one may suspect some suppurative process which has gradually destroyed the kidney and has rendered it inactive.

Mental Hygiene and the Special Child.—B. C. Downing states that neither heredity, environment, nor personal choice alone explains the facts of social life. One of the most significant statements of Dugdale in his book on the Jukes family is: "The tendency of heredity is to produce an environment which perpetuates that heredity." This seems to be largely overlooked by the present students of heredity in man, who stand for eugenics in the United States. The pioneer workers in the field of the feeble-minded and insane in the United States were influenced by this statement of Dugdale, which is backed by two significant facts: "One pair of the Jukes family moved away from the original home, and in the new neighborhood the children developed fairly well. One of the women who was both a harlot and a criminal died in the poorhouse leaving a daughter a year old. The child was adopted into a normal family and lived a normal life." This side of the story of the Jukes needs to be better known. Preventive eduction and preventive medicine should work hand in hand. Open-air hospital schools for neurotic children should be established in every city.

Etiology of Perineal Lacerations.—By J. C. Edgar. (See MEDICAL RECORD, March 23, 1912, page 570.)

The Use of Spinal Fluid in the Treatment of Chronic Syphilis.—W. Browning and W. Lintz point out that the antibodies or immune bodies are recognized as curative agents in specific affections. During the earlier and systemic period of lues the antibodies appear in the general circulation and not in the spinal fluid. In the later spinal and parasyphilitic stages this tends to be reversed; the antibodies then being in abeyance in the general circulation, but occurring in somewhat concentrated form in the spinal fluid. The spinal subarachnoidal sac in the human subject has no absorbents. It consequently retains whatever material accumulates in it. During the active hours of life this is practically a suspended sac, a kind of settling tank for the cerebrospinal fluid and its ingredients. Not only biologically (as exemplified by the Wassermann test), but even macroscopically the spinal fluid in these cases usually shows that it carries abnormal constituents. Antibodies and antigens are known to exist in a solution in a colloidal state, and therefore cannot diffuse through any retaining membrane. Consequently those in the spinal sac cannot reach injurious toxins or organisms in tissues near or far. The rational thing then is to transfer them from this inert position to the general circulation and thus give them a chance to exert their proper activity.

Dorsal Root Section in Treatment of Spastic Cerebral Diplegia.—By L. P. Clark and A. S. Taylor. (See MEDICAL RECORD, Vol. 80, page 643.)

The School and the Doctor.—G. Straubenmüller states that if the duty of the school physician outside of the detection of contagious diseases is to be advisory and preventive; if he is to help teachers and principals in the treatment and training of children by expert advice, based on personal observation; if he is to assist in determining the point of mental fatigue, beyond which a child cannot go without harm to itself; if he is to determine the causes of the increase of myopia as the children advance in school; if he is to visit classrooms to study his problems—then there is needed a co-operation between school and doctor quite different from that which prevails at present under systems devised by boards of health in this country. As no one can serve two masters equally well at the same time, as the doctor's relation to the school department in his new duties will be closer and more intimate than to any other city department, as his recommendations in most cases will concern the school authorities more than the authorities of the department of health, it is quite obvious to which department he should be assigned. This work calls for trained physicians and for mature judgment. Even if we did not know of the experience of other large cities, common sense would indicate that the young and inexperienced physician, now usually assigned to the schools, with no training for this higher kind of work, could not possibly measure up to the right standards.

Intravenous Administration of Salvarsan.—S. H. Likes and H. Schoenreich state that the apparatus which they employ is very simple and consists of a graduated syringe, with metal plunger and slip-on joints, a detachable two-way stopcock, two pieces of rubber tubing about 30 centimeters in length, a glass rod, a pipette, a 250 c.c. graduate, and two medicine glasses. The ampoule of salvarsan is placed in one of the medicine glasses previously filled with alcohol. The powder is prepared in the graduate according to the official directions. The advantages of the graduate are, first, mixing the powder in this receptacle prevents pouring and repouring, all of which help to contaminate the fluid. Second, being of thick glass, and being used immediately after sterilization, it maintains the heat of the salvarsan solution more uniformly and longer than a thin beaker, or it may be conveniently placed in a basin of warm water during the process of injection. Third, it is simple and inexpensive. The stopcock is connected to the syringe, and the rubber tubes are connected to the stopcock. By introducing the tube ends into the medicine glass, which has been previously filled with saline, the syringe and rubber tubes are filled with the latter, and so manipulated as to expel all air. To one rubber tube is attached the needle and the other is placed in the salvarsan solution. Thus the operation is simple; one operator holds the needle very steadily, whereas the other manipulates the syringe.

Pseudomalarial Types of Pyelitis.—D. Vanderhoof states that of forty-seven cases of pyelitis which he had seen during the past five years, twenty-one had been treated for malaria. The clinical features of these two affections may be almost identical. The differentiation, however, is not difficult, but the confusion of the two conditions will continue until physicians realize that quinine is a specific in malaria, and that it is useless to continue this remedy if the febrile disturbance persists. Furthermore, quinine, even in moderate doses, is irritating to an infected kidney. The constitutional symptoms of a low-grade chronic infection of the genitourinary tract simulate pulmonary tuberculosis, but in the absence of cough the condition is often regarded as a chronic malaria. The urinary findings in these cases may appear almost insignificant, but a urine that is apparently clear on gross inspection will show the presence of a few pus-cells, often accompanied by an occasional red blood cell. Pyelitis is the cause of many unexplained fevers, and this is especially true in the case of young children.

Germicidal Action of Basic Fuchsin.—E. S. May concludes from the results of his investigations with basic fuchsin that this is a germicidal agent which is more powerful than phenol (carbolic acid) and one which has a greater diffusibility and is less toxic. It has a marked stimulative action on epithelial and granulation tissue growth.

Malignant Pneumococcus Tonsillitis.—L. K. Hirshberg states that about the second week of January, 1912, it became evident in Baltimore that an unusual type of tonsillitis, with adenitis, peritonitis, and septicemic complications was epidemic. Physicians practising internal medicine could not fully differentiate the variety of tonsillar-pharyngeal infection prevailing from the common streptostaphylococcic variety. The most striking clinical picture in this epidemic was the sharp onset, with the invasion always in the throat; general adenitis; great virulence; the fulminate type of death in forty-eight hours in the lethal cases; the impossibility of proving milk, water, or food responsible in the spread of the epidemic; and the constant presence of the pneumococcus as a possible causative organism.

Multiple Diverticula of Ileum.—F. E. Walker reports the case of a girl, aged eleven years, who was suffering from typhoid fever. She complained of pain in the appendiceal zone, and within ten hours the pain was so marked as to signify an intense infection and inflammation, having all the appearance of an oncoming rupture. The pulse and temperature rose steadily, the thermometer registering 106° F.; the pulse was 164. Vomiting set in and was profuse. An incision of liberal length was made along the outer border of the rectus muscles. A large amount of straw-colored fluid was released and a portion of the omentum, completely free from any adhesions, presented itself in the opening. The cecum was almost rigid and the appendix was not visible. A large semisolid and irregular-shaped mass was felt about two inches from the ileocecal valve; it consisted of the apendix, greatly enlarged and inflamed and firmly adherent to the under surface of the ileum and to one small and one large diverticulum of the ileum. A third diverticulum was in close proximity to the tip of the appendix, but not attached to it. The large diverticulum was filled with a fecal mass. The tip of the appendix carried three small concretions. The base of the appendix was slightly gangrenous, the body and tip were injected and the blood-vessels stood out prominently. The appendix was removed. The small diverticulum was pursed into the bowel, while the other two pouches were removed, inverted and sutured over as in an enterostomy. All the symptoms rapidly subsided after the operation; the wound healed nicely, although the typhoid condition ran its usual course, and the patient finally recovered sufficiently to return to her home.

Orchitis Secondary to Tonsillitis.—I. H. Prouty reports a case of orchitis which was in all probability a metastatic infection derived from the primary foci in the tonsils. In view of the bactericidal properties of hexamethylenamine when decomposed within the body, it occurred to the author that possibly the drug might favorably influence the course of the orchitis. What appeared at first to be a severe inflammation of the testicle very rapidly improved within forty-eight hours after the administration of the drug was begun.

Telegraphists' Cramp. An Extract from the Report of the Department Committee, General Post Office, on the Subject, with Additional Matter. H. T. Thompson and J. Sinclair.

Skin Eruptions.—H. G. Adamson states that the toxic erythemas, urticarias, and purpuras may be regarded as inflammatory reactions to the action of poisons, which act particularly upon the vessel walls and upon the tissues around. Possibly these poisons are toxins or products of living cells, either introduced as such or manufactured by the damage of the living cells by chemical or physical agents—i. e. they are foreign proteids. These foreign proteids act as do the toxins of microbes. They give rise not only to the local reactions (seen in the erythematous rashes) but to general reactions of defence. Hence they tend to produce a condition of hypersensitiveness, which is really the result of an effort of the body to rid itself of alien proteids, a stage toward the production of immunity.

Secondary Infections in Pulmonary Tuberculosis.—A. C. Inman concludes that in nearly every case of open tuberculosis of the lungs the tubercle bacillus is the predominant infecting agent. The blood examinations have shown that "secondary infections" do occur. In all cases "resting febrile" there was evidence of such infection. Even in the "ambulant afebrile" group such infection could not be excluded. The temperature chart alone cannot determine the presence or absence of a secondary infection. A consideration of the morbid anatomy of advanced tuberculosis, and of the uncontrolled autoinoculations spontaneously occurring in such cases, precludes the hope of a successful issue from specific treatment directed against the secondary infections; the situation is more encouraging in afebrile cases.

Treatment of Condylomata Acuminata.—D. Watson states that the treatment which has been found to be most simple, effective, and free from objection is the application of lactic acid. The mode of employment depends upon the condition present. In the male circumcision is performed when necessary, pedunculated warts may be removed with scissors, and pure lactic acid is applied to the base after the bleeding has been controlled. Other growths are treated with a continuous 1 per cent. wet dressing or the occasional application of a strong solution. In the female, when there

are several large masses, each portion is isolated and [illegible] surrounded by strips of lint wet with a ½ to 1 per cent solution. The base of these growths may in addition be touched at intervals of a few days with the pure acid. Smaller growths are painted with the undiluted acid or a strong solution, and when there is a large field of minute growths the wet dressing is employed. The dressings are changed as frequently as the amount of discharge necessitates, and at each change the parts are thoroughly bathed with an antiseptic, in the case of females a sitz bath being used. The largest masses wither and drop off, small growths are inhibited, and cure results without the formation of any cicatrices and without pain. The only disadvantage the author has encountered in the use of lactic acid is the occasional occurrence of a general erythema when the treatment is pushed too energetically. This erythema is of trifling significance and quickly subsides on the temporary withdrawal of the acid and the substitution of a zinc and calomel dusting powder or ointment. On this account, however, it may be necessary when large areas are involved to intermit the treatment for two days in each week, and to protect the surrounding healthy tissues with vaseline in order to discourage excessive absorption of the acid. As soon as the seats of gonorrheal infection—urethra, cervix, rectum, etc.—can be reached appropriate treatment is initiated, and this, combined with strict cleanliness, has an important influence in preventing the appearances of fresh growths.

Carcinoma of the Jejunum.—E. T. Tatlow notes that statistics on the subject of intestinal carcinomata differ considerably with regard to the relative frequency of cancer of the small intestine. According to Sutton, in every 100 cases of intestinal cancer 75 occur in the rectum, 23 in the large intestine, and 2 in the small. Possibly these statistics indicate that carcinoma of the small intestine is rarer than it really is. All authorities agree, however, that carcinoma becomes more infrequent in the higher portions of the intestinal tract, and that carcinoma of the ileum is not so uncommon as carcinoma of the jejunum. The author reports three cases of this condition. All three patients showed the characteristic group of symptoms due to the toxemia of intestinal putrefaction, together with the mechanical obstruction of the bowel—namely, impaired digestion, loss of appetite, loss of weight, loss of color, and increasing constipation, accompanied by colic more or less severe in character.

Gastroenterostomy.—J. C. Renton states that this operation is indicated in the following conditions: dilated stomachs, due to chronic dyspepsia; stenosis of the pylorus, due to ulceration and contraction; ulceration of the stomach with hemorrhage; in cases of ruptured gastric ulcer at the pylorus; in cases where an ulcer has been cut out, the operation is of great value; in hour-glass contraction of the stomach, due to an ulcer contracting in the middle of the stomach, in such cases a double gastroenterostomy being necessary, or a gastrogastrostomy; atonic conditions of the stomach in which all medical treatment seems to be of no avail; duodenal ulcer with hemorrhage; malignant disease of the pylorus and stomach, either with or without gastrectomy. The author has performed gastroenterostomy in 81 cases with a mortality of 5 per cent.

Gilliam's Operation for Retroversion of the Uterus.—F. Ivens describes Gilliam's operation of round ligament ventrisuspension. This operation is practically extraperitoneal and almost as safe as the Alexander operation. The author concludes that Gilliam's operation is uniformly successful in suitable cases—that is, when the round ligaments are not too attenuated. If the operation is done under good conditions there is little risk beyond that of the anesthetic. As it causes no dystocia, it is strongly indicated in young women. There is no tendency to relapse after labor or abortion. Owing to the hypertrophy of the round ligaments, the operation is a valuable adjunct to a perineorrhaphy in cases of uterine and vaginal prolapse.

Treatment of Coccygodynia.—O. Beddard has had occasion to treat a few cases of coccygodynia in which the pain was so obviously resulting from pressure upon the coccyx, particularly in the sitting posture, that he sought for some apparatus which would obviate this and prove not inconvenient in use. Three such cases occurred in nulliparous unmarried women with a history of pain coming on after sitting for a length of time—as, for example, in church or on a bicycle. Examination showed a prominence of the coccyx which would render it liable to pressure on an ordinary seating surface, and it seemed as though such pressure could be avoided if the tubera ischii could be maintained on raised supports. The author found that this could be effected by a simple contrivance made of fine longcloth shaped on the lines of a napkin provided with two hollow rubber rings to receive the tubera. The rubber rings are 1 inch in depth and 2½ inches in diameter, their contained circles being 1¼ inches in diameter. They are held within circular pockets, which close with snap fasteners, with their centers 4½ inches apart. The garment should accurately and closely fit the body, and be worn next the skin. It is kept in position by a broad silk elastic band passing round the waist, and a similar band passes across just above the pubes; narrower silk elastic bands lie in the folds of the groins, and can be almost instantly undone or done up with the snap fasteners.

Causation of Parenchymatous Nephritis.—G. W. Watson concludes that acute nephritis is not a very common disorder. It is usually due to the direct effect of some infectious fever, catarrh, or septic process. The great majority of cases recover completely. The diagnosis of primary acute nephritis can seldom be made with certainty during the acute attack, and therefore a prognosis cannot safely be given until after an interval of at least a few weeks.

Foreign Bodies in the Vermiform Appendix.—S. Boyd states that according to Kelly and Hurdon the commonest foreign body met with in the appendix is a pin. These authors give a list of 40 cases in which this was found. All the cases were complicated by periappendicular suppuration, and many of them were fatal. Bullets and shot have also been met with, in most cases derived from eating game. Other foreign bodies recorded are the following: Pieces of bone, pieces of fish-fin, bristles of a toothbrush, fishbones, a nail and parasites—*Ascaris lumbricoides, Oxyuris vermicularis*—and a segment of tapeworm. Barnet and Macfie have published a case of gangrenous appendicitis in a hernial sac in which a clove was found protruding from the perforation in the appendix. Apple-pits, grape-seeds, and fig-seeds have also been found. Calcareous enteroliths and true gallstones are very rarely seen. Battle has suggested that the increase in the frequency of appendicitis in recent years may be due to min-

ute particles of iron derived from the rollers used in grinding wheat. He suggests that these particles find their way into the appendix, where they form the nucleus of a concretion, and he has been able to demonstrate the presence of such a nucleus. Battle also collected four cases in which hairs were present, and in some of these cases concretions had formed around the hairs.

Severe Anaphylaxis in Practice.—Asam reports a case in which he nearly lost a patient following an injection of antidiphtheritic serum. The case occurred in an adult who about ten years before had gone through two attacks of diphtheria in consecutive years. He received serum on each occasion, and the second application caused no anaphylactic phenomena, although the patient suffered commonly both from hay fever and asthma. On the present occasion he waked up with a diphtheritic patch on one tonsil, and from the previous history no time was lost in injecting serum. Prophylactic calcium chlorate was given as usual. Fifteen minutes after injection patient was attacked with paroxysms suggesting acute asthma and hay fever. The face swelled greatly, exactly as in erysipelas, and a scarlatinoid rash appeared on the chest, and spread over the entire surface. At the site of the injection in the thigh an erysipeloid rash had already appeared. The diphtheria seemed to have been arrested. The rash was attended with intense itching and occasional appearances of wheals. The patient was menaced in several ways. The extreme degree of swelling in the face involved the upper air passages to some extent. Recovery occurred. In cases of this sort (the patient was always unpleasantly affected by proximity to horses and stables) the danger of anaphylaxis from horse serum leads the practitioner to test serum by oral exhibition. The author urges that a trial be made of this possibility on a large scale.

Anaphylaxis from Repeated Intravenous Injections of Salvarsan.—Iwaschenzow describes the following syndrome which sometimes develops after consecutive injections of salvarsan in nerve syphilis: sudden redness and swelling of the face, dyspnea, cough, sense of heat and pressure in the head, twitchings and paresthesias in the extremities, feelings of anxiety and oppression. These symptoms last for a short time only—half a minute to five minutes. The heart is not implicated. The anaphylaxis is due to salvarsan purely and in no wise to the solvent or technique. The reaction is dependent on the dose and interval and the intravenous method. The author states this anaphylaxis is favored by simultaneously reducing the dose and prolonging the interval.

Multiplicity of Bacterial Toxins.—According to Bessau there are already known to exist three distinct types of bacterial poisons. The first, or toxin in the old and common sense, is the specific toxin of the particular species of bacterium which because of this specificity brings about the formation of specific antisubstances, antitoxins, which neutralize the toxins. The second form is the endotoxin. These form so-called immune bodies which do not neutralize endotoxins. The third form of toxin, that which produces anaphylactic phenomena, and is known as anaphylatoxin, is nonspecific. We already possess tests for the recognition of the presence of these bodies under certain circumstances, and may in time be able to trace the influence of each in a given disease picture.

Hyperemesis as a Pregnancy Toxicosis.—Seitz first mentions the great frequency of the vomiting of pregnancy (about 50 per cent.). Between the harmless morning vomiting and the severest types with fatal termination we have every transition. That a reflex factor is present may be conceded, but the growing uterus on the one hand or the retrodeviated or adherent uterus on the other can hardly be the efficient cause. The psychogenic theory is based chiefly on the fact that the affection is sometimes amenable to suggestion. The destructive visceral lesions often found at autopsy show conclusively that hyperemesis is no neurosis, although hysterical mimicry of the clinical picture no doubt sometimes occurs. We may conclude that in the recovered case, similar lesions in the liver or kidneys have been present in slight or minimal degrees. The parenchymatous alterations are followed by the formation of autolytic toxins which irritate the vomiting center. That psychotherapy seems at times to save these patients is not strange when we bear in mind that other remedies of a detoxicating character are always employed (certain diet, enteroclysis, etc.). Moreover, the irritated vomiting center is to some extent controllable through suggestion. This center is evidently sensibilized to minute quantities of some autotoxic substance. It is possible to give apomorphine to a suggestible person and then prevent its action by suggestion. The pathological finds in the fatal cases bear a notable resemblance to those of acute yellow atrophy of the liver and eclampsia, yet the finds are by no means identical. Clinically there is more or less parallelism between acute yellow atrophy and hyperemesis. We see in both cerebral disturbance, subcutaneous hemorrhages, and icterus. Cases occur in which the two affections appear to be one and the same or at least a transition form. For the present, however, it is well to regard them as distinct entities. There is a considerable resemblance, clinically, between cases of hyperemesis and cases of eclampsia, but it is rare to find structural alterations of the kidneys in hyperemesis, and moreover convulsions do not tend to occur in this condition. On the other hand, the author says, the atypical eclampsias, especially the forms which occur without convulsions, resemble notably certain cases of hyperemesis of pregnancy.

Treatment of the Climacteric Disturbances in Women.—Jung states that the involution of the female genitals may be attended with hardly any disturbances. The most common among the latter have reference to the circulation and are vasomotor in character—hot flushes, vertigo, palpitation. There may be a general nervous irritability, alterations in personality, moodiness, and even increased sexual desire. In the normal subject the disturbances are mild and transitory. When they are serious and persistent, resembling those produced by castrating young women, they may be looked upon as abnormal; although some women may be castrated without much disturbance of function. The element which may render these cases abnormal is by some held to be simply the general neuropathic or psychopathic constitution, but the author is not an adherent of this view. In any case the symptoms are severe enough in the majority of women to call for relief. As organotherapy has failed in this respect we have no certain causal therapy. The author would treat the vasomotor irritability by withholding every substance or practice which raises the blood-pressure—notably wine and coffee. Diet should be bland and incline toward the vegetarian. Regulation of the bowels and one or two hours daily in the open air are necessary. Hydrotherapy is of great benefit, and the only drugs recommended are valerian and an effervescent bromide at times. Of much greater significance may be the local treatment, there being some danger from climacteric hemorrhages and carcinoma. In any doubtful state of affairs, Jung maintains, it may be advisable to extirpate what he calls the now useless genitals. Nevertheless the author admits that a cutting operation may not be necessary, as the same end may perhaps be gained more simply by radiotherapy.

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

THE PHYSICAL EXAMINATION.

UNDERWEIGHT.—Underweight seems to exert no harmful influence as long as it does not exceed 20 per cent. below the standard. The mortality rises, however, to a point where it is of consequence when the weight of applicants as a class goes below the 20 per cent. mark.

The bad effects of underweight are especially noted in the younger ages. While moderate overweight is a favorable condition in this stage of life, underweight on the contrary is unfavorable and in some cases indicates a tendency to or the commencing of disease. This is particularly true of young lightweight dyspeptics, this class having a decidedly excessive mortality rate, many of these applicants developing pulmonary disorders. A mortality of about 110 per cent. may be expected among young underweights when the weight runs from 20 to 25 per cent. below the standard; in other words, when they are moderate underweights. The rate increases as the weight falls still lower.

As age advances, lower mortality rates are encountered, so that during the ages of from 30 to 40, the rate may be estimated at about 100 per cent., which is still rather high. After the age of 40 the mortality becomes fairly satisfactory, as it ranges from about 90 to 95 per cent. General experience teaches that moderate underweight in those over 50 years of age is by no means a disturbing element, for these are the applicants who may be expected to stand acute illnesses far better than the stout ones, and who have more chance of living to become octogenarians, finally "drying up and blowing away."

Underweight as an Advantage.—By consulting the table of the Causes of Death in a previous section on "Obesity an Abnormal Condition," it is seen that underweights have the advantage in a varying degree in typhoid, malaria, diabetes, diseases of the nervous system, diseases of the circulatory system, diseases of the liver and digestive system and diseases of the kidneys and genito-urinary system. It is also seen that in none of the cases considered did any person die of old age among the overweights, whereas a fairly good percentage is noted for the underweights.

Sir Dyce Duckworth during a discussion of relative weights (Proceedings of The Life Assurance Medical Officers' Association, London, 1901), recounted a story told him by Sir William Jenner; the latter had been called down to the country to see a patient suffering from pneumonia. The family practitioner met him at the station to say, "I am afraid this is a bad case and I do not expect the man to pull through. He is a lean, poor, miserable, thin man and spitting up large quantities of blood." Jenner answered, "You have told me two good things that make me think favorably of the case, because the leaner the patient and the more blood he spits up in pneumonia, the more likely he is to pull through." The patient recovered.

Underweight as a Disadvantage.—In the same table the excessive rate of deaths due to disease of the respiratory system is evident. For instance, pneumonia is seen to be nearly twice as fatal among underweights as among overweights. This is apparently a glaring inconsistency to much that has been said, as it has been asserted that the prognosis is more serious in the overweights. The seeming contradiction may be explained by the assumption that overweights have a certain immunity from pneumonia but do badly when attacked, while underweights are more than usually susceptible to the pneumococcus.

Underweight and Tuberculosis.—The association of underweight and a tubercular family history in the young is undeniably serious, the mortality running as high as 180 per cent. in the ages below 35. Above that age the influence of tuberculosis depends upon the number of cases in the family, the mortality dropping to about 107 per cent. among the lightweights who have two or three or even more cases of tuberculosis in the family record.

Dr. Marsh gave some facts (6th Annual Meeting of the Association of Life Insurance Medical Directors) which are of interest in connection with the subject. While studying the deaths from consumption of 1,994 cases with no tuberculosis in the family history and 2,700 with tuberculosis in the record, he deduced the following facts from a consideration of the personal condition of weight in each class. The list of cases with untainted record showed nearly twice as many deaths among those below as among those above the average weight. The cases with tainted records showed a larger amount of consumption in both those above and below the average weight, but again there were twice as many deaths from consumption in those below as in those above the average weight. By further analysis it was plainly seen that, while the combination of a record of consumption in the family history and a personal condition of underweight indicates an unusual liability to consumption, these factors differ considerably in their degree of influence. The effect of family history is almost insignificant compared to that of the weight and a good record of weight largely overbalances a badly tainted family history. The combination of the two factors indicated the *maximum*, and the absence of both the *minimum* of susceptibility.

ENDOWMENT POLICIES FOR OVERWEIGHTS AND UNDERWEIGHTS.—Some of these cases, while not desirable for a policy on the life plan, are nevertheless entitled to something better than rejection. The examiner, however, having given full details of the weight, measurements and other facts, should usually leave the question of acceptance or rating up to the home office.

Overweights.—The chief factors for consideration in selecting heavyweights are the family history, personal history, habits, occupation, residence and physique. If all or most of these elements are satisfactory, there will usually be no hesitation in granting a policy on the life plan to moderate overweights (between 20 and 30 per cent. above standard), and an endowment policy to excessive overweights (over 30 per cent.), provided the weight is not too excessive.

The family history is of some importance as indicating the longevity, and a record of deaths in early or middle life, especially from diseases denoting degeneration, such as diseases of the blood vessels, heart or kidneys, would be an adverse factor.

A personal history of rheumatism, gout, albuminuria, glycosuria or digestive disturbances would add materially to the liability.

The question of habits is of the highest importance in deciding upon overweights, for they should

not be accepted unless the consumption of alcohol is limited to a small daily amount. Total abstinence is a decided point in favor of these risks.

Occupation affects the life of an overweight, according as it is one requiring outdoor, active life, or the contrary.

Residence would chiefly affect the risk on account of climate. It may be safely assumed that an overweight will thrive better in a cool, bracing climate than in one where inertia and the debilitating effects of heat must be reckoned with.

The physique will naturally have to be studied. The risk is better or worse according to whether his overweight is due to a preponderance of fat or muscle, and whether the abdominal measurement is at least a half inch less than the expanded chest.

As overweights are liable to be cut off by the degenerative diseases which do not usually appear before 50 or 60 years of age, an endowment policy maturing in this period of life may be granted if the overweight and other conditions are not so adverse as to point to the danger of death at a still earlier age. Unfavorable overweights would be carried at an excessive loss, even on the endowment plan, and consequently would have to be balanced by an unusually good mortality among the normal policy holders, clearly an injustice.

Underweights.—The endowment policy is not often appropriate for the undesirable risks in this class, as the risk incurred by the company is too immediate and not deferred as in the case of overweights. The only intelligent plan for dealing with many of these cases is that by which a policy at a rated-up age can be issued. Occasionally, however, companies which do not accept sub-standard risks or write policies with rated-up premiums, may issue endowment policies in individual cases in which there is some merit.

The Mortality and the Causes of Death in the First Five Years After Insurance.—Georg Florschütz says that the Life Insurance Bank of Gotha in 1904 constructed a table of premiums not only according to the expected mortality because of age of the insured but likewise because of the years of insurance. The latter data were, of course, taken simply from the experience that the company has had in the previous years. The expected mortality table thus constructed proved, however, much higher than the actual occurrence, the mortality figures being something like 40 per cent. better than those derived from the figures. Florschütz has taken great pains in studying the causes that have been responsible for this favorable outcome, and presents numerous tables of the causes of death among those insured by the company from 1904 to 1910. The following table is an abbreviation of one of his and shows the actual number of deaths from various diseases as compared with the expected deaths, and the percentage of the actual deaths in terms of calculated deaths:

Causes of Death	Actual Deaths	Expected Deaths	Percentage
1. Infectious diseases	92	132.60	69
2. Tuberculosis	66	233.12	28
3. Cancer	36	25.72	140
4. Apoplexy	20	23.13	86
5. Progressive paralysis	10	7.52	133
6. Appendicitis	19	11.04	174
7. Accident	37	37.97	97
8. Suicide	48	40.80	118
9. Other causes	117	227.19	51
Total deaths	445	739.09	60

The most striking item in this table is the remarkable drop in mortality from tuberculosis. While previously the mortality from this disease among those insured by the Gotha Company was about equal to the general mortality from it, between the years 1904 and 1910 it sank to 28 per cent. of the expected mortality. Of course, the fall in general mortality explains a certain amount of this drop, but the effect of careful medical examination of the applicants is responsible for the greatest part of it. This is a great argument for competent medical insurance service: the high percentage of deaths from tuberculosis during the first few years of insurance is not an argument against medical examinations of applicants, but against incompetence in such examinations.

Of course, medical examination is of no value in preventing deaths from infectious diseases, and the diminution of deaths from these causes (69 per cent. of the expected number) simply shows the effect of modern prophylactic and therapeutic measures. The difference of over 30 per cent. between this drop and the drop in mortality from tuberculosis is a good measure of the efficiency of examinations. Tropical diseases show seven deaths in Florschütz's tables, only one of them being due to "black water" fever or, perhaps, to malaria. This is another indication of the wide-felt effect of modern sanitation.

The number of actual deaths from progressive paralysis is higher than was expected. As signs and symptoms of this disease usually precede death by a few years, medical examination seems to have been at fault in this case. Florschütz wonders whether the advent of the Wassermann reaction and of salvarsan will change the picture for the future years.

The deaths from appendicitis show the highest rise over expected numbers, and mere increase in exactness in making this diagnosis is not enough to explain the difference. The common belief of the increased frequency of appendicitis is supported by these insurance figures. The deaths from cancer, likewise, show an increase, and the explanation of this must be similar to the increase of deaths from appendicitis, that is, an actual increase in the incidence of the disease.

The increase in the number of suicides may be explained by numerous social causes, but it is quite possible that one important cause is the new insurance policy, which includes a "suicide clause" that vitiates the policy if death from suicide takes place before the expiration of two years from date of insurance. The effect of this is shown by the increase of such deaths over the expected number as soon as the two years have elapsed. It is quite possible that the danger of leaving one's family without the proceeds of insurance acts as a great deterrent to suicide in the first two years of insurance.—*Zeitschrift für die gesammte Versicherungs-Wissenschaft*, March 1, 1912.

Group Insurance.—A contract has just been closed by an insurance company to insure all the employees of a Chicago firm who have been six months or more in its service, by a blanket policy under what is known as the group plan. More than 2,500 lives are covered, and the insurance aggregates $4,000,000. The employees are covered on the basis of their salaries. The firm is also qualifying under the Illinois Workmen's Compensation act, and is providing health, accident, and disability insurance to its employees.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

(Special Report to the MEDICAL RECORD.)

(*Concluded from page 834.*)

SECTION ON MEDICINE (JOINT SESSION OF SECTIONS ON MEDICINE AND SURGERY).

Thursday, April 18—Third Day

Symposium on Poliomyelitis.

Symptoms, Difficulties and Possibilities in Early Diagnosis.—Dr. R. FOSTER KENNEDY of New York said that this disease was a primary general infection with local meningeal symptoms due to vascular changes and general symptoms produced by the specific virus. It was often difficult to diagnose early. As an example he cited the case of a boy who was to go on a sea trip who began to complain of headache, and while on the companionway of the steamer fell, and when he was picked up a paralysis from the neck down was noted. He developed incontinence of urine and hyperesthesia, but finally made a practically complete recovery. The speaker said the onset of this disease was usually sudden, with febrile manifestations, the temperature ranging between 101° and 102°. This might be accompanied by headache and vomiting. The pulse as a rule was not accelerated. The symptoms might not be severe enough to cause the patient to take to bed for the first two or three days. Coma and stupor might be indicative of cerebral involvement, although that diagnosis could only be made later, when the cerebral symptoms became marked. Hyperesthesia, pain in the neck and legs, Kernig's sign, and rigidity of the neck were symptoms also present. Influenza was said to differ from this disease in that catarrhal symptoms were present, the specific organism could be obtained from the discharges, and it occurred in a different time of the year, namely, during the spring and winter. Summer diarrhea differed in the occurrence of diarrhea, high fever, and sweating. In rheumatic fever the typical swellings were found. In tuberculous meningitis there always was a long prodromal course. The various meningitides, as tuberculous and cerebrospinal, could be distinguished by lumbar puncture. In tuberculous meningitis the fluid obtained appeared clear or slightly turbid, with a fibrinous flocculus on standing for a short time. The globulin reaction was positive and Fehling's solution was not reduced. To be noted was an increase in lymphocytes, and in 80 to 85 per cent. the presence of the tubercle bacillus was to be shown by testing the clot and appropriate staining on a slide. In epidemic spinal meningitis the fluid was turbid, and only in the early stages could a reduction of Fehling's be obtained. A polynucleosis of from 94 to 65 per cent. and the presence of Gram negative extra- and intracellular diplococci could be demonstrated. In poliomyelitis the fluid was clear or slightly opalescent, with a less marked clot formation. Early the globulin content was slightly raised, to disappear in three weeks. Fehling's solution was reduced. During the first one or two days the cytology was mainly polynuclear cells, and then changed to a marked lymphocytosis. No organism could be demonstrated by ordinary bacteriological means. He remarked that by serological tests the presence of abortive cases had been proven. The reflexes should be taken many times during the day, as a change, especially if unilateral, might be indicative of this disease. Differentiation from postdiphtheritic polyneuritis was also mentioned.

Pathology.—Dr. FRANCIS W. PEABODY read this paper. The infection, he said, was always from the upper respiratory tract, along the lymphatics, accompanying the filaments of the olfactory nerves. There occurred first a hyperemia, with a collection of round cells about the vessels. This caused a perivascular infiltration, which occurred early, and might be so great as to compress the vessel. This was followed by hemorrhage varying from minute to extensive in degree. The final process was an edema in the tissues. All three factors, he said, were dependent on the vascular changes. The degeneration of the nerve cells was ascribed to these factors. If early improvement of this vascular involvement occurred recovery might take place. The nerve cells showed granular degeneration and necrotic changes. These were then invaded by phagocytes, which removed the detritus, due to degeneration. The section might not even show the presence of any nerve cells. These changes were found mainly in the anterior horns, and to a marked degree in the cells of the posterior ganglia, and to a lesser degree in the medulla, pons, and brain. The other organs of the body showed parenchymatous changes. There was a general adenopathy, with enlargement of the lymph nodes and Peyer's patches. Under the microscope these showed an endothelial hyperplasia, the latter cells, in the author's opinion, partaking of the qualities of phagocytes. The liver showed areas of focal necrosis, especially in the neighborhood of the blood-vessels, and this lesion was very constant. In the liver regeneration of liver cells was noted to be very rapid. All these changes, the author remarked, resembled very much those seen in typhoid fever, and he believed that they were toxic in origin, due to the virus, as was shown by experiments on monkeys. He also said that the evidence was strong that the mode of ingress and egress of the organism was by means of the tonsil and the nasal mucosa. The lesions above mentioned were then shown by lantern slides.

The Acute Stage.—Dr. GEORGE DRAPER of New York presented this subject. He classified the cases as the flaccid type, in which the lesion was in the lower neurone tract and the spastic, in the upper neurone, and those in which no paralysis occurred. In the flaccid type, he said, the child lay on its back with a tired apathetic look, chin pointed up, and occasional slow movement of the eyeballs. It was easily aroused from this drowsy state, and when doctor or nurse approached the bedside for the purpose of manipulation it was easily aroused, would appear to be annoyed or cry, and lapse into the sleepy state again when left alone. Some might even assume a meningitic attitude. A few of the cases did not seem to be sick. There was a constant enlargement of the cervical and axillary lymph nodes. The rigidity of the neck varied in degree, sometimes being quite pronounced. This sign and also Kernig's symptoms were protective and voluntary on the part of the patient. In Landry's ascending type of paralysis, when the respiratory muscles were involved, the child became alert and concentrated all its attention and efforts to the task of breathing. For this reason he regarded on exceptional clear mentality in this disease as a very bad prognostic sign. The onset of the other paralyses in this group were usually abrupt and only in a few cases preceded by pain. Paralysis was hard to discover at first in infants, and in some none was found, the only evidence of muscular involvement being shown by the child crumpling up when stood on its feet. In some the head became flaccid. The superficial or deep reflexes varied, but were, as a rule, present. Sweating was not constant, and was found to be localized to a certain portion of the body. All cases were constipated, and in a few there was retention of urine. Pain in some form was always present, and was most frequently due to passive manipulation, mostly on bending the spine, as in preparation for lumbar puncture, and bending of the neck. These symptoms varied in persistence from a few days to several weeks. Spontaneous pain was less frequent, but in some cases severe, or paroxysmal. The spastic paralyses due to an upper neurone affection the writer called the bulbospinal group. In these cases the stupor was apt to be deep. The onset did not differ from the usual type. Coma-vigil, with waxy, mask-like, immobile features, and twitching or tremors was found. These cases were also easily aroused and resembled very much cases of tuberculous meningitis or of drugged individuals. The temperature in this type varied. The duration was from four to six days. All recovered in the same way from the first to the fourth week. The convalescence was steady. In this type there might be a change of mental condition. The third group of cases were those termed the abortive type, in which the toxic symptoms occurred but no paralyses were found.

Medical Treatment.—Dr. DAVID E. HOAG of New York divided the medical treatment into the early stage and the stage of paralysis. He said there was no satisfactory treatment for the early stage. Urotropin might be given in divided doses as a spinal antiseptic. Rest, counterirritation, and diet were the important things, with change in the child's position from time to time. Hot, wet packs, turpentine stupes, or ice bags should be applied to the spine. The bowels were to be kept open with calomel, rhubarb and soda, or castor oil and enemata. In the later stages, he said, the child should be treated with the aid of the orthopedist. Improvement was never due to treatment. Sometimes one or two muscles only were affected. The limbs should always be kept in normal positions. Physical and mechanical treatment were to be combined. There were two varieties of muscle training with exercise, he said. The first was passive, which was done by the parents or nurse under the direction of the

doctor. This form should act as suggestive to the patient, and the latter should attempt the same motions. The second form was advanced exercises with appliances which could be used for play or work. Fear of pain and discomfort should be overcome. Child should not be spoiled by petting. Massage might be useful, done 15 minutes before exercising, as it prevented tendency to muscular wasting. Electricity in the form of galvanism or faradism was useful. Treatment was to be persistent and hope for final improvement was not to be lost.

Prevention and Correction of Mechanical Deformities by Mechanical Treatment.—Dr. Wisner R. Townsend of New York said that the cases recovering from this disease varied from 20 to 25 per cent. Deformities could be prevented. Allowing them to occur and then treating them he considered unscientific. The occurrence of deformities depended on the factors: gravity, on non-paralyzed muscles producing traction, on the arrested growth and development of the tissues around the paralyzed muscles and upon weight. The effects might often be remote from the paralysis. Treatment for prevention, he emphasized, should be instituted early. Deformities developed at an average time of within three months, in severe cases earlier. At the Hospital for Ruptured and Crippled results where mechanical appliances were applied early were very gratifying. He said the prevention of deformities depended on the general practitioner. With the application of braces other forms of treatment should not be neglected.

Surgical Treatment.—Dr. Henry Ling Taylor of New York said the most frequent condition treated by the surgeon as a sequel to poliomyelitis was the inability to stand and walk. Station and locomotion were hampered by the deformities. The patient should be examined for unstable knee, hip, or spine, and for the distribution of muscular power. The latter might be more important than the estimation of total power in the limb. The limb should be brought into proper alignment with the body by dividing contracted tissues and lengthening others. Stability could be maintained by braces or proper surgical procedures. Braces should only be worn during the day. The surgical means mentioned were tendon transplantation, silk tendons, and arthrodesis. After operation careful mechanical treatment should be instituted and braces worn for a year or more, until the limb became strong. Failure to splint was responsible for most failures. Neuroplasty the writer condemned. In adults, in extreme cases, he said good results were not uncommon. Even after twenty years muscular action has been found to be present. Trunk palsies might be responsible for inability to walk, and here the brace or corset might be of benefit.

Dr. Rufus I. Cole of the Rockefeller Institute, New York, emphasized the fact that in poliomyelitis the nerve cells were degenerated more as the result of vascular changes than of toxins. At the Rockefeller Hospital the cases were studied, in the early stage first to limit the spread of the disease, and second to provide specific serum treatment if possible. In the first the disease should be recognized early for the purpose of isolation. Regarding treatment, after nerve cell degeneration took place, he said, treatment was inadequate. The blood count in this disease varied between 12,000 and 20,000 leucocyte, with a relative diminution of the lymphocyte. He thought the term encephalitis applied to the spastic types.

Symposium on Perverted Thyroid Function.

Symptomatology.—Dr. George Dock of St. Louis, Mo., said that he was convinced that a state of hypothyroidism existed before hyperthyroidea set in. He cited two cases in proof of this. Also he mentioned the following facts in support of the statement. The early dysmenorrhea and menorrhagia had a common hypothyroid basis. The so-called rheumatism of thyroidism was due to the hypothyroid state preceding hyperthyroidea. Some cases were improved after the administration of thyroid extracts. These facts, he said, pointed to a condition of hypothyroidea antedating the hyperthyroidea and were frequently overlooked. Hyperthyroidism he considered due to an excess of functionable thyroid tissue, and was modified by the interrelation of other glands in the body with the thyroid. He explained the term dysthyroidism by defining it as a dissociation of thyroid function from that of other organs as the adrenals, thymus gland, etc. The swelling of the thyroid gland was, in his opinion, the most constant symptom of thyroidism, and it was nearly always enlarged, although the degree of the enlargement might be small. The vascular murmur was more frequent than the thrill and easily recognized. Alterations of the pulse and heart action were always present, and in the latter the hypertrophy and dilatation with good compensation were characteristic. Tachycardia, which he called a hyposymptom, also occurred. He said the pigmentary changes were unimportant, although vasomotor changes, as a feeling of warmth, occurred. Nervous symptoms resembling neurasthenia were most marked. In one-half the cases there was insomnia. Tremor was present and always appeared early. By observing Litten's shadow a weakness of the diaphragm was noted. The gastrointestinal symptoms were not important; fever was rare. The eye symptoms appeared only very late and were probably due to secondary irritation of the adrenals. The diagnosis was to be made only by studying the symptoms present and looking for those that were absent. In cases of doubt he said it was better to resort to surgery rather than to wait for a diagnosis by therapeutic tests.

Atypical Types.—Dr. Alexander Lambert of New York said that if typical cases were those where the four cardinal symptoms of exophthalmos, tachycardia, thyroid enlargement, and tremor existed, very few cases could be considered typical and very many atypical. When one considered the interrelation of the thyroid with other ductless glands of the body and its effect on the pancreas, on the sympathetic nervous system, etc., one could see how variable the types were. For instance, he mentioned that in disease of the thyroid the adrenal and sympathetic systems were stimulated and the pancreatic function was inhibited. The degree of reciprocal action taking place in any of these correlated organs, and the amount of hormone liberated, governed the type of case and the variety of symptoms. One might get only a tachycardia or a change in the heart action, with hypertrophy and dilatation, combined with slight or no tremor. Single or double exophthalmos, a high blood pressure, gastrointestinal symptoms, such as vomiting and diarrhea, and pigmentation might be present in combined adrenal and thyroid disease. The gastroenteric disturbances were due to inhibition of pancreatic function and were unreliable. For these reasons he was unable to classify the atypical types, as the disease was not a single entity, and the atypical forms depended upon other ductless glands besides the thyroid. The latter might be the least affected and yet upset the equilibrium of the ductless glands.

Pathology.—Dr. William C. MacCarty of Rochester, Minn., said that as a result of examining 2,500 thyroids removed at operation in the Mayo Clinic the specimens could be divided into two groups: Those that were symmetrical and those that were of an asymmetrical, nodular type. The first group varied from normal to many times the normal size. On cut section they were acinous and non-acinous, and distended with a jelly-like material. This amount of colloid material varied and showed no relation to the size of the specimen. Microscopically there were noted small acini lined with epithelum, with and without colloid material, with and without epithelial hyperplasia. The size of the acini varied, but not enough to destroy the symmetry of the gland. When a normal gland became abnormal was not determined as yet, he said. In his reports to the clinician the author stated that he used no diagnostic terminology, but sent in a descriptive one. The asymmetrical glands usually contained adenomata and cysts. In these the capsule was thickened, fibrous and even calcareous. Some might contain no colloid material, while others contained some colloidal acini. Occasional hyperplastic areas occurred.

The Medical Treatment.—Dr. S. S. Beebe of New York emphasized the importance of an early diagnosis of this condition. He saw many cases of from four to eight years' duration which had not been recognized. Every case of increase in pulse rate and nervousness should be investigated, he believed. He said exophthalmos was the least important symptom to consider. The patients should be treated as though they were affected with a serious disease. It was safe to believe that the overactivity of the thyroid was the fundamental disturbance. For this reason he produced an anti-serum by inoculating the nucleoproteid extract of a diseased gland into a sheep for six or eight weeks. The sheep's serum was then administered by hypodermic injection in 2,200 cases. The early typical cases occurring in young women from 16 to 24 years of age gave the best results. Serum restored the normal activity in from 60 to 80 per cent. of cases. In the later typical cases very many were improved, while the late mixed cases were difficult to treat and went on to hyperthyroidism. In these all treatment was unsatisfactory. He said that rest in bed was imperative for from three to eight weeks, while total abstinence from tea, coffee, alcohol, tobacco, meat, and meat soups must be insisted upon. It was also important to guard against throat infections, as these disturbed the progress in treatment. He said the disease was not necessarily a surgical one.

The Surgical Treatment.—Dr. Martin B. Tinker of Ithaca said that in determining whether operation should or should not be advised the general condition and symptoms of the patient should be investigated. Operation should always be delayed until the marked symptoms had been allayed. Goiter, he remarked, was not an exclusively surgical or medical condition. The physician and surgeon should always cooperate. All cases should have a judicious after-treatment. In his experience the fatalities during the past three years from operation on the thyroid had been few. The fatal results were in very large goiters, of long standing, with serious impairment of vital functions. He had refused to operate on many cases, which died a short time later. He spoke of the benefits of Kronlein's operation for resection of the outer wall of the orbit to relieve exophthalmos. He said that partial removal of the gland relieved many patients and cured a number of them. He had never removed too much. He remarked that the number of medical fatalities had been much greater than under surgery. He said he was now doing preliminary ligation of the thyroid artery.

Syphilis of the Stomach.—Dr. Jerome Meyers of Albany reported a case of a male, twenty-four years of age, whom he saw May 27, 1911. The patient had had syphilis five years before and was well treated until one year since. In the past three months he had lost about twenty pounds in weight. For the past six or seven weeks he had been complaining of a dull pain in the right costal region, which later was localized on the left side, and came on one-half hour after eating. He vomited but once. Physical examination disclosed a slightly palpable spleen, with some resistance over the gastric region. The knee jerks were absent and the blood count was normal. On May 31 test for blood in a gastric extraction and in the feces was negative. He was put on ulcer diet and medical treatment for ulcer. He was in the hospital at this time, and a careful physical examination revealed a mass in the stomach. He also ran a temperature suggestive of tuberculosis. A von Pirquet reaction was negative, as was a blood culture, but the Wassermann was strongly positive. A radiograph showed a pyloric stenosis and cleared up the diagnosis of syphilis of the stomach. This diagnosis was corroborated when, by antisyphilitic treatment, the patient recovered. This condition occurred mainly in males between the ages of thirty and forty and forty and fifty years. The diagnosis, the author said, was to be made: (1) by the history of luetic infection and the positive Wassermann test, (2) by failure to cure the condition by other means, and (3) by the group of symptoms, namely, pain, gastric tenderness, emaciation, and hemorrhage. The pain in 67 per cent. of reported cases occurred immediately after meals. The gastric tenderness as a rule was very marked in 30 per cent. The emaciation was a marked symptom in 47 per cent., and the hemorrhage depended upon the site of the lesion and might be fatal. Vomiting was indicative of the site of the lesion. The physical examination in these cases revealed the same signs as ulcer, carcinoma, etc. The prognosis, he said, was good provided the patient was not too debilitated from stenosis or adhesions. Treatment was of the usual antisyphilitic character.

SECTION ON SURGERY.

Wednesday, April 17—Second Day.

The Chairman, Dr. Parker Syms of New York, in the Chair.

Cancer of the Prostate.—Dr. Eugene Fuller of New York presented this paper, the object of which was to emphasize certain points, the appreciation of which would aid in the diagnosis and management of this class of cases. He said that it was his impression that one in seven or eight cases which had come under his observation with symptoms of prostatic obstruction had been found to have cancer as a cause rather than benign senile hypertrophy. The great majority of individuals so afflicted were elderly, corresponding in age with those harboring senile hypertrophy. In a small minority of cases the patients so suffering were younger than one would expect to find with senile hypertrophy, perhaps around fifty or in the late forties. In this class of cases the disease was terribly rapid in its development and fatality. These cases might be divided into two groups. In the first and principal one cancer grafted itself on the part as a primary pathological process. In the second and minor group a senile hypertrophy became cancerous. In these latter cases the irritating effects of trauma and infections were favorable to the implantation of malignancy. In considering the clinical histories of the first group, an increase in urinary frequency was first noted. The urinary discomfort increased until overflow or retention ensued. The most striking clinical differential point in this connection between cancer and senile hypertrophy was the quickness of development and progression of the urinary symptoms in the cancerous condition. In senile hypertrophy one usually got a history of three years or more from the commencement of the urinary symptoms until the advent of serious evidence of urinary obstruction. In the cancerous cases perhaps not more than a month, and usually not more than six months marked the period in question. In cancer pain was apt to be a more pronounced feature than with benign hypertrophy. Where the neoplasm had progressed beyond the confines of the prostate so as to involve the pelvic nerve trunks, pains radiated from the pelvis down one or both thighs, and there were also deep-seated suprapubic or sacral pains. There was apt to be a loss of weight and strength with a considerable degree of cachexia. Hematuria was more usual with cancer than with other forms of prostatic obstruction. When bleeding occurred during tenesmus at the end of urination, in a case free from vesical infection, the surgeon should always have the existence of this condition in mind in making a diagnosis. In cases of the second group the advent of this secondary complication was apt to be associated with an aggravation of the previously existing symptoms together with the appearance of some of the features already described in connection with the first group of cases. In making a physical examination in these cases the evidence presented to the touch per rectum was of great importance. The feel was apt to show the prostate not only enlarged but nodular, irregular, and unusual in outline, often hard and in unyielding areas. The margins of the organ were found to have been obliterated. Extensions in a lateral direction filled up the space between the gland and the pelvic wall, soldering the prostate to the bony structure of the pelvis. The extensions backward filled the postprostatic space so that sometimes the seminal vesicles could not be outlined. The final aid to diagnosis lay in urethral and bladder exploration. Urethral exploration by itself was generally of little aid. The cystoscope might be of much positive aid, especially the instrument with a small caliber and a brilliant telescope which allowed a view of the vesicle neck. An absence of muscular hypertrophy in connection with the bladder was a suspicious circumstance. The management of these cases, especially those of the main group, was of importance. If a diagnosis could be made very early while the disease was wholly confined to the prostate proper, a prompt prostatectomy with a careful and radical removal of the entire gland would be the ideal treatment. Such a diagnosis was rarely made in the early stage of the disease. When such a radical operation was suggested the patient in the early stage would rarely consent to the operation without confirmatory evidence and much time was wasted so that the main chance was lost. Where the disease had extended beyond the confines of the prostate there was no likelihood that any operation could radically free the patient of his trouble. The aim of the surgeon in these cases was to prolong the patient's life and to secure him the greatest possible comfort. In these cases he was not inclined to operate until the obstruction to urination had become so marked that the necessity for radical treatment was evident to the patient. If in cases of this class the operation was performed before the patient had become especially inconvenienced by his disease it was probable that the development of the growth subsequent to operation would soon render the patient as uncomfortable or more so than before operation. Such being the case it was easy to picture the state of his mind. On the other hand, if operation was delayed until it would give relief to serious and painful symptoms the patient would appreciate this relief and would bear with equanimity the minor ills and discomforts associated with a non-obstructive progression of the growth. In cases of the second group this argument did not hold. In these cases prostatectomy should be urged and performed as soon as the consent of the patient could be obtained. When symptoms of grave discomfort gradually developed many months after prostatectomy they were generally due to the gradual progress of the disease into other parts. The writer further considered extensions involving the ureters and the development of uremic symptoms.

Dr. Nathan Jacobson of Syracuse said he was one of the first men in this country to have written on this subject and he wished to emphasize the point that these cancers of the prostate were not so uncommon as supposed. Metastases sometimes declared themselves in other parts of the body before the presence of the primary growth in the prostate was recognized. These cancers sometimes attained great size; one case was reported in a man seventy-seven years of age where the growth weighed two and one-half pounds. There was no way to make a diagnosis clini-

cally so long as the cancer was confined to the gland. It was more likely to be sarcoma when occurring in men under thirty and cancer when in those over fifty years of age. It was best to assume when hard nodular masses were present that they were dealing with cancer. He called attention to pain as a diagnostic point in cancer, especially when referred to the sacral and lumbar nerves. When the disease had spread beyond the gland there was no operation that justified the hope of cure. When the disease had extended to the bladder he had obtained better results with suprapubic drainage than with perineal.

Dr. James N. Vander Veer of Albany emphasized Dr. Jacobson's remarks in regard to pain as a diagnostic point especially when it radiated down the legs; in few did it radiate over the suprapubic region until the disease was well advanced. When pain of this character and hard nodular masses were present operation should not be delayed. The trouble was that the general practitioner did not recognize the condition, and the cases came to operation too late. He favored operation by the perineal route.

Dr. Albert Vander Veer of Albany spoke of the great progress that had been made in the last twenty-five years in the treatment of these cases and thought they were now at a place where they might go still further and emphasize the necessity for earlier operation. In his series of nearly one hundred cases the return of the disease after operation was not so serious. His patients lived longer than eleven or eighteen months.

Dr. Fuller in closing the discussion, said that there was no class of cases in which there was so much need of a careful pathologist as in these. Owing to the structure of the gland, it required care and experience in order to differentiate cancer from benign conditions. In insidious cases in young men it was not well to rush too precipitately into operation. One should remember that tuberculous conditions and encysted calculi might cause a great deal of pain.

Rupture of the Kidney in Children.—Dr. Charles L. Gibson of New York read this paper in which he reported four cases of rupture of the kidney in children. This accident was more liable to happen to children than to adults and the lesion might be of any degree of severity from a contusion to a complete rupture. Where there was doubt as to the lesion an exploratory lumbar incision should be made as practically all cases of rupture of the kidney died if not operated upon, while the mortality of those cases subjected to operation varied in different series from 14 to 20 per cent. The main indication was to provide free drainage. In borderland cases a few hours might be allowed to elapse before determining upon operation.

Dr. Eugene Fuller of New York agreed with the reader of the paper in regard to the advisability of an exploratory operation when there was a suspicion of rupture of the kidney.

Dr. Irving S. Haynes of New York said that hemorrhage was not a reliable sign in lesions of the kidney. This symptom was only indicative of the milder lesions; there was an absence of blood from the urine in the severer forms. He cited two cases of extensive lesions of the kidney in children where there was an absence of pathognomonic symptoms.

Intestinal Injuries Due to Contusion of the Abdomen.—Dr. Gilbert D. Gregor of Watertown read this paper in which he considered such injuries as were apt to occur in rural districts and where hospital facilities were not at hand. The most frequent mechanism was in the nature of a blow-out instead of crushing and tearing of the bowel between two contusing forces. The elements entering into such injuries were the high velocity of the blow and the small point of impact, surprising the abdominal muscles which were unprepared to resist and inflicting more severe injury in an inflated condition of the bowel. In diagnosis the primary shock was to be disregarded, but shock continuing or developing after four or five hours or increase of pulse rate at that time, associated with increasing abdominal pain, vomiting, and rigidity was sufficient evidence to warrant an exploratory operation. In severe injuries the mortality depended on the length of time that elapsed before operation. In those operated upon after the lapse of twenty-four hours the mortality was from 70 to 80 per cent. He reported four cases; one unoperated case died and of three cases operated upon two recovered and one died.

Dr. Robert T. Morris of New York made two points. 1. He agreed as to the importance of rigidity but it should be remembered that it required some strength on the part of the abdominal muscles in order that they might become rigid; this was nature's splint. The shock might be so severe as to prevent this effort of repair on the part of Nature. 2. It was wise not to do too much to these patients in an operative way shortly after the injury, at a time when the patient was not prepared to withstand an additional attack. Make provision for drainage if necessary and conserve the strength of the patient, leaving subsequent work to a later time.

Dr. A. T. Bristow of Brooklyn endorsed what Dr. Morris had said in regard to conserving the strength of the patient and cited a case in illustration in which it seemed very evident that this procedure had saved the life of the patient.

Dr. E. M. Stanton of Schenectady called attention to the obliteration of liver dullness as an early symptom in these abdominal injuries.

Bismuth Paste (Beck's Paste): Its Therapeutic Uses in Surgery.—Dr. Emil G. Beck of Chicago read this paper. He said that during the past five or six years he had done considerable experimenting with this method and he wished to bring out a few points that were misunderstood. This paste was useful first as a diagnostic measure; sinuses and fistulas could be filled with it for the purpose of taking radiographs. In the second place it was used for the purpose of healing these old sinuses and fistulas; and in the third place it could be used to prevent sinus formation by employing it in abscesses and thus avoiding the development of sinuses. It could be used in sinuses of the bones and joints, in empyema, in the accessory sinuses of the nose and face, in rectal fistulas and in sinuses after surgical operation. In a series of over 800 cases he had never had a fatal case of bismuth poisoning. Where such accidents occurred they were due to faulty technique. The two reasons for failure were faulty technique and using the paste in an inflammatory condition that would get well without it. It was a strange fact that old sinuses were cured easier than those of shorter duration. Other reasons for failure to get good results might be the presence of a foreign body in the sinus or the fact that the sinus was not completely filled by the paste; if there was the smallest area remaining unfilled there would be reinfection. Dr. Beck gave a lantern slide exhibition illustrating the conditions in which he used this paste.

Dr. Moschcowitz of New York said that the value of Beck's paste for diagnostic purposes could not be gainsaid, but in his hands it had not given as favorable therapeutic results as Dr. Beck had reported. He had visited Dr. Beck's clinic and was sure he had learned the method of using the paste correctly. He thought it had a very limited field of usefulness. This remark was not to be taken as disparaging to the method but merely as a report of his personal experience.

Dr. B. H. Whitbeck of New York related his experience with Beck's paste at Sea Breeze, Coney Island, where they had children with tuberculosis of the bones and joints; they had had some good results. In some instances good results were obtained only after several months' treatment and there were several instances in which, after apparent cure, the sinuses broke down later.

Gastric and Duodenal Ulcers.—Dr. Grant C. Madill of Ogdensburg read this paper. He said that operation was indicated as soon as the diagnosis could be established. He spoke of hemorrhage as a symptom and said that it occurred in 90 per cent. of the cases of chronic ulcer. Obstruction of the pylorus was a positive indication for operation. When carcinoma developed the pathology was different and operation depended on indications, but a cure was seldom effected. Acute ulcer belonged to the province of the internist. In one-half to three-fourths of the cases a cure could be effected in from four to six weeks; if they were not cured by that time surgery became necessary. Now that the operative mortality was only a little more than 1 per cent. in simple cases, more cases should be operated upon in the early stage.

Dr. Edgar Vander Veer of Albany said that in considering this subject the question of diagnosis was the important one. Ulcer in the stomach or duodenum should be treated like ulcer in any other part of the body. The minute a case was diagnosed as one of ulcer it became surgical. He had had two cases of perforating gastric ulcer both of which had occurred suddenly and he had made the diagnosis on the histories of the cases rather than on clinical evidence. If a bismuth x-ray was taken they would find that where there was no triangular shadow in the upper portion of the duodenum no ulcer was present, but that this triangular portion of the duodenum disappeared in the presence of ulcer and the mucosa was thrown up into puckers. This point had been proved in all such cases operated upon.

Dr. John B. Deaver of Philadelphia called attention to pain and rigidity as symptoms of perforating ulcer and said that but a small percentage of hemorrhage was due

to ulcer. Hemorrhage might occur from varicose veins, cirrhosis of the liver, and septic appendicitis.

Dr. Robert T. Morris of New York called attention to three points: 1. That the value of the *x*-ray was as great in these cases as in fractures. 2. That fibroid appendix caused a disturbance of function which gave symptoms similar to duodenal ulcer. 3. That the death rate might be lowered by giving attention to little refinements in operation.

Dr. W. W. Skinner of Geneva said that he agreed with those who had stated that many cases diagnosed as ulcer of the stomach or duodenum were cases of appendicitis; several cases of this nature had come to his notice.

Dr. Grant C. Madill of Ogdensburg, in closing the discussion, said that in answer to Surgeon General Stokes' question as to the operation of choice in a patient having pylorospasm in whom the first operation, a gastroenterostomy, was not successful, he thought that either an infolding or an excision of the pylorus would answer the requirements.

A Plea for Early Diagnosis in Surgical Affections.—Dr. Alvah H. Traver of Albany read this paper. He said it was unfair on the part of the general practitioner to delay calling in the surgeon until surgical measures could no longer be satisfactory. In early operation there was practically no mortality and the layman should be made to understand that the danger lay not in surgery but in *delayed* surgery. It was better to operate occasionally unnecessarily than to be responsible for deaths due to neglect of operative procedures. The writer then gave statistics showing the advantages of early operation in appendicitis, intestinal obstruction, and cancer of the breast. The technique of surgical operations for these conditions was about perfect and the only hope for a further reduction in mortality rates was in earlier diagnosis and earlier operation.

Dr. Robert T. Morris of New York said that one way to persuade patients to submit to an early operation was to tell them that if the operation was performed at once it would be a slight one; if delayed it would be an extensive one.

Dr. Moschcowitz of New York said he wished to make more emphatic the point that surgery had done about all it could. He had operated upon 100 cases of cancer of the breast and had not lost a single case. He had not cured all, but in not one instance did the disease recur anywhere near the primary lesion; deaths had been due to metastases in the spine and other parts of the body far distant from the primary lesion, which metastases were in existence at the time of operation.

Insufflation Anesthesia: Its Value in Thoracic and in General Surgery.—Dr. Charles A. Elsberg read this paper. He said that up to within the last few years, the advance of intrathoracic surgery was prevented by the fear of the dangers of open pneumothorax. The negative pressure chamber of Sauerbruch and the positive pressure apparatus of Brauer sufficed to overcome these dangers but both methods were complicated. Two years ago, Meltzer and Auer discovered a simple method which they called intratracheal insufflation of air and ether. Experiments of Meltzer and Auer, Elsberg and Carrel showed that intratracheal insufflation was very efficient as a method of anesthesia in animals, and by its means all of the dangers of open pneumothorax were avoided. In a large number of experiments, one or both pleural cavities in dogs were opened and many intrathoracic operations performed. The method was first tried in the human being by Elsberg, who devised an electrically-driven apparatus for the purpose. With this apparatus many hundreds of patients were anesthetized, and many intrathoracic operations performed. For intubation silk woven catheters are used, the catheter being introduced into the trachea through the larynx by the aid of the Jackson laryngoscope. The method of introduction was described in detail, and remarks made on the size of the tube to be used and the depth to which it should be inserted. Dr. Elsberg described in detail the apparatus he had devised and demonstrated its workings. He then spoke of the characteristics of the anesthesia, and emphasized that vomiting was relatively rare after intratracheal insufflation anesthesia. Experience had shown that the method of anesthesia was very valuable for many other operations than those within the thorax. The anesthesia seemed to be especially well borne by weak and cachectic individuals and shock seemed to be rare after insufflation anesthesia. The patients awoke very quickly after the anesthesia was stopped. The method was of extreme value in operations upon the head and neck. The anesthetist could be a number of feet away from the patient and was never in the way of the operator or his assistants. The method was valuable in operations in the mouth, for there was no danger that blood could run down into the larynx because the stream of air and ether which was passing upward in the trachea alongside of the catheter blew out all of the blood that was in the pharynx. As aspiration of vomitus was impossible, this method of anesthesia was to be used in operations for intestinal obstruction. Dr. Elsberg then described in detail the advantages of intratracheal insufflation in thoracic surgery and reported a number of intrathoracic operations which he had performed. He referred also to a number of other operations which he had performed under insufflation anesthesia. Finally, he recommended the method of insufflation of pure air as an ideal one for artificial respiration.

Dr. John B. Deaver of Philadelphia, Pa., congratulated Dr. Elsberg on his work and said that they were using this method in the University Hospital in Philadelphia most satisfactorily.

Dr. Samuel Lloyd of New York said that the lungs would not collapse as long as only one side of the thorax was opened and the patient was not completely under anesthesia. He had resected the lower lobe four or five times and his rule was to stop the anesthesia before opening the pleura. As soon as the anesthetic was stopped the reflexes reasserted themselves and the lungs expanded.

Dr. Clarence McWilliams said that he did not consider Dr. Elsberg's method free from danger. He had seen it used in a case of suspected adherent pericardium; the patient died and there was nothing else to which the death could be attributed except the anesthesia.

Dr. Elsberg said that in empyema with adhesions the lung would not collapse when the chest was opened, but in the majority of cases it did collapse when one pleural cavity was opened. They had found that in every case in which something had gone wrong there had been an error in technique.

Surgery of the Bile Ducts.—Dr. John B. Deaver of Philadelphia, Pa., read this paper. After dwelling on the importance of studying living pathology he stated that with the exception of malignant disease all conditions which called for surgical interference upon any part of the biliary tract had their origin in infection; even malignant disease seemed to bear some relation to antecedent infections. The infecting agent seemed in all likelihood to arrive by way of the portal circulation. Microorganisms might, however, enter the biliary tract directly from the duodenum; this seemed to be the case in those instances of cholecystitis and cholangitis directly consequent upon an intestinal catarrh. In these infections there seemed to be a preponderance of those due to the colon bacillus In one series of cases the *Bacillus typhosus* had been found in a greater percentage of cases. In contradistinction to the old view that most cases of gallstones had no symptoms, it was now known that all of them had symptoms and most of them very evident ones. Since infection was the underlying cause they must rely upon drainage in treating this condition. Every operation upon the biliary tract must serve a double purpose; it must meet the immediate mechanical demands of the conditions found, and it must furnish drainage for a sufficient time to cure the disease. If the surgeon could get these cases in the early stage there would be nothing to meet but the infection, but unfortunately it was at this time that the disease was most difficult to diagnose. All cases of indigestion should be carefully scrutinized for evidences of localization in the gall-bladder. Slight epigastric distress, occasional tenderness in the right hypochondrium, sometimes accompanied by slight rigor, a catch during inspiration, excessive flatulency, a faint icteroid tinge of the skin, a perceptible increase in the tension of the upper rectus muscle as compared with its fellow, were highly significant of beginning disease of the bile passages. This was the field for medical therapy. The time for operation was when medical treatment of these inaugural symptoms failed. Failing prompt relief the patient became subject to many dangers and complications, among them gallstones, adhesions, ulcerations, infiltration, perforation, gangrene, cicatricial contraction, and stenosis. Lastly, as the result of gall-bladder infections, they might have pancreatitis, acute or chronic. Aside from traumatic and neoplastic affections of the biliary ducts the conditions calling for surgery were non-calculous cholecystitis, calculous cholecystitis and its complications, and pancreatic disease. The indications for operation in disease of the biliary ducts and the gall-bladder were: (1) More than one attack of true biliary colic. (2) Symptoms suggestive of upper abdominal adhesions and chronic biliary insufficiency. (3) Hydrops of the gall-bladder. (4) Obstruction of the common duct. (5) The occurrence of acute infections com-

plicating previously existing biliary disease. (6) The evidences of pancreatic disease. Dr. Deaver thought the simple rule "fair, fat, and forty, and belches gas" would be a safer maxim for students if they wished them to recognize gall-bladder disease than the picture so faithfully embalmed in the textbooks. The average age at which patients were likely to develop this disease was earlier than formerly taught. In a series of 142 cases the average age was 40 years, the average duration of symptoms six years, so the average age of infection was 34 years. The most favorable time for operation was between attacks of complete occlusion. He took issue, however, with those seeing a patient during acute obstruction who decided to wait until the obstruction had been relieved before operating. When there was positive evidence of pancreatic disease operation was indicated even in the entire absence of symptoms pointing to disease of the biliary tract. He did not think much of the Cammidge reaction. Operation must accomplish three things; namely, meet the pathological condition and relieve it, remedy if possible the underlying cause, and prevent recurrence. He emphasized the importance of drainage in all grades of cholangitis and particularly after cholecystectomy in the presence of liver infection and pancreatic involvement. For stone in the gall-bladder he considered cholecystostomy the best operation. It had a slightly lower mortality and was followed by fewer adhesions than cholecystectomy and left the gall-bladder as a possible future outlet in case of serious biliary or pancreatic disease. He practised excision of the gall-bladder in cases of malignancy, hydrops of the gall-bladder, and chronic empyema. He urged the danger of procrastination and deplored the dawdling with duodenal buckets, fallacious laboratory methods, and the like.

Biliary Colic Without Gallstones.—Dr. IRVING S. HAYNES of New York read this paper in which he said that aside from gallstones, biliary colic might be due to several other causes, chief of which were "tarry" bile "sandy" bile, "sandpaper" condition of the mucous membrane of the gall-bladder, adhesions about the gall-bladder or ducts producing constrictions or kinks in them, stenoses of the ducts, and thickening in the head of the pancreas. Typical cases were cited of each of these conditions and a summary of the symptoms formulated with these conclusions: That it was impossible to construct a symptom-complex that would differentiate between biliary colics due to and those independent of gallstones. A possible clue was found in the fact that in spite of the long history of suffering the patients looked unusually well. That the attacks seem shorter and were so quickly recovered from. That these patients did not seek operative relief so early as where gallstones were the cause. Medical treatment could only be prophylactic. If the early indications of intestinal infection were appreciated and properly treated by diet, antifermentatives, and cholagogues it might be possible to relieve this precalculous stage and prevent the formation of gallstones. If the conditions here described were present there was no curative treatment except by surgical means. In most cases simple drainage was sufficient. With the "sandpaper gall-bladder," or in the presence of extensive adhesions, or active infection, the gall-bladder must be removed. Failure to do a radical operation would give the poor results quoted by Moynihan, Stanton, and Davis. The reason for this was that in this type of gall-bladder disease many times the simpler operation did not remove the infection. If the infection was not removed the disease would return as soon as the external wound closed. Only by a cholecystectomy could the infection be removed. In most cases, then, this must be the operation of choice.

Dr JOSEPH D. BRYANT of New York said that inasmuch as bile, and the arrest of bile, and its infection had to do with the development of stone, it was fitting to begin the study of the disease where the disease began, namely, in the mucous membrane of the biliary tract and this was characterized by the same inflammatory processes as the mucous membrane elsewhere in the body. All conditions which involved a change in the outline of the duct and gave rise to disease should be detected and removed or there would soon be a return of disease conditions. Running along the common duct there were lymphatics and a series of lymph nodes which by enlargement might interfere with the duct; if these were left undisturbed at operation they would soon cause the same obstruction as primarily. There was no doubt about infection, or that it got in through the portal system or the duodenum. Drainage should be thorough and should be kept in until the absence of infection was assured.

Dr. EDWIN M. STANTON of Schenectady said that as long as the operation secured free drainage cases could be cured, but that if there was a recurrence of obstruction there would be reinfection. The mortality of these operations was not high and the end results were as good as could be expected. He thought the operative mortality could be reduced about one-half. In a series of 702 bodies coming to autopsy 81 were found to have gallstones; this gave an idea of the possibilities in this branch of surgery. A committee should be appointed to investigate the mortality from gall-bladder operations in this State.

Dr. CHARLES G. MCMULLEN of Schenectady said that he did not think these cases were attended with very satisfactory results; not more than 50 per cent. were cured. They needed more careful diagnosis, and in cases not really cholecystitis some more efficient form of treatment. He thought they could accomplish their object better by cholecystenterostomy than by cholecystectomy.

Dr. I. S. HAYNES of New York said that though the point of the last speaker was well taken he remained unconvinced and still favored cholecystectomy because by other methods adhesions were formed which had to be attended to later.

The Diagnosis and Treatment of Intestinal Obstruction.—Dr. CLARENCE A. MCWILLIAMS of New York read this paper which dealt with mechanical ileus. In a case of possible acute obstruction the first care should be to exclude external hernia. The abdomen should be carefully examined by inspection, palpation, percussion, and auscultation; also the rectum and vagina. At times something might be learned by extending the colon with fluid or air through the rectal tube. Should a tumor be detected or a stricture felt by the finger inserted into the rectum, or blood and slime cover the finger thus inserted and a sausage-shaped tumor be detected, or the bowel be found to be loaded with hardened feces, one might make a diagnosis of tumor obstructing the bowel, or stricture of the rectum, or intussusception, or impaction of feces. When physical examination was negative the patient should be seen again in six hours. An initial dose of morphine was permissible but should not be repeated until a diagnosis was made. He outlined the symptoms attending acute and chronic obstruction and said that it should not be forgotten that chronic symptoms might at any time terminate in complete obstruction. Before determining that true obstruction was present it was important to examine the urine to exclude the possibility of uremia. Cases of acute intussusception presented puzzling symptoms, there being no acute condition in the abdomen which presented such variations from the typical text-book picture. The writer considered a class of cases comprising some of the rarer lesions of the abdomen, the diagnosis of which before operation seemed impossible, yet if the necessity for operation were recognized no harm would be done. He cited several illustrative cases. Obstruction might occur more than once in the same individual and it might occur a long time after an appendix operation. There were a few points common to the treatment of all forms of surgical obstruction. It was a good plan to empty the stomach by means of the stomach tube before anesthesia was started. Where the situation of the obstruction was not known a median incision above the bubes had best be made. In determining the location of the obstruction the cecum should first be palpated; if distended then the obstruction must be lower down in the large intestine; if the cecum was found to be collapsed, then the small intestine must contain the obstruction. This search must not be made in a haphazard way, thus increasing shock by unnecessary handling of the intestines. In the search one should not allow the intestines to escape from the abdomen. When the gut was extensively distended it might be deemed wise to drain it of its contents; this was only necessary when the distention was so great that it would probably be unable to empty itself by natural channels. If the patient was very much collapsed and standing the operation badly, or it was difficult to find the cause of obstruction, attempts should be given up and an enterostomy done in the most distended coil. A radical operation could be done later after the patient had recuperated. If the cause of obstruction was found to be irremovable it was best to establish an astomosis between the distended bowel above and the empty bowel below the obstruction. The author went briefly into the treatment of the individual causes of obstruction, and called attention to a curious cause of chronic obstruction and the most frequent cause of volvulus of the sigmoid colon, the so-called "retractile mesosigmoiditis." The treatment of this where the bowel was not severely affected was by dividing the bands of scar tissue which contracted the meson; if this failed it was better to resect the involved bowel.

Dr. MARTIN B. TINKER of Ithaca called attention to the bismuth test meal and the bismuth enema followed by x-ray pictures in determining the location of the obstruc-

tion. Ether was not the anesthetic of choice; many of these operations could be done under local anesthesia and if this was impossible nitrous oxide gas was preferable.

Dr. Joseph D. Bryant of New York emphasized the danger of giving cathartics in intestinal obstruction. One should work from below. Dr. Edward C. Janeway had suggested the use of copious injections of sweet oil which he had found very useful.

Dr. Clarence McWilliams of New York said local anesthesia would not be satisfactory in many of these cases but he agreed that nitrous oxide gas was preferable when it could be properly administered.

Surgical Constipation.—Dr. Samuel Goodwin Gant of New York read this paper, in which, after defining surgical constipation or obstipation, he said that atonic constipation and the forms of acute and chronic intestinal obstruction which killed or greatly endangered life were frequently discussed in medical societies and in current literature, but that obstipation of a lesser degree, which impeded the fecal current and delayed evacuations without causing other manifestations than those due to fecal retention, rarely attracted attention. The writer maintained that 50 per cent. of his patients treated for constipation suffered from the surgical variety and believed that in 25 per cent. of all cases of costiveness the trouble was due to mechanical defects. Dr. Gant reported cases previously unsuccessfully treated for habitual constipation which were caused by operative measures. He called attention to the many points of difficult passage to the feces which lay between the cecum and the sphincter muscle and showed how a slight distortion of the bowel might result in delayed or irregular evacuations. He enumerated thirty-five pathological conditions, any one of which was sufficient to induce surgical constipation, and said that in his cases there had been a single less often than multiple causes to account for the obstipation. Often the patient suffered from both atonic and surgical constipation, and in these cases both operation and after-treatment were needed. In making a diagnosis he had found it advisable to ascertain the duration of the costiveness and whether the patient had suffered previously from typhoid fever, peritonitis, ulcerative colitis, or other affections which might have led to the formation of adhesions, stricture, angulation, or twisting of the gut. Obstipation could be classified as rectal or abdominal, and was very much more easily located in the former than in the latter. Abdominal constipation could be diagnosed by percussion and palpation with or without the aid of inflation; in obscure cases the *x*-ray or exploratory incision was necessary to locate the lesion. Dr. Gant held that there was no excuse for a mistaken diagnosis when the obstruction was located in the lower sigmoid or rectum. When the block was located in the abdomen it required two or three quarts of water to secure an evacuation, but a pint or less would accomplish the same result when the impediment was in the rectum. The chief discomfort of abdominal constipation was incident to the retention of gas, while that of rectal obstipation was due to sensations of weight and fullness. Of 500 patients treated surgically by the writer for constipation the majority were permanently cured, many others were improved, while 10 per cent. received no benefit. With the exception of cancer and stricture the majority of rectal impedimenta responsible for constipation were simple in character and correctible under local anesthesia and the lesions which most often caused abdominal obstipation could be eliminated with but little danger under general narcosis. Dr. Gant then described operations indicated in the treatment of many of the conditions known to cause surgical constipation. In closing he emphasized the prevalence of surgical constipation, its comparatively easy diagnosis, and the good results which followed surgical treatment.

The Pathogenesis, Anatomy, and Cure of Prolapse of the Rectum.—Dr. Alexis Moschcowitz of New York presented this paper. He said that his theory and operation were based upon the demonstrable fact that prolapse of the rectum was a hernia. In all its features, etiological, pathological, clinical, and therapeutic, it conformed to the well-recognized principles of hernia in other parts of the body. He elaborated this theory in detail as he had done in a paper read before the Surgical Section, New York Academy of Medicine, December 1, 1911. The speaker considered the symptoms, medical treatment, and some of the surgical procedures which had been employed, of which latter there were over 200, which was good evidence that none of them were entirely satisfactory. He had tried some of these methods and recurrence was almost the universal rule. In the operation which he had devised he had endeavored to carry out the principles employed in an operation for the cure of hernia. He described his operation as published in the Medical Record, December 30, 1911. Thus far he had operated upon nine cases, but on account of the fatal issue of the ninth case there were but eight available for estimating the final outcome. This could be judged from the standpoint of the patient and that of the surgeon. It was surprising that the patient was better satisfied with this than the surgeon. Five of the cases which were reported were actually cured anatomically as well as symptomatically; the remaining three he thought were about 90 per cent. cured. Finally, Dr. Moschcowitz compared similar operations with this one, and showed wherein they had failed to grasp his theory and that they all recommended colopexy as a part of their operation. However, he did not consider priority a matter of importance, but only wished to throw light on the subject.

Dr. Dwight Murray of Syracuse emphasized the importance of making a thorough rectal examination in patients suffering from constipation, instead of merely prescribing drugs, as was too often done. He thought that constipation was the primary cause of all these conditions, and not the result. Medical colleges were at fault in not giving their students more instruction in rectal diseases instead of putting that branch of surgery under general surgery.

Dr. J. M. Lynch of New York thought the Dr. Moschowitz operation open to criticism because it narrowed the caliber of the bowel in an inconvenient place and stricture was liable to follow. He had done an amputation in five cases and had had good results.

Dr. Moschcowitz, in closing the discussion, said that it was a mistake to include intussusception in this subject, and that, of course, prolapse of the anus so-called should be excluded.

Third Day—Thursday, April 18.

Wounds of Naval Warfare.—Surgeon-General Stokes of the United States Navy made his address by invitation. He said that he welcomed the opportunity to speak because he thought the work of medical men in the Navy was not generally appreciated. Their work was by no means confined to surgery in times of war; they had 5,000 beds in their medical department. It was recognized that the men in the ranks were a military asset and must be kept in the best possible physical condition, and this involved systematic physical training and a great deal of military detail. They were constantly at work studying to improve the conditions under which their men worked; for example, they had been making observations in the fireroom and had found that some of the so-called heat prostrations were due to coal gas, and not to high temperature. When it was pointed out that gunnery at the present time was twelve hundred times more effective than it was during the Spanish-American War; that a battle between two dreadnoughts could not possibly last more than five minutes until the ammunition carried was exhausted; that a battle between the two largest fleets afloat could not last more than twenty minutes; that gun range was fourteen miles and a moving target could be struck at from nine to ten miles; that the battery of a single ship threw from ten to twelve tons of metal per minute; that each gun hurled a 1,400-pound projectile at 2,900 foot seconds; one might get some idea of the work for which the Naval surgeon must be prepared. In addition, the substances used in the propelling and bursting forces of the ammunition were poisonous, and the shells were hot, so that most wounds were both infected and seared. The effects of the powder-gas increased the shock beyond what would ordinarily result from the wound. In a single ship they planned for a casualty list of from 20 to 30 per cent. As this work was more than the surgeons and their corps of assistants could care for during and immediately after battle they trained the line officers and these in turn trained the men in first aid to the injured; they were instructed in the application of occlusive dressings, the control of hemorrhage, and the resuscitation of the drowned. They were planning for a medical reserve corps for the Navy, and Congress had promised that their measure should go through this year. They could then get transports and additional surgeons in time of war or disaster. The transportation of the wounded had always been a problem, and Surgeon-General Stokes had devised a wire frame which he exhibited, closed on three sides and so arranged as to splint the entire body and to prevent eversion. It would be found useful in many other circumstances where the sick or wounded had to be moved outside of naval and military service.

Induction of Labor at Term.—Dr. GEORGE W. KOSMAK of New York read this paper. He discussed the theories advanced for the onset of labor and said that the normal term of gestation, 280 days, had many exceptions; it had been estimated that 15 per cent. of all gestations were protracted. As the exact duration of pregnancy was often in doubt one had to be governed by the relative size of the child and the pelvis in determining the advisability of inducing labor. The growth of the fetus during the latter months of gestation was very rapid, so rapid that a child that weighed seven pounds at term would weigh nearly fourteen pounds if carried *in utero* another month. In addition to the increase in size the bones became much harder, as they all knew. The larger size of the child and the harder bones would point to a prolonged labor attended with possibly a mutilating operation and a slow recovery. With these facts in view the rational procedure was to induce labor within four or five days after term. This was a simple procedure either by the use of bags or gauze packing and was attended with no danger to the mother and offered far better chances of life to the child. He could not understand why physicians were so prejudiced in regard to interfering in such cases where the results of delay might be dystocia, loss of the child, a mutilating operation and a long convalescence.

The Use of Fetal Serum to Cause the Onset of Labor. Dr. ABRAHAM J. RONGY of New York read this paper, which gave an account of his experiments with fetal serum and the results.—As the cause of the onset of labor was still in the dark it was not surprising that some had been studying it along the lines of immunity. He described the experiments that had been performed on rats which demonstrated that the blood of pregnant rats produced a very severe reaction in those not in that condition, and that the blood of a rat at about term introduced into one in the early stages of gestation sometimes produced abortion. They then experimented with blood serum of parturient women. He related the history of eight cases in which he had succeeded in inducing labor by the injection of fetal serum. The fetal serum was prepared in the usual way employed with other human blood sera. He found that the most severe reactions were obtained when small doses were given followed by large ones. In one case serious urinary conditions were removed by the injection of the serum. It was too soon to draw any definite conclusions or to explain many of the phenomena attendant upon this procedure.

Dr. ROSS MCPHERSON of New York said that he had tried fetal serum in 28 cases and had had only one case in which labor pains were even simulated and in this case they subsided after two hours. He had given intravenous injections of ten to fifteen centimeters.

Dr. ABRAHAM J. RONGY of New York said it was his custom to give four or five c.c. at first and about three hours later to administer 25 or 30 c.c. The dose might have to be repeated; he had given as many as six doses before procuring the desired reaction.

Abdominal Cesarean Section.—Dr. ROSS MCPHERSON of New York read this paper, which was based on the records of 352 cases from the New York Lying-In Hospital. He thought the reason for the prejudice against this operation was that it had usually been performed only after every other resource had failed and when the mother and child were not in condition to undergo the operation. The mother was then exhausted and probably infected. The prognosis for the operation was good if a few cardinal principles were carried out. In operations determined upon before or at the time of labor the mortality was only two per cent; while it rose to four per cent. if the operation was performed after labor had been in progress for two hours. The speaker then considered the following indications: deformity, disproportion, placenta previa, neoplasms and rupture of the membranes. In the series of 352 cases 284 had been performed for some deformity; in eliminating those cases in which the women were moribund when operated upon the mortality was 9.5 per cent. This series reached back over a period of twenty years and the early mortality was much higher than that of more recent years. The speaker particularly emphasized the point that the eleventh hour was not the time to perform a cesarean section.

Dr. GEORGE W. KOSMAK of New York City said that this mortality seemed large, but it should be remembered that it was taken from the records of a large hospital where patients were received in all stages of labor. The fact should be impressed on the profession at large that cesarean section was not a last resort but an operation of choice. They should consider it in examining a patient and determine the degree of contraction. The pregnant woman should come under the care of an accoucheur at least three months before labor; she was frequently not examined until she came to labor. It was especially important that primiparæ should be examined. One should not limit a consideration of contractions to the anteroposterior diameter of the pelvis, but should include also the lateral dimensions and those of the pelvic outlet in deciding on a method of delivery.

Dr. ABRAHAM J. RONGY of New York said 40 per cent of the labors in New York City were attended by midwives, and sometimes the woman had been in labor forty-eight hours before the obstetrician saw her. What was to be done with these cases? Emphatically they were not cases for cesarean section. These were the cases in which a pubiotomy was indicated.

Dr. ROSS MCPHERSON of New York, in closing the discussion, said that he acknowledged that the mortality was too high, but it was not really so high when one remembered that some of the cases were operated upon eighteen or twenty years ago. In his own series of forty cases he had not lost a mother and only one child. Cesarean section in cases coming to operation late was about as fatal as any operation could be. While he did not like the operation of pubiotomy, there was a small class of cases to which it was applicable, but it was not applicable where the pelvis had a conjugate of less than seven and one-half cm.; in such a case it would have to be a choice between cesarean section and craniotomy.

Prolapse of the Uterus: Its Surgical Treatment.—Dr. CHARLES CLIFFORD BARROWS of New York presented this paper in which, after reviewing the results following the various methods of performing hysterectomy and those of the different fixation and suspension operations, he said they all told the same story, the patient returned in as bad a condition as before the operation. He believed that a reason for many of these failures was that the operation interfered with the blood supply of the tissues of the pelvic floor. His operation, which he described by means of charts, included amputation of the cervix, repair of the primeum, and shortening the broad ligaments by the Alexander method. He had been unable to follow up the hospital cases, but reported five cases occurring in private practice where the results of the procedure were very successful. The method was particularly applicable to fleshy women and to young women who had rapid prolapse. The essence of his theory was that prolapse of the uterus with the attached bladder and rectum was a hernia. Dr. Barrows exhibited charts by which he demonstrated the steps in his operation. He completed the procedure by removing a section from the lower anterior vaginal wall. In a series of 16 cases, 13 operated upon by Dr. Polk and three by himself, some three years ago and all over three months ago, the integrity of the pelvic floor had been retained in every case. It might be too soon to pass judgment upon the cases operated upon more recently.

Dr. RALPH WALDO of New York said he thought this method would prevent cystocele. He had been using an interposition operation and in over two hundred operations the results had been more satisfactory than by any other operation.

Uterine Fibroids Complicating Pregnancy.—Dr. RALPH WALDO read this paper, in which he first considered the salient points of fibroids in general. He said that during pregnancy they were apt to increase in size and they underwent involution with the uterus afterward, seldom becoming smaller than before the beginning of the pregnancy. Fibroids produced a tendency to abort during the early months of pregnancy, but after the third or fourth month the pregnancy was liable to go to term, even though the fibroid was multiple and very large. In many instances even a large fibroid in the lower portion of the uterus did not preclude delivery by forceps in a normal manner. In delivery at term where interstitial or submucous fibroids were present there was danger of postpartum hemorrhage and there might be such a weakening of the uterine wall that rupture took place. He did not think it a good practice in these cases to induce labor. If labor was established and the problem became serious one should resort to cesarean section. The induction of abortion because of the presence of fibroids was a great mistake, neither was it advisable to practice enucleation of the fibroid as abortion was liable to follow in a few weeks. The induction of abortion was dangerous owing to the possibility of the fibroid becoming gangrenous. In the presence of a gangrenous fibroid no time should be lost before resorting to a radical operation.

Dr. WILLIS E. FORD of Utica said that in six cases in which large fibroids were present he had seen practically normal delivery which was followed in three instances by

the partial disappearance of the fibroid. The blood should be removed only when it was so low down as to preclude the possibility of delivery. There was little danger from a simple intramural growth, but there was danger of hemorrhage from multiple fibroids.

Dr. WALDO said he wished to add his testimony to the statements that if the fibroids were not very large the patient could go to term without any harm and that the induction of abortion was dangerous owing to the tendency of the fibroid to become gangrenous.

Radical Operation for Cancer of the Uterus.—Dr LE ROY BROUN of New York read this paper. He reviewed the history of operations for hysterectomy for cancer of the uterus in Europe and in this country and this showed that the value of the operation had not been as fully appreciated in this country as abroad. He discussed the *pros* and *cons* of gland removal, stating that he did not think it advisable to prolong the operation on patients already in a weakened state by an exhaustive search for glands; if there were enlarged glands in the field of operation they should be removed. All were agreed that the operation should be extensive and there should be a thorough removal of parametric tissue. The steps of his operation were to sterilize the field, open the abdomen, and do an exploratory operation to find out if the glands on the uterosacral ligament were involved; if these were involved it was of no use proceeding. If they were not involved he did an extensive operation cutting off the uterosacral ligaments close to the sacrum, removing all the parametrium possible and going an inch or more down the vagina. Dr. Broun illustrated the operation with charts. Dr. Broun then spoke of the need of a more general dissemination of knowledge regarding cancer of the uterus among the laity, and said that the physician who when consulted by a patient did not make a physical examination and insist upon a microscopical one did not do his duty. In Europe women had been educated on this subject and statistics from a number of the large continental hospitals showed that 60 per cent. of the patients applying for treatment for this condition could be operated upon; in this country only 25 or 30 per cent. of those applying were still in the operable stage.

Dr. JOHN A. SAMPSON of Albany reported his results in 24 cases operated upon since 1905 by the Bertheim method. Of these five died. The presence of cancer in the lymph nodes was demonstrated in seven out of 11 cases examined. Four of these cases were free from cancer at the end of six years.

Dr. WILLIS E. FORD of Utica said the cancer problem was bigger than the tuberculosis problem. He lived in what was called the cancer belt of New York State, where the disease was very prevalent and he saw a great deal of it. He was not convinced that cancer was a local disease. He did not think an operation should be continued over an hour and one-half, certainly not for three or four hours, by a search for affected glands, as the attendant shock and loss of blood increased the probabilities of recurrence. He had had some success with autogenous serums and believed in following an operation by this mode of treatment. Even if one removed every gland he could not be sure there would be no recurrence.

Dr. WILLIAM SEAMAN BAINBRIDGE of New York said that he hoped the time would come when every woman over the age of forty would be examined at regular intervals. In cases that were inoperable so far as offering hope of cure for cancer it should be remembered that there might be other complicating pelvic conditions that might be relieved and that in this way the patient might be made more comfortable. In inoperable cancer he advised ligation of the internal iliac artery in two places on both sides, together with ligation of the ovarian arteries and removal of the ovaries.

Dr. H. C. TAYLOR of New York said that the question of radical operation hinged upon primary mortality; in early cases this should not be much higher than in the less radical procedures. He emphasized three points: 1. That they should get these cases earlier. 2. They should have a campaign among physicians at large. 3. They should instruct women in the first symptoms of cancer by all means available.

Dr. RALPH WALDO of New York said an operation was justified by its clinical results. Going beyond the perimetrium for enlarged glands subjected the patient to an increased danger out of proportion to the results thus obtained.

Dr. LE ROY BROUN of New York in closing the discussion, said that in 106 cases which Wertheim reported there were only five in which he had removed lymph nodes. He did not believe that it could be done in thirty minutes, as had been stated and it added very much to the seriousness of the operation.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

UNIVERSITY OF THE STATE OF NEW YORK MEDICAL EXAMINATION

January 30, 1912

ANATOMY

1. Locate the following bony points: (*a*) processus mastoideus, (*b*) olecranon, (*c*) malleolus lateralis, (*d*) acromion, (*e*) spina ischiadica.

2. State the names and give the attachments of the muscles of mastication.

3. Describe the arteria femoralis as to (*a*) origin, (*b*) course, (*c*) branches.

4. Describe the vena cava inferior.

5. State the origin and give the course of the musculospiral nerve (nervus radialis) and mention the names of *two* of its terminal branches.

6. Describe the spleen and give its relations to surrounding structures and organs.

7. State the origin, course, and distribution to the stomach of the left vagus (pneumogastric) nerve.

8. Give the minute anatomy of the lobules of the liver.

9. What muscles are attached to (*a*) the posterior border of the ulna, (*b*) the spine of the scapula?

10. Give the topographic anatomy of (*a*) the internal abdominal ring, (*b*) the external abdominal ring.

11. Describe the articulation of the head of a rib, in the middle of the series, with the vertebræ.

12. Give a detailed description of the rectum. State the blood supply and the nerve supply of the rectum.

PHYSIOLOGY.

1. State the number of white corpuscles in a cubic millimeter of blood. State the function of white corpuscles.

2. State facts relating to the ratio between the oxygen absorbed and the carbon dioxide given off in respiration.

3. Describe the nervous mechanism of gastric secretion and of stomach movements.

4. Describe in detail each step in the digestion of a meal containing proteins, carbohydrates, fats, water, and inorganic salts.

5. Describe the character and the physiological function of the secretion of the sebaceous glands.

6. Which of the cranial nerves are nerves of special sense? Give the origin of each nerve mentioned.

7. Describe the advantages and the disadvantages of sugar as an article of diet for (*a*) those living a vigorous out-of-door life, (*b*) those living a sedentary life, (*c*) those who are poorly nourished.

8. Define a calorie. How many calories are produced by the average male adult in 24 hours?

9. Describe the development of the spermatozoa.

10. State the effect on respiration of (*a*) division of one phrenic nerve, (*b*) division of both phrenic nerves.

11. Describe the movements of the spleen and state what is known concerning its function.

12. State the average weight of feces evacuated by a normal male adult in 24 hours. What proportion of feces is (*a*) liquid, (*b*) solid?

CHEMISTRY

1. Convert 41° Fahrenheit into centigrade degrees. State the Fahrenheit equivalent of zero centigrade.

2. Define (*a*) base, (*b*) salt, (*c*) acid. Illustrate, giving names and formulas.

3. Describe SO_2 as to (*a*) occurrence, (*b*) physical properties, (*c*) chemical properties, (*d*) uses as a disinfectant.

4. What is an alkaloid? What is the source of (*a*) atropine, (*b*) cocaine, (*c*) codeine?

5. Describe the process of manufacture of ethyl alcohol by fermentation and express in an equation the final reaction showing the formation of ethyl alcohol.

6. Describe a test for iodine.

7. Write the symbols of 10 elements and the formulas of 10 compounds, giving the name in each case.

8. State the physical and the chemical properties of ammonia.

9. Give the names, formulas, and chemical properties of *three* important potassium salts.

10. Where in the human system does lactic acid occur? How is lactic acid made?

11. Define carbohydrates and state their general properties. Where do carbohydrates occur in nature?

12. Describe chlorine as to (*a*) occurrence, (*b*) preparation, (*c*) properties, (*d*) important compounds, (*e*) chemical uses.

HYGIENE AND SANITATION.

1. Where should air inlets and air outlets for ventilating purposes be installed in a public hall? State reasons.

2. What are the essential requisites of a house water-filter?

3. What diseases are specially liable to be conveyed by the ingestion of milk?

4. State the procedure for disinfecting mattresses, blankets, and other heavy material of the sickroom.

5. What changes are effected in meats that are boiled? What points are to be observed in preparing soups?

6. Should the dead be buried or cremated? State reasons.

7. What controls the period of infectiveness of a disease? Illustrate.

8. State the course and relate the sequelæ of a successful vaccination.

9. What action have bacteria on sewage? What is the septic tank method of sewage purification?

10. How may articles of food and of drink be made sterile and safe for ingestion? Illustrate the procedure by at least *two* examples.

11. What pathological changes ensue from the constant use of alcohol as a beverage? Mention diseases the predisposition to which is increased by the habitual use of alcohol.

12. What is glanders (equinia)? How may glanders infection occur?

OBSTETRICS AND GYNECOLOGY.

1. Describe the nature and the functions of the amniotic fluid.

2. Give the management of the after-coming head in breech presentation.

3. Give the technique of obstetric asepsis and antisepsis during (*a*) pregnancy, (*b*) parturition, (*c*) the puerperium.

4. What are the causes of cystitis in the female? Describe methods of examination of the bladder of the female.

5. Give the management of the third stage of labor.

6. Differentiate erosion of the uterine cervix and ulceration of the uterine cervix. Give the etiology of each condition.

7. Describe the management of the various forms of placenta prævia.

8. Give in detail the immediate treatment of a severe laceration of the perineum.

9. Give the causes and the management of prolapsed cord.

10. What are the indications for the use of obstetric forceps?

11. Give the etiology of mastitis. What prophylactic measures should be applied to prevent mastitis during the puerperium?

12. Differentiate the ordinary morning sickness of pregnancy and the pernicious vomiting of pregnancy. What are the causes of the pernicious vomiting of pregnancy and what relation do they bear to the management of the condition?

SURGERY.

1. Describe tuberculous peritonitis. Give the surgical treatment of tuberculous peritonitis.

2. Give the surgical management of impacted fracture of the neck of the femur.

3. Give the technique of ether anesthesia. State the precautions to be observed and give the dangers and the danger signals in ether anesthesia.

4. Differentiate chancre and chancroid.

5. Discuss the dangers of expectant treatment of acute appendicitis.

6. Describe cholelithiasis and give its surgical treatment.

7. Give the surgical treatment of extensive burns.

8. Describe anthrax and give its surgical treatment.

9. Describe the operative technique and the after-treatment of penetrating wound of the stomach.

10. Describe a mechanical method of treating shock due to hemorrhage.

11. Give the signs and the symptoms of ectropion and state methods for its surgical relief.

12. Describe the objective and the subjective indications of compression of the brain.

DIAGNOSIS.

1. Describe the physical signs and the symptoms of acute pericarditis before and after effusion.

2. Give a clinical picture of epidemic cerebrospinal meningitis.

3. State the symptoms and the methods of diagnosis of dilatation of the stomach.

4. Describe the signs, symptoms, and usual course of toxic (commonly alcoholic) cirrhosis of the liver.

5. State the signs and the symptoms that warrant a diagnosis of diffuse (general) arteriosclerosis.

6. Give the clinical history of an average case of acute articular rheumatism.

7. State the symptoms of pus formation and retention.

8. In what diseases may enlargement of the spleen occur? Describe the methods of determining and identifying an enlarged spleen.

9. State the result of a microscopic examination of the blood in (*a*) typhoid fever, (*b*) malarial fever, (*c*) trichinosis.

10. Describe herpes zoster.

11. Differentiate cardiac asthma and bronchial asthma.

12. State the physical signs and relate some of the causes of ascites.

PATHOLOGY.

1. Describe the pathological changes in (*a*) simple fibrinous pleuritis, (*b*) serofibrinous pleuritis, (*c*) suppurative pleuritis.

2. What is the microscopic appearance of the affected tissues in acute hyperplastic splenitis?

3. Describe the alteration in structure of the mucosa in acute catarrhal enteritis.

4. How may carcinomata be disseminated through the lymph channels? State the appearance of the lymph vessels under such conditions.

5. Describe the hematozoon of estivoautumnal malaria and give its life history.

6. What organism is the probable exciting agent in syphilis? Give the macroscopic and the microscopic appearance of a syphilitic gumma in the liver.

BACTERIOLOGY.

7. In a suspected case of pulmonary tuberculosis what laboratory methods should be employed to establish the diagnosis? Give the methods in detail.

8. What are pathogenic bacteria and by what means do they incite disease processes? Does cultivation on artificial media affect the virulence of pathogenic bacteria? Illustrate.

9. Describe in detail Gram's method of staining. Mention *two* species of micrococci that may be distinguished from each other by this method.

10. State the general characteristics of *Bacillus pestis*. How may a pure culture of *Bacillus pestis* be obtained?

11. Mention *three* pathogenic anaërobic bacteria that may be conveyed from the soil.

12. What is disinfection? Give in detail a method of determining the strength of a fluid disinfectant.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

UNIVERSITY OF THE STATE OF NEW YORK MEDICAL EXAMINATION.

January 30, 1912.

ANATOMY.

1. (*a*) The *processus mastoideus* is behind the auditory meatus, on the mastoid portion of the temporal bone.

(*b*) The *olecranon* is the upper and back part of the ulna, at the back of the elbow-joint.

(*c*) The *malleolus lateralis*, or external malleolus, is situated at the lower extremity of the fibula, and forms the outer side of the ankle-joint.

(*d*) The *acromion* forms the outer end of the spine of the scapula, and overhangs the glenoid cavity; it can be felt immediately over the top of the shoulder-joint.

(*e*) The *spina ischiadica* is a triangular eminence near the center of the posterior border of the ischium.

2. The muscles of mastication are: Temporal, masseter, internal pterygoid, external pterygoid, and buccinator. For *attachments*, see Cunningham's "Anatomy" (1909), page 401; or Gray's "Anatomy" (1910), pages 377 to 380.

3. See Cunningham's "Anatomy" (1909), page 858; or Gray's "Anatomy" (1910), page 685.

4. See Cunningham's "Anatomy" (1909), page 892; or Gray's "Anatomy" (1910), page 751.

5. See Cunningham's "Anatomy" (1909), page 632; or Gray's "Anatomy" (1910), page 1040.

6. See Cunningham's "Anatomy" (1909), page 1210; or Gray's "Anatomy" (1910), page 1444.

7. See Cunningham's "Anatomy" (1909), pages 600 and 603; or Gray's "Anatomy" (1910), pages 1006 and 1010.

8. See Cunningham's "Anatomy" (1909), page 1121; or Gray's "Anatomy" (1910), page 1320.

9. *To the posterior border of the ulna* are attached:

Triceps, anconeus, supinator brevis, extensor ossis metacarpi pollicis, extensor indicis, flexor carpi ulnaris, and extensor carpi ulnaris. To the spine of the scapula are attached: Trapezius and deltoid.

10. See Cunningham's "Anatomy" (1909) pages 1205, 422, and 428; or Gray's "Anatomy" (1910), 438 and 427.

11. See Cunningham's "Anatomy" (1909), page 260; or Gray's "Anatomy" (1910), page 282.

12. See Cunningham's "Anatomy" (1909), pages 1087 and 1095; or Gray's "Anatomy" (1910), 1307 and 1311.

PHYSIOLOGY.

1. There are, normally, about 7,000 to 10,000 white corpuscles in a cubic millimeter of blood.

The functions of the white corpuscles are to: (1) Serve as a protection to the body from the incursions of pathogenic microorganisms; (2) take some part in the process of the coagulation of the blood; (3) aid in the absorption of fats and peptones from the intestine, and (4) help to maintain the proper proteid content of the blood plasma.

2. The ratio between the oxygen absorbed and the carbon dioxide given off in respiration is called the respiratory quotient. Thus inspired air contains 21 parts of oxygen, expired air 16; inspired air 0.04 of CO_2, expired air 4.04. The respiratory quotient is represented by the fraction $\frac{4.04 - 0.04}{21 - 16} = .8$. This is the normal figure, but the ratio is very variable, depending on age, temperature, food, air, and exercise.

"There are various reasons which account for these differences. It is to be borne in mind, in the first place, that the sources of carbon dioxide in the animal body are numerous. The oxygen which is absorbed at any given time does not immediately appear in the carbon dioxide given off; it may be absorbed and enter into combinations, which may retain it for a considerable time; so that at any given time the amount of oxygen absorbed may be greater than that given off in the carbon dioxide or *vice versa*. Then, too, more CO_2 is formed in proportion to the amount of oxygen absorbed by the decomposition of some substances than others. Thus when carbohydrates constitute the diet the amount of oxygen which they contain is enough to satisfy their hydrogen, but fats and proteids need more, and in the formation of water they use up oxygen; from this it follows that more oxygen is absorbed during an animal than during a vegetable diet. When the amount of carbon dioxide given off equals the amount of oxygen absorbed, the respiratory quotient is 1. It is found that before feeding the quotient is 0.84 to 0.89; when meat or fat is given, 0.76; with potatoes, 0.93; and with glucose, 1.03. The respiratory quotient is higher in adults than in children; during the day than at night; during wakefulness than during sleep; during activity than during rest." (From Raymond's *Physiology*.)

3. The *nervous mechanism of gastric secretion* is probably reflex. The stimulus is the presence of food and its passage into the stomach; the afferent nerves are fifth and ninth cranial, perhaps also the vagus and sympathetic; the center is in the nucleus of the vagus; the efferent nerves are the vagi; and the terminal organs are the gastric glands.

For the *movements of the stomach*, see Gray's "Anatomy" (1910), page 1280.

4. The *proteids* are digested in the stomach (by the pepsin) and in the small intestine (by the trypsin); the *carbohydrates* are digested in the mouth (by the ptyalin) and in the small intestine by the amylopsin; the *fats* in the small intestine (by the steapsin and the bile).

5. The secretion of the sebaceous glands is the sebum. *Sebum* is a fatty material; acid in reaction; contains isocholesterin, albumin, and fat. Its function is to keep the skin and hairs soft and pliable; it serves as a protection, and is an aid in the maintaining of body temperature; it may also be excrementitious.

6. *Cranial nerves of special sense:* First, or olfactory, special sense of smell; second, or optic, of sight; eighth, or auditory, of hearing. For *origin* of these nerves, see Cunningham's "Anatomy" (1909), pages 675 and 688; or Gray's "Anatomy" (1910), pages 976, 977, and 1003.

7. SUGAR AS AN ARTICLE OF DIET. (*a*) *Vigorous persons leading an outdoor life. Advantages:* The body sugars are an ever-ready source of energy, and as these are most readily and economically formed from ingested sugar persons leading a vigorous outdoor life require more than the average. *Disadvantages:* Sugar cannot be considered a substitute for the protein needed to replace that consumed in the wear and tear of life, and therefore sugar must not be used as the sole article of diet.

(*b*) *Persons living a sedentary life. Advantages:* Although these people do not require a great deal of handy fuel, nevertheless less protein is required to maintain the normal balance if a moderate quantity of sugar is taken. *Disadvantages:* Excessive sugar leads to a lessened intake of protein and fat, and therefore diminishes the mineral constituents (which usually follow with the fats used for food). Furthermore, in diminishing the fat intake it tends to produce bile stasis, with its usual results. Still further, an excess of sugar leads to intestinal fermentation with distension.

(*c*) *Persons who are poorly nourished. Advantages:* Here especially is a great demand for just such an easily available source of energy as is supplied by sugar. Sugar is easily digested and promotes the deposition of fat, and spares body protein. *Disadvantages:* Same as in (*b*), with special emphasis on the interference with the taking of the necessary mineral constituents.

8. A calorie is the amount of heat required to raise a gram of water through one degree Centigrade. The average male adult produces about 40,000 to 50,000 calories for each kilogram of his weight during 24 hours.

9. See Cunningham's "Anatomy" (1909), page 14; or Gray's "Anatomy" (1910), page 1382.

10. "*Section of one phrenic nerve* causes paralysis of the corresponding side of the diaphragm; *section of both phrenics* is followed by paralysis of the entire diaphragm. So important are these nerves in respiration that in most cases after section death occurs from asphyxia within several hours. In such cases not only is the work of inspiration thrown upon the other inspiratory muscles, but the effectiveness of the latter is greatly compromised by the relaxed condition of the diaphragm, which permits of its being drawn into the thoracic cavity with each inspiration, thus hindering the expansion of the lungs." (*American Text-Book of Physiology.*)

11. *Movements of the spleen:* "It has been shown that there is a slow expansion and contraction of the organ synchronous with the digestion periods. After a meal the spleen begins to increase in size, reaching a maximum at about the fifth hour, and then slowly returns to its previous size. This movement, the meaning of which is not known, is probably due to a slow vasodilatation, together, perhaps, with a relaxation of the tonic contraction of the musculature of the trabeculæ. In addition to this slow movement Roy has shown that there is a rhythmical contraction and relaxation of the organ, occurring in cats and dogs at intervals of about one minute. Roy supposes that these contractions are effected through the intrinsic musculature of the organ—that is, the plain muscle tissue present in the capsule and trabeculæ—and he believes that the contractions serve to keep up a circulation through the spleen and to make its vascular supply more or less independent of variations in general arterial pressure."—(Howell's *Physiology.*)

"It was subsequently shown by Schafer and Moore that the splenic volume is extremely responsive to all fluctuations of the arterial blood-pressure; that though the spleen may passively expand and recoil in response to the rise and fall of the blood-pressure, nevertheless the reverse conditions may obtain; viz., that the splenic volume may diminish as the pressure rises, if the splenic arterioles contract simultaneously with the contraction of the arterioles generally. On the contrary, the splenic volume may increase coincident with a dilatation of the splenic and systemic arterioles." (Brubaker's *Physiology.*)

The function of the spleen: The following theories have been held: (1) It is a source of production of the white blood corpuscles; (2) it is a source of production of the red blood corpuscles during fetal life; (3) it is a place where the red blood corpuscles are destroyed; (4) uric acid is produced in the spleen; (5) an enzyme is produced in the spleen and is carried by the blood to the pancreas, where it converts the trypsinogen into trypsin.

12. The average weight of feces evacuated by a normal male adult in 24 hours is about 7 or 8 ounces; of this about 70 to 80 per cent. is liquid, and about 20 to 30 per cent. is solid.

CHEMISTRY.

1. To convert Fahrenheit to Centigrade, we subtract 32, multiply by 5, and divide by 9.

$$\frac{(41 - 32) \times 5}{9} = \frac{9 \times 5}{9} = 5$$

So 41° F. = 5° C. 32° F. is the equivalent of zero C.

2. (*a*) *Bases* are ternary compounds capable of entering into double decomposition with an acid to produce a salt

and water. *Examples.* Potassium hydroxide, KOH; Calcium hydroxide, $Ca(OH)_2$.

(*b*) *Salts* are substances formed by the substitution of an electropositive element for part or all of the replaceable hydrogen of an acid. *Examples:* Sodium nitrate, $NaNO_3$; Monopotassic sulphate, $KHSO_4$.

(*c*) *Acids* are compounds of an electronegative element or radical with hydrogen, part or all of which hydrogen they can part with in exchange for an electropositive element, without formation of a base. *Examples.* Sulphuric acid, H_2SO_4; nitric acid, HNO_3.

3. *Sulphur dioxide* occurs in volcanic gases and in solution in some mineral waters. It is a colorless, suffocating gas, with a disagreeable taste; it is very soluble in water, soluble in alcohol, and liquefies at 14° F. It is neither combustible nor a supporter of combustion; it is a reducing agent, being itself oxidized to sulphuric acid. It combines with water to form true sulphurous acid.

As a disinfectant: "Sulphur (dioxide, SO_2), though not so positive in its action as chlorine, is much more frequently employed on account of the lesser risk and trouble connected with it. It probably kills the germs not containing spores if sufficiently concentrated and in the presence of moisture, and is, therefore, useful in the fumigation of rooms and of articles that cannot be subjected to steam heat or chemical solutions. But it will bleach or tarnish many articles, and for this reason and the fact that it is much inferior to formaldehyde, it will hereafter probably be almost entirely supplanted by the latter whenever that can be obtained. To secure sufficient concentration at least three pounds of sulphur should be burned for every 1000 cubic feet of air-space, care, of course, being taken that there may be no risk of igniting the floor or any articles in the room." (Egbert's *Hygiene.*)

4. *An alkaloid* is an organic, basic, nitrogenous substance, alkaline in reaction, and capable of combining with acids to form salts in the same way that ammonia does. *Atropine* is derived from *Atropa belladonna; Cocaine,* from *Erythroxylon coca; Codeine,* from opium.

5. The process of manufacturing ethyl alcohol is divisible into three parts: (1) The grain is *malted, i.e.* it is caused to germinate. In this stage of the process a peculiar substance, called *diastase,* is produced, which causes the transformation of starch into glucose. (2) The saccharine liquid is brought in contact with *yeast,* a plant whose nutrition is attended with *fermentation,* by which glucose is decomposed into alcohol and carbon dioxide: $C_6H_{12}O_6 = 2C_2H_5OH + 2CO_2$. (3) The alcohol is more or less perfectly separated from other substances by distillation.

6. Free iodine colors starch paste a dark violet-blue.

7. Hydrogen, H; Oxygen, O; Carbon, C; Nitrogen, N; Mercury, Hg; Silver, Ag; Lead, Pb; Sulphur, S; Arsenic, As; Iron, Fe.

Sodium chloride, NaCl; Potassium iodide, KI; Hydrogen dioxide, H_2O_2; Sulphuric acid, H_2SO_4; Nitrogen monoxide, N_2O; ammonia, NH_3; Phosphoric acid, H_3PO_4; Carbon dioxide, CO_2; Silver nitrate, $AgNO_3$; Mercurous chloride, Hg_2Cl_2.

8. *Ammonia* is a colorless gas, with a pungent odor and an acid taste. It is readily soluble in water, aso in alcohol and in ether. On being heated it is decomposed into nitrogen and hydrogen; it is not readily combustible, but it will burn in an atmosphere of oxygen.

9. (1) *Potassium iodide,* KI, is a transparent crystalline solid, anhydrous, soluble in water and in alcohol; it is decomposed by chlorine, and by nitric and nitrous acids. Its solutions dissolve iodine and many metallic iodides.

(2) *Potassium chlorate,* $KClO_3$, is a transparent crystalline solid, anhydrous, soluble in water; at a high degree of heat it fuses, and if heated still further it decomposes into potassium chloride and perchlorate. It is an active oxidizing agent, and if carelessly mixed with certain oxidizable substances an explosion may result.

(3) *Potassium permanganate,* $K_2Mn_2O_8$, is a crystalline solid, soluble in water, giving it a mahogany color; it is a valuable oxidizing agent.

10. *Lactic acid* is found in the stomach during the digestion of carbohydrates. Lactic acid is made by oxidation of alpha-propylene glycol:

$CH_3.CHOH.CH_2OH + O_2 = CH_3.CHOH.COOH + H_2O$.

Sarcolactic acid is found in muscular tissue (during contraction), spleen, lymphatic glands, thyroid, thymus, blood, and bile.

11. *Carbohydrates.* "The name carbohydrates was originally given to the group of compounds found chiefly in vegetables, and containing in the molecule *six* or a *multiple of six* atoms of carbon in combination with hydrogen and oxygen in the proportion to form water, as in glucose, $C_6H_{12}O_6$. The name is not well chosen, as it indicates carbon in combination with water, and also because at present members of the group are known which contain hydrogen and oxygen in other proportions than that of water. For convenience the name is retained, and applies to a group of substances including the various sugars, starches, gums, etc. They form the chief solid constituent of vegetables, and also are products of animal life, easily ferment or are readily converted into fermentable substances, are neutral, non-volatile, and, if soluble, optically active. They are usually white solids, and the sugars have a sweet taste. They are usually strong reducing agents, and by oxidation form saccharic, mucic, and oxalic acids." (McGlannan's *Organic Chemistry.*)

12. *Chlorine* does not occur free in nature, but is chiefly found in sodium chloride. It is prepared by heating together manganese dioxide and hydrochloric acid:

$$MnO_2 + 4HCl = MnCl_2 + 2H_2O + Cl_2.$$

Chlorine is a greenish-yellow gas, with a very penetrating and suffocating odor; it is heavier than air, soluble in water, and is very irritant to the air passages. It combines readily with the elements, a candle burns in chlorine with a faint flame and dense smoke; in the presence of water it is an active bleaching and disinfecting agent. *Important compounds* are: Hydrochloric acid, chloric acid, perchloric acids, and their salts; also chloroform and chlorals; chlorine is used for bleaching and disinfecting.

HYGIENE AND SANITATION

1. *Inlets and outlets for ventilating:* "There is considerable difference of opinion as to the best locations for inlets and outlets, and as the conditions are necessarily different in every case and so many factors are to be considered, it is difficult to lay down any general rules. It should be an aim, however, to have the air well distributed and to have no direct draughts from the inlets either upon the occupants or to the outlets. Usually the outlets should be located near the top of the room, owing to the tendency of the used air to rise, and because, in unventilated rooms, the foulest air for some time after its contamination will be found nearest the ceiling. The products of combustion from lights, etc., will also practically all be in the upper strata of air. If, however, provision is or can be made for a constant and sufficiently strong aspirating force in the outlet ducts, it may be advisable to withdraw the used air from near the floor level and below the inlet openings, though not in too close proximity to them, since in this way a more thorough distribution of the incoming air and a greater dispersion of its contained heat are secured. The location of the inlets should depend on the temperature of the incoming air: if it is cold it should be admitted near the ceiling, so that it may diffuse and be partially warmed before reaching the inmates of the room; if it is warmed it may come in near the floor or below the middle level of the room."—(Egbert's *Hygiene.*)

2. *The requisites of a good filter* are (according to Parkes): (1) That every part shall be accessible for cleansing or renewing the medium. (2) That the filtering medium shall have a sufficient purifying power and be present in sufficient quantity. (3) That the medium gives nothing to the water favoring the growth of low forms of life. (4) That the purifying power be reasonably lasting. (5) That there be nothing in the construction of the filter itself capable of undergoing putrefaction or of yielding metallic or other impurities to the water. (6) That the filtering material shall not clog, and that the flow of water be reasonably rapid; to which may be added: 7. That the filtering medium be such that it can be readily cleansed and sterilized, or else so cheap that the removal and replenishing may not be neglected when necessary on account of the expense.

3. *Diseases specially liable to be conveyed by the ingestion of milk:* Tuberculosis, typhoid fever, scarlet fever, diphtheria, tonsillitis, cholera, and gastrointestinal disorders.

4. Disinfection of mattresses, blankets, and other heavy material is best effected by steam under pressure; of course, the ideal plan would be to burn the articles.

5. *When meat is boiled* the hemoglobin is decomposed, the raw appearance is removed, the proteids are coagulated, the salts and extractives are dissolved in the water, the fats are split up (physically) and float on the surface of the water; the meat is made more tender, and the fibrous connective tissue is dissolved, thus allowing the fibers of the meat to become separated.

Points to be observed in preparing soups are, according to Friedenwald and Ruhrah: Both meats and vegetables should be cut into small pieces. The soup should be started with cold water poured over the meats and the

heat applied gradually and the soup allowed to simmer, in order to dissolve as much of the nutriment as possible. If heated rapidly the albumin in the meat coagulates, and little but the extractives passes into the soup. The vegetables are added when the soup is nearly done. The fat is then to be removed.

6. The dead should be cremated. *The advantages of cremation over earth burial* are: (1) Economy; cremation is very much cheaper, and there is no need for the community to purchase large tracts of valuable land for the accommodation of the dead. (2) Health; it is said that earth-burial causes the air to become poisoned, the burial grounds to become offensive, the soil to become laden with disease germs of every description, water to become poisoned, and diseases to be directly originated or propagated. (3) Body-snatching and desecration of tombs will be impossible.

7. The period of infectiveness of a disease is controlled by: The number and virulence of the bacteria causing the disease, the vitality and ease with which the bacteria can enter another person. Most of the pathogenic bacteria live only a short time outside the body; hence, speedy contact (either direct or indirect) is necessary.

8. See French's "Practice of Medicine" (1910), page 312; or Osler's "Practice of Medicine" (1909), page 125.

9. "The actual changes which take place in sewage, as the result of bacterial action, are somewhat complex and obscure, but they have been aptly described by Rideal as consisting mainly of three stages. In the first stage, or that of anaërobic liquefaction and preparation by hydrolysis, the albuminous matters, cellulose, and fats are broken up into soluble nitrogenous compounds, fatty acids, phenol derivatives, gases, and ammonia. In the second stage, or that of semi-anaërobic disintegration of the intermediate dissolved bodies, a further formation of ammonia, nitrites and gases takes place. In the third stage, or that of aeration and nitrification, ammonia and carbon residues are changed into water, carbon dioxide, and nitrates."

A septic tank is a specially constructed tank for the treatment of sewage; in it the sewage as such is destroyed, and new substances are built up in its place. In *Cameron's septic tank* system "the sewage is first led into a tank from which air and light are excluded. Digestive changes take place in the sewage within this tank as the result of anaërobic bacterial action, which is favored by the darkness, the absence of air, and the perfect stillness at which the sewage is maintained. The solid matter is rendered soluble and dissolved." (Notter and Firth's *Hygiene.*)

10. Meat and fish can be frozen and salted; vegetables and fruits can be dried.

11. See French's "Practice of Medicine" (1910), page 985; or Osler's "Practice of Medicine" (1909), page 370.

12. See French's "Practice of Medicine" (1910), page 455; or Osler's "Practice of Medicine" (1909), page 261.

OBSTETRICS AND GYNECOLOGY.

1. The *liquor amnii* is the fluid contained in the amniotic sac; it is alkaline in reaction, has a specific gravity of about 1.001 to 1.008, its quantity is variable, but is generally about two pints. It consists chiefly of water, but contains small amounts of albumin, epithelial cells, urea, phosphates, chlorides, etc. Its source is unsettled.

Function: (*a*) *During Pregnancy:* (1) As a protection to the fetus against pressure and shocks from without. (2) As a protection to the uterus from excessive fetal movements. (3) It distends the uterus, and thus allows for the growth and movements of the fetus. (4) It receives the excretions of the fetus. (5) It surrounds the fetus with a medium of equable temperature, and serves to prevent loss of heat. (6) It prevents the formation of adhesions between the fetus and the walls of the amniotic sac. (7) It has been supposed, by some, to afford some slight nutrition to the fetus. (*b*) *During Labor:* It acts as a fluid wedge, and dilates the os uteri and the cervix; it also slightly lubricates the parts.

2. See Jellett's "Midwifery" (1910), pages 427 and 1073; or Hirst's "Obstetrics" (1909), page 838.

3. See Jellett's "Midwifery" (1910), page 148; or Hirst's "Obstetrics" (1909), pages 732 and 778.

4. *Causes of cystitis in the female:* Various pathogenic bacteria, foreign bodies, traumatism, retention of urine, unclean catheters, cold.

For methods of bladder examination, see Rose and Carless' "Surgery" (1911), page 1210; or Da Costa's "Surgery" (1911), page 1297; or Hirst's "Obstetrics" (1909), page 244.

5. See Jellett's "Midwifery" (1910), page 350; or Hirst's "Obstetrics" (1909), pages 323, 339, and 343.

6. An *erosion* of the cervix is an area on the vaginal surface of the cervix which is covered with columnar epithelium, and consequently presents a reddened, inflamed appearance. Some confusion has resulted from the application of the term *ulceration* to this condition. There is no ulcer and no granulating surface, for the whole area is still covered with epithelium. The erosion is caused by an irritating vaginal or uterine discharge (*e.g.* gonorrhea, endometritis). An *ulcer* of the cervix presents a clear-cut border, sometimes raised and indurated, and the base of the ulcer is formed by granulation tissue; the cervix has lost some of its epithelial covering. It may be caused by irritation from pessary or discharge, chancroid infection, syphilis, tuberculosis, or malignant disease. (From Crossen's *Diseases of Women.*)

2. See Rose and Carless' "Surgery" (1911), page 539; or Da Costa's "Surgery" (1911), pages 593 and 599.

3. See Rose and Carless' "Surgery" (1911), pages 1351, 1353, and 1354; or Da Costa's "Surgery" (1911), pages 1193, 1196, and 1197.

4.

CHANCRE.	CHANCROID.
First lesion of a constitutional disease, viz., syphilis.	A local disease.
Due to syphilitic infection.	Due to contact with secretion from chancroid.
Generally a venereal infection.	Always a venereal infection.
May occur anywhere on the body.	Nearly always on genitals.
Period of incubation never so short as ten days.	Period of incubation always less than ten days (generally about three.)
Generally single.	Generally multiple.
Not autoinoculable.	Autoinoculable.
Secretion slight.	Secretion profuse and purulent.
Slightly or not at all painful.	Generally painful.
As a rule only occurs once in any patient.	May reoccur in same patient.
Buboes are painless and seldom suppurate.	Buboes are painful and usually suppurate.

6. See Rose and Carless' "Surgery" (1911), 1074 and 1077; or Da Costa's "Surgery" (1911), 1030, 1036 and 1115.

7. See Rose and Carless' "Surgery" (1911), page 118; or Da Costa's "Surgery" (1911), page 1219.

8. See Rose and Carless' "Surgery" (1911), page 131; or Da Costa's "Surgery" (1911), pages 301 and 303.

9. See Rose and Carless' "Surgery" (1911), page 1001; or Da Costa's "Surgery" (1911), page 960.

10. See Rose and Carless' "Surgery" (1911), page 278; or Da Costa's "Surgery" (1911), page 264.

11. ECTROPION. *Symptoms*: "Epiphora (from eversion of punctum) causing excoriations and eczema of the lower lid, which, in turn, through contraction, increase the deformity. The exposed conjunctiva becomes reddened and hypertrophied. In marked cases the cornea may suffer, as a result of imperfect closure of the lids."—(May's *Diseases of the Eye.*)

Operative treatment consists in: (1) Snellen's sutures; (2) reduction of the length of the border of the eyelid; (3) tarsorrhaphy; or (4) blepharoplasty.

12. See Rose and Carless' "Surgery" (1911), page 765; or Da Costa's "Surgery" (1911), page 800.

DIAGNOSIS.

4. See French's "Practice of Medicine" (1910), page 845; or Osler's "Practice of Medicine" (1909), page 558.

5. See French's "Practice of Medicine" (1910), page 642; or Osler's "Practice of Medicine" (1909), page 851.

6. See French's "Practice of Medicine" (1910), page 225; or Osler's "Practice of Medicine" (1909), page 221.

7. See Rose and Carless' "Surgery" (1911), pages 66, 36, 59, and 83; or Da Costa's "Surgery" (1911), 140 and 145.

8. ENLARGEMENT OF THE SPLEEN.—"Excessive chronic enlargement is most frequently due to leucemia, splenic anemia, or chronic malaria; lesser degrees may be met with in cirrhosis of the liver, rickets, pernicious anemia, passive congestion, or actual portal obstruction. Acute enlargement is most often encountered in septicemia, malarial fever, typhoid and typhus, erysipelas, acute miliary tuberculosis, tuberculous peritonitis, cerebrospinal meningitis, smallpox, diphtheria, scarlet fever, relapsing fever, infarct, plague, and certain other tropical diseases."—(Greene's "*Medical Diagnosis.*")

An enlarged spleen is diagnosed by palpation. "The position of the patient should be right lateral if minor enlargements are to be noted, as in typhoid fever or other acute infections, and the right hand should make pressure posteriorly while the left makes palpation. Abdominal distention defeats palpation save in great enlargement and the normal spleen is not palpable. If greatly enlarged the dorsal position is to be preferred and the condition can hardly be overlooked, unless with a tense wall the careless or hurried examiner fails to get below the actual border or to distinguish between muscular resistance on the one side and the splenic mass on the other. In these cases the chief notch in the anterior border is sharply defined and quite distinctive. In all cases where doubt arises as to the nature of a large tumor in the splenic area it should be remembered that a splenic growth or tumor is superficial, that its dullness is marked and can be carried directly back to its normal area behind the ninth, tenth, and eleventh ribs, that it ordinarily moves directly with respiration, and that if the colon be inflated splenic tumor dullness is not impaired. On the contrary, large renal tumors extend more deeply, are relatively fixed or immovable, are likely to be reniform or nodular, and are crossed by an area of resonance if the colon be distended with air. As in the case of the liver, a downward displacement of the diaphragm may produce an apparent increase in the lower splenic area just as an emphysematous lung or a pneumothorax may cause an apparent diminution in its upper percussion area."—(Greene's *Medical Diagnosis.*)

9. In *typhoid:* Widal reaction may be obtained; red cells are moderately decreased, there is slight diminution of hemoglobin; no leucocytosis as a rule, and generally a hypoleucocytosis.

In *malarial fever.* The plasmodium malariæ will be found; red cells and hemoglobin are diminished.

In *trichinosis.* Large increase in the number of eosinophiles, and decrease in number of polynuclears; the trichinella embryos may be found.

10. See French's "Practice of Medicine" (1910), page 1028, or Osler's "Practice of Medicine" (1909), page 900.

11. For *bronchial asthma* see French's "Practice of Medicine" (1910), page 675; or Osler's "Practice of Medicine" (1909), page 610.

In *cardiac asthma* the dyspnea is not accompanied by dry sonorous râles and the other physical signs of bronchial asthma; but moist crepitations may be heard.

12. See French's "Practice of Medicine" (1910), page 880; or Osler's "Practice of Medicine" (1909), page 589.

PATHOLOGY AND BACTERIOLOGY.

1. See French's "Practice of Medicine" (1910), pages 706, 707, and 711; or Osler's "Practice of Medicine" (1909), pages 643, 645, and 649.

2. *In acute hyperplastic splenitis* there will be found, on microscopical examination, "a pulp distended with blood, an enormous number of leucocytes, and red cells, many of the latter fragmented. If bacteria are circulating in the blood the splenic interstices may be distended by the invaders. The pulp cells may be found in all stages of their life history, karyokinetic, active, cloudy, granular, and fragmenting; the displaced and softened fibrous network manifests the separation of fibers incident to edema and vascular distention. Commonly, the splenic pulp contains a large number of phagocytes in which may be found bacteria. Some of the phagocytic cells are leucocytes, others are derived from the large endothelial cells lining the pulp sinuses; many of the phagocytes contain erythrocytes. Areas of focal necrosis are practically always present, and in some of these fibrin may be demonstrated."—(Coplin's *Pathology.*)

3. See French's "Practice of Medicine" (1910), page 789; or Osler's "Practice of Medicine" (1909), page 498.

4. In carcinoma "metastasis, as a rule, follows the lymphatic channels, and thus primarily involves the lymphatic glands in the neighborhood of the growth. The process may be explained as follows: Some of the epithelial cells in their advancing proliferation penetrate the lymphatic channels and are carried in the lymph stream to the nearest lymphatic gland, where they again proliferate and form secondary nodules; from these a similar extension occurs, and eventually widespread metastasis results."—(Stengel's *Pathology.*) And see Da Costa's "Surgery" (1911), pages 384 and 385.

5. See French's "Practice of Medicine" (1910), page 235; or Osler's "Practice of Medicine" (1909), page 13.

6. See French's "Practice of Medicine" (1910), pages 426, 428, and 430; or Osler's "Practice of Medicine" (1909), pages 266, 267, and 275.

7. See French's "Practice of Medicine" (1910), pages 301 and 1203; or Osler's "Practice of Medicine" (1909, pages 285, 335, and 340.

8. *Pathogenic bacteria* are such as (under certain circumstances) may produce disease.

"As to the mechanism which bacteria make use of in order to produce disease, according to our present knowledge, they work chiefly through the poisonous substances formed by them and deposited in the bodies of the persons suffering from the disease. The theory that bacteria have an important influence through the destruction of substances taken by them from the body of the patient for food is no longer entitled to much weight; neither are we able in most cases to account for the phenomena of disease by any mechanical action on the part of the bodies of bacteria. That such action does occasionally take place may be seen in experimental anthrax in mice, where the blood capillaries of the liver and kidneys may be completely plugged with masses of anthrax bacilli. The diseases in which the circulating blood is swarming with bacteria are much commoner in the lower animals than in man."—(Williams' *Bacteriology.*)

Cultivation on artificial media does affect the virulence of pathogenic bacteria. Thus *pneumococci* which have been kept upon artificial media are less virulent than *pneumococci* freshly isolated from the bodies of man or animals.

9. *Gram's method of staining:* Stain a cover glass preparation for two or three minutes in anilin gentian-violet. Wash in water. Treat with Gram's solution (iodine, 1 gram; potassium iodide, 2 grams; water, 300 c.c.) for a minute and a half, when the preparation becomes nearly black. Decolorize with strong or absolute alcohol for at least five minutes, wash, dry, and mount. Sometimes a contrast stain of Bismarck brown or eosin is used.

The *diplococcus of pneumonia* is stained by Gram's method; and the *micrococcus catarrhalis* is not stained by Gram's method.

10. *Bacillus pestis* is non-motile, with rounded ends, is about 1½ mikrons in length and a little more than half a mikron in breadth; it stains readily with all the anilin dyes, but not by Gram's method; it has no spores, is not encapsulated, non-flagellated, non-chromogenic, aërobic and optionally anaërobic, and is the specific pathogenic organism for bubonic plague.

"When cultures are made from the blood of softened contents of the buboes the bacillus may be obtained in pure culture."

11. Three pathogenic anaërobic bacteria that may be conveyed from the soil: Bacillus of tetanus, bacillus of malignant edema, and bacillus of symptomatic anthrax (black leg).

12. *Disinfection* is the process of destroying or removing pathogenic microorganisms.

A method of determining the strength of a fluid disinfectant: "To a measured quantity of a virulent bouillon culture of the test organism is added a given amount of the germicide. After varying lengths of time inoculations are made from this mixture into culture media, preferably bouillon, and note is made of the presence or absence of growth under suitable conditions of temperature and the like. The shortest exposure to the weakest solution of the substance necessary to kill the test organism is taken as the germicidal value of that substance for the particular organism used."—(Williams' *Bacteriology.*)

OBSERVATIONS ON SOME CLINICAL FEATURES OF SCARLATINA.*

By HENRY W. BERG, M.D.,

NEW YORK.

ATTENDING PHYSICIAN TO THE WILLARD PARKER HOSPITAL; ASSOCIATE PHYSICIAN, MOUNT SINAI HOSPITAL; ASSOCIATE IN PEDIATRICS, COLUMBIA UNIVERSITY.

THE customary classification of scarlatina into severe, moderately severe, and mild cases, with hemorrhagic cases as a separate group, is obviously open to many objections. It is based on the more or less clinically vague and pathologically unessential criterion of severity. It therefore lacks conviction. I have substituted for it a classification useful for the purpose of grouping various clinical types of the disease and one which is based upon essential clinical characteristics.

Scarlatina is a generally toxic disease at the same time that it is an infectious one. This is obvious from the omnipresent lymphadenitis, from the universal involvement of the blood, and all the organs and tissues of the body, and from the fact that its complications include inflammations of all of the body structures. Whatever the causative organism, bacterial or protozoon, it is surely one that disseminates a toxin throughout the body. The classification I have adopted therefore is one based upon the degree of toxicity, an essential phenomenon of all cases.

This classification is

Scarlatina simplex—mild, severe.

Severe toxic scarlatina—non-hemorrhagic, hemorrhagic.

Scarlatina with mixed infections, or septic scarlatina.

Surgical scarlatina, if looked upon as really a scarlatina, would belong to the group of severe toxic scarlatina. I consider it a septic manifestation, and therefore not a scarlatina at all but simply general sepsis with an erythematous rash.

The essential clinical distinctions between these different groups of cases is based upon the fact that in the simple scarlatinas the emunctories of the body are able to get rid of the toxic materials produced as fast as the pathogenetic forces manufacture them, while in toxic scarlatina the body tissues are more or less inundated by the excess of toxic accumulations which the protective and extruding forces of the body have been unable to neutralize and expel. In other words, in this latter class of cases the toxic products are in excess of the powers of the body to neutralize.

When the clinical picture of the case shows in addition to the purely toxic phenomena the symptoms of infections with the pus-producing organisms such as the streptococcus, staphylococcus, etc., resulting in inflammatory complications of various organs and tissues, either in the beginning or in the course of the disease, we have a clinical entity so different from the purely toxic picture of the disease as to make a separate grouping clinically useful and hence the classification of septic scarlatinas.

All that I claim for such a grouping of scarlatinal cases is that it is not arbitrary but relies upon essential clinical and pathogenetic differences and is therefore convincing and useful in the logical consideration of the disease.

The eruption of scarlatina as such has many points of interest. As is well known, it is a red, punctate, erythematous rash, in ordinary, more or less severe, cases. It is sometimes very difficult to differentiate this rash from that of the toxic scarlatiniform erythemas, such as some of the serum rashes. One factor has been of great aid to me in the differentiation of these skin lesions, namely that the toxic scarlatiniform erythemas *lack uniformity*. In other words, the eruption of scarlatina is scarlatiniform throughout, while the toxic erythemas have here and there urticarial and morbiliform patches. One patch of urticaria in an otherwise scarlatiniform eruption will throw doubt upon a suspected scarlatina, and in the absence of other distinguishing but secondary features of scarlatina the diagnosis of toxic erythema will be warranted.

In the desquamative stage of the eruption the diagnosis of scarlatinal desquamation is readily made by one who has seen this characteristic desquamation. The desquamation of this disease, however, may be confounded with that of dermatitis exfoliativa or the pseudo-desquamation of some types of eczema. Never with that of measles, however, which is of much finer and branny character than that of scarlatina.

The differentiation of scarlatinal desquamation from that of the various types of desquamative dermatitis is readily made by remembering that the skin that has been recently spontaneously freed from the squama of scarlatina is soft and velvety to the touch, pink in color, and perfect in texture. In desquamating dermatitis, the skin underlying the squama, when exposed, is found rough and hard and in some of the conditions covered with a moist exudation. It certainly has not in these latter conditions the characters of perfect, new, infantile skin.

A few words as to the anginas of scarlatina. These fall naturally into three classes, the recognition of which is clinically and therapeutically useful.

1. Toxic angina, due to the toxic cause of scarlatina *per se* and present to a greater or less extent in every case of scarlatina.

2. Septic angina, due to the complicating influence of the pus organism upon the basic toxic angina.

3. Diphtheritic angina, due to complicating influ-

*Read before the Section on Pediatrics, New York Academy of Medicine, April 11, 1912.

ence of the Klebs-Loeffler bacillus upon the first and second group.

The cervical lymphadenitis accompanying each of these varieties of angina corresponds in character to the pathogenesis of the angina. Toxic cervical lymphadenitis is a manifestation to a greater or less extent of every case of scarlatina. The most marked adenitis is apt to be present in the septic cases—although severe toxic scarlatina is frequently accompanied by very extensive cervical adenitis. Extreme and painful enlargement of the glands underneath the sternocleidomastoids gives rise to pain in the lateral and anteposterior motions of the head. To prevent this the patient involuntarily holds the head rigid, thus simulating cervical rigidity and pseudo-opisthotonos, which must be differentiated from the similar symptom present in a complicating meningitis. The enormous glandular enlargement in some of these cases, together with the accompanying cellulitis in the deeper planes of the neck, occasionally compresses the jugular and other veins of the neck, thus interfering with the venous return from the head and even brain, and giving rise to cyanosis and edema of the face and neck and doubtlessly causing passive cerebral hyperemia, with brain symptoms simulating those of a complicating meningitis.

The clinician receives much aid from accurate graphic curves of the temperature and the rates of the pulse and respiration in a case of scarlet fever. The pyrexia curve particularly tells much not only of the severity of the infection, but the approximate day of the disease during the eruptive stage, as well as the presence of a complicating condition. In a moderately severe case there is a sudden rise of temperature in the beginning with the onset of the throat symptoms and vomiting, to the high average of the temperature during the whole fastigium. The height of the fastigium is maintained in an uncomplicated case during five days until the eruption begins to fade; then resolution by lysis sets in. The stage of lytical resolution in an uncomplicated case may take from three to ten days before the temperature reaches and maintains the normal. The pulse rate during the whole of this febrile stage varies directly as the temperature, so that the curves almost fit into each other.

The greatest importance of an accurate graphic record of the temperature curve, however, lies in the fact of the reliability of these characteristic curves in uncomplicated cases; so that in a general way any extensive rise or fall from the level maintained during the fastigium, or a rise interrupting the progressive lytical resolution indicates an intercurrent or complicating condition and is not to be looked upon as an essential part of the scarlatinal pyrexia.

Thus the graphic curve attached to the history of a scarlet fever case of considerable pyrexia coming under hospital care on the fourth day, for instance, will show on the second day after admission the beginning of resolution by lysis. The day when lysis begins can safely be taken as the fifth or sixth day, and thus we have a clue to the duration of the disease before coming under observation. A sudden rise during the lytical stage indicates to the physician the existence of a complication, for which he searches and sooner or later finds, if he is persistent and competent. Frequently the variety of the complication can be recognized by the character of the unusual curve, together with the changes in the pulse and respiration rate. Increase in rapidity of pulse and respiration, for example, with a somewhat septic fever curve might point to a bronchopneumonia; a suspension of the lytical temperature curve, with greatly increased pulse rate and only moderate increase in respiration frequently indicates a cardiac complication; an interruption of the stage of lysis by an increased fever curve of septic character, with a lower pulse rate than the height of the fever calls for, frequently indicates a meningitis or a meningismus attending an otitis media or mastoid.

An acute glomerular nephritis, too, will be characterized by a temperature above the figure normal to the stage of the disease in which it sets in together with a lower pulse rate than is called for by the temperature of the case.

One of the most important complications of scarlatina is undoubtedly nephritis. This is not anywhere near as frequent a complication of scarlatina in hospital practice as one would be led to expect from the frequency with which one sees it in consultation cases in private practice. This is probably due to two causes: First, patients are kept strictly in bed in the hospital until desquamation is almost complete; and, second, patients are kept on a fluid, mostly milk, diet, until the patients have well passed the stage of acute symptoms. These are the most important factors in the preventive therapy of the complications of scarlatina, and particularly nephritis. Dr. Sexton tells me that in 1910 and 1911 we treated at the Willard Parker Hospital 4,186 cases of scarlatina, 17 per cent. of which showed albumin in the urine, with only 90 cases of real nephritis; needless to say albumin in the urine of an infectious disease case does not mean that there is necessarily nephritis. Nevertheless when nephritis does occur it is an extremely interesting complication both from a therapeutic and prognostic standpoint. Most of the cases of scarlatinal nephritis occur during the stage of desquamation, or rather after the eruptive stage is entirely completed and preceding the desquamative stage. Very rarely, indeed, is post-scarlatinal nephritis seen to begin in the post-desquamative stage. When it occurs thus late its beginning has usually been overlooked or it is a nephritis complicating one of the complications of the scarlet fever.

The most severe types of real nephritis in scarlatina are cases in which the urine is *rapidly diminished in amount* after the beginning of the appearance of albumin—blood cells appear and increase in quantity; the urine becomes smoky and sometimes even dark red and almost black; occasionally clots are seen in the bottom of the vessel. There are but few casts at this stage of the nephritis; the sp. gr. of the urine is very high; the percentage of urea much diminished; the amount of urine voided is very small, sometimes terminating in complete anuria, lasting many hours and even days and threatening imminent death from uremia. In these cases there is pyrexia due to the nephritis, there is also a myocarditis with rapidly developing hypertrophy of the left ventricle and pulse of high tension. There is as a rule some *dropsy*, which becomes more or less general, and there is in almost every case more or less dyspnea. Pathologically these are in their beginning cases of glomerular nephritis, which causes all the clinical phenomena above referred to, even the anuria and the resulting acute uremia and death. Many, however, that recover as well as many that die develop the lesions of acute parenchymatous nephritis.

In many of these cases of glomerulonephritis which have developed under my observation there has been an acute and rapid incidence of the symptoms of the nephritis; albuminuria, hematuria, diminution of urine to anuria, fever and edema have rapidly increased; in a few days the case has changed from a convalescent to an extremely sick patient suffering from a possibly fatal condition; the symptoms reach a critical stage during which death may occur; or the character of the urine begins to improve. The albumin begins to diminish rapidly, larger amounts of urine are passed, there is less blood in the urine. The cerebral symptoms subside. If there have been convulsions they no longer recur, if there has been high temperature it resolves by a rapid lysis, a lysis more rapid than that of the scarlatinal temperature curve.

Those who have seen much of this type of glomerulonephritis will recognize the clinical picture I have drawn of these cases. The important point in connection with these cases is that once the improvement begins, it is apt to continue to recovery or go on to the production of chronic interstitial nephritis without acute symptoms, and the prognosis is changed from extremely grave to an absolutely good one as regards life. The point I wish to emphasize is the almost critical resolution of these cases, a crisis almost as evident as that of a lobar pneumonia.

The limited time given in such a discussion as that of this evening precludes any attempt at systematic consideration of clinical scarlatina, not to speak of its complications. The subject would require volumes. I do not apologize, therefore, for limiting my efforts to a few clinical observations from the scarlatina wards of more or less general interest. There are hundreds of points of this character that might profitably engage our attention. I stop only because of the time limit.

CREOSOTE AND CALCIUM MEDICATION IN RESPIRATORY AFFECTIONS IN CHILDREN AND IN PULMONARY TUBERCULOSIS.

RUSSELL'S GENERALIZATIONS IN TUBERCULOSIS.

By IRA VAN GIESON, M.D.,

AND

H. L. LYNAH, M.D.,

NEW YORK

This paper consists of two parts. One part done conjointly relates to some observations on the use of an old remedy in a modified form in the respiratory affections in a number of children with measles. Another part by the senior author contains the results of the use of creosote in experimental tuberculosis with some elementary considerations on the subject of calcium medication and lime assimilation in tuberculosis, especially pulmonary tuberculosis. This latter consideration was prompted by a study of the investigations of John F. Russell and association with him in his clinics for the study and treatment of pulmonary tuberculosis.

Were it not for complications, and foremost among them disturbances of the respiratory tract, measles would be a comparatively mild and harmless disease. For in this most widely spread of all infectious diseases where susceptibility is all but universal, and natural immunity almost nil, the toxemia rarely causes death. The exceptions are the malignant and hemorrhagic types, which fortunately are rare. Here the disease is fatal for and by itself.

The formidable factor in measles is bronchitis and bronchopneumonia. Colitis and nephritis are indeed complicating factors, but far less serious than the bronchitis and patchy pneumonia. Some observers, and especially Henoch, go so far as to state that in every fatal case of measles patches of pneumonia can always be demonstrated. This is tantamount to saying that the thing which kills in measles is this respiratory complication.

Along with the bronchopneumonia, as an accompaniment, perhaps as a forerunner leading up to or extending into it, is the coryza, catarrh, or inflammation of the larynx, trachea, larger and smaller bronchi. It seems as if the coryza in measles were the starting ground of the pulmonary disaster. And it seems as though, speaking loosely perhaps, an inflammatory or catarrhal process creeps down directly from the coryzal territory through larynx and trachea and finally extends to the alveoli and lung.

If the coryza, then, is the point of departure for the respiratory complications, the frequency of the bronchopneumonia is not at all strange, for nearly every patient has the coryza as one of the characteristic signs. Naturally the pulmonary complications are invited by children who are not vigorous before the onset of measles. And it is to be expected more in children in asylums and hospitals than in those who are robust and well cared for.

The value of controlling and even anticipating this disaster in measles is obvious. We have had some little first hand experience with large numbers of children with measles in the Willard Park Hospital and are familiar with these respiratory complications, their onset, frequency, extension, and their havoc. To combat them is of paramount importance and our purpose is to relate some experiences in handling, and as we believe in some measure in controlling, these complications. For we think we have found out something of value to those who are concerned with the treatment of the respiratory affections of children and in adults as well.

Inflammation of the larynx in measles is heralded by hoarseness and croupy cough. Loss of voice may also occur and symptoms of obstruction may be so pronounced as to simulate laryngeal diphtheria. Severe laryngeal inflammation is a menacing complication and second only to pneumonia as a fatal issue. The bronchopneumonia, bronchiolitis, and accompanying bronchitis have their customary signs and symptoms. Among them are inspiratory rib depression, shallow breathing with high diaphragm, rapid weak pulse, cough, dyspnea, and cyanosis. Any untoward elevation of the temperature should lead to the suspicion of bronchopneumonia.

Now there is nothing new in the treatment of bronchitis and lung affections with creosote, nor in its application to children. But there is something new and valuable, we think, in the use of creosote freed from its toxic and irritating elements. Every one knows that the drawback of creosote is primarily its interference with digestion and its irritating effect upon the stomach, and that this too often counterbalances the good of this really valuable drug. Albuminuria and hemoglobinuria may also occur after large and continuous doses of creosote. These contraindications it seems may be due to a certain element in the composition of creosote which adds nothing to its value but on the contrary

is responsible for the irritating and toxic properties. Among pharmaceutical chemists this creosote problem has been one of long standing and various methods have been tried in its solution.

To accomplish the problem of a bland and yet efficient creosote it has been split up into various component parts. For instance, the guaiacol, cresol, and creosotal groups. It is questionable whether this has solved the problem, for these preparations are not wholly free from the toxic or irritating properties nor do they give the whole virtue or equivalent of the composite drug iself. The children could as well retain or tolerate these preparations, at least when administered so as to give the pretended equivalent of creosote, as in an emulsion of refined creosote with lime salts. And then there are also other preparations of this drug which solve the problem in a very simple way: the creosote is so diluted that its irritating effects are done away with—and also most of its remedial value.

The deleterious agents in creosote it appears are certain triatomic acid radicles. These radicles are first eliminated by careful fractional distillation before emulsifying and mixing with lime salts in the form of calcium hypophosphite. Thus there is no loss of the active principles of medical value in the creosote, but there has been eliminated its notorious drawback. And our opinion, now unchanged, in the perspective of three years in the treatment of these children, is that a bland creosote may be obtained, yet fully active and which can be taken abundantly and persistently with no harm or interference with stomach and kidney. "Pure" beechwood creosote may be pure and uniform as a product of the destructive distillation of the wood, but is far from pure as a medicinal agent.

The globules of the calcium creosote emulsion which looks very much like milk, are about one-third the diameter of red blood cells. And when the emulsion is mixed with human red blood cells there is no immediate hemolysis or laking. The lime creosote mixture is stable and the globules do not coalesce, nor is it likely that they unite in the stomach, which must be the case to some extent at any rate, when "pure" raw creosote is prescribed, shaken in milk or whiskey, or with eggs, and which, in part, is very likely responsible for the gastric irritation.

A summary of some fifty cases of measles treated with creosote and lime salts follows. A rather striking point in this is the tolerance of the drug by the children. Of course, as with any other drug, idiosyncrasy and individual sensitiveness may be met with here and there.

After these observations in the administration of creosote in the respiratory affections in children in measles, the treatment of creosote in tuberculosis was undertaken during the following year in experimentally tuberculous animals. This in turn during the succeeding time led up to the problem of the rationale of calcium medication combined with creosote. And this again intruded the very large, complex, and urgently important consideration—as it seems to us—of lime starvation as the essential cause of tuberculosis as presented in the work of Russell. So in being led into the study of a creosote calcium compound in the province of tuberculosis and thence in being brought to the endeavor of considering the problem of lime assimilation versus lime medication in tuberculosis, the investigation ran out of its original bounds.

Originally the problem of treating respiratory complications in children with creosote and calcium seemed attractive because the tolerance of the drug made the administration of large and continuous doses possible in accessible patients at the Board of Health Hospitals. In the extension of the investigation undertaken by one of us especially, the evidence of lime starvation as the main or essential cause of tuberculosis was verified clinically in the treatment of pulmonary tuberculosis by lime assimilation in Russell's clinics and experimentally in the cantrast of lime-starved and lime-fed dogs inoculated with tubercle bacilli.

We are limited in this consideration of Russell's generalization that lime starvation is an essential and determining cause of tuberculosis to the briefest generic statements and considerations. This may sound arbitrary without a full discussion of the evidence or verification in the treatment of tuberculosis. As a matter of fact, we have abundant evidence both inductive and deductive which may be given in detail later.

After nearly two years devoted to the testing of the validity not only by personal clinical verification but by seemingly unimpeachable laboratory experiments I (Van Gieson) respectfully and very earnestly commend this generalization of Russell to the attention of every thoughtful physician who is concerned with tuberculosis as a great problem of humanity or has the particular welfare of the consumptive at heart. Russell's generalization is that lime starvation is the essential cause of tuberculosis, and as a corallary, the remedy is restitution of lime poverty by lime assimilation. This is coincident with restitution and healing of the disease and a reversal of the steps of its process. This puts the control and treatment of tuberculosis within the grasp of a definite scientific principle.

In passing over this portion of the study relating to tuberculosis beyond the briefest summary we may consi ler the experimental test of creosote administered in tuberculous animals—rabbits and guinea pigs. The test was quite extensive and was carried over a considerable period of time. The results are not encouraging. The treated animals fared neither better nor worse than the untreated control animals inoculated with the same quantities of the same bovine and humna tubercle bacillus cultures under precisely the same conditions. Nor were there any appreciable changes in the character of the lesions in the two contrasted sets of animals. The tuberculous process and involvement went on quite heedless of the relatively enormous and continuous doses of creosote administered intravenously and intraperitoneally.

The reputation of creosote in pulmonary tuberculosis, it would appear, rests on its operation through secondary channels and by-ways; the control of cough and bronchitis, and apparently the hindering of the purulent character of the sputum and perhaps the palliation also of the secondary infections. To this may be added the favorable effect in antiseptic and contra-fermentative condition of the intestinal tract. This is indeed accomplishing a good deal. And in certain benign types of pulmonary tuberculosis—nearly fifty per cent. of the overt cases—which tend to recover or progress so slowly that the disease is not much of a burden, the administration of creosote, when tolerated, leaves little of which to complain. But the experimental test of creosote forces one to be skeptical as to whether the drug really strikes at the main root and issue of the disease. Indeed this is only stating with the gravity of rather elaborate laboratory backing—

somewhat the fashion of the day—what we were quite well aware of all the time. How can creosote administration correct lime starvation?

The animal experiments in the administration of refined creosote are quite interesting in the rather extraordinary confirmation of the solution of the problem of obtaining a tolerant form of the drug. The peritoneal cavity of the guinea pig, as is well known, is an exceedingly sensitive test for toxic or irritating agents. It is said that even a full injection of salt solution, if it fails to be perfectly isotonic, will produce redness and irritation. Hence it was rather surprising that pigs by the dozen could be given intraperitoneal injections of 5 c.c., the equivalent of three minims of creosote every other day, apparently indefinitely. At least I treated pigs in this manner for six and eight weeks, and with never any accident except in one or two cases of pregnancy in which, apparently, trauma of the needle was responsible for peritonitis. This is an enormous dose for these small animals weighing but three to four hundred grams and some of them were riddled with tuberculosis besides. The pigs excreted the creosote so actively that their cages were redolent with it.

I then gave intravenous injections, 5 c.c. of the undiluted creosote calcium emulsion in rabbits inoculated with tubercle bacilli, quite prepared to see the animals die. Now and then the rabbits lay down on their sides after the injection or sprawled out on the floor with rapid tumultuous heart action and flabby muscles. But in five minutes or so these animals would go back to their carrots as if nothing had disturbed them. Subsequently it appeared that this was brought about by giving the injection too rapidly. If the emulsion was warmed to 102°, and given slowly, one c.c. in two minutes, or thereabouts, the reaction was quite insignificant. One rabbit received some thirty of these injections, each equal to three minims of creosote, twice a week. Other rabbits received alternate venous and subcutaneous injections of 5 c.c., the latter never producing any ill effects.

This is also an enormous dose for these animals. The equivalent of it in an adult human being would at least be *a whole drachm* of *creosote*. These animals seemed reeking and saturated with the drug and freely excreted it in urine and feces. And yet on autopsy, none of these rabbits, even after protracted treatment, ever showed any lesions in general, or evidences of cirrhosis of liver or kidney in particular, ascribable to the creosote. One rabbit did show a very outspoken grade of cirrhosis of the liver, but as this was the only exception, it seemed quite proper to regard this as an example of cirrhosis found occasionally in rabbits naturally, perhaps from coccidiosis.

From these results I felt justified in considering the propriety of administering creosote in human beings not only internally but hypodermatically and intravenously as well. But it appears that animal experiments of this kind do not always afford certain prophesies or guarantees that like efforts can be produced under similar conditions in man. Hypodermatic injections were given twice a week in six cases of pulmonary tuberculosis. And while quick results and immediate improvement as a result of medication in tuberculosis are too often a delusion and an expression of enthusiasm on the part of both physician and patient, these patients, if only transiently, did show improvement in hacking cough, sleep, and general condition. The injections were, however, painful. At the fifth or sixth injection the whole set of patients developed superficial and benign abscesses, readily healing, but terminating the treatment.

This seemed strange. If the intraperitoneal injections caused no trouble in pigs, why should these small abscesses arise? It would seem that the emulsion in the peritoneum, spread over a large surface, was so rapidly distributed and absorbed, that there was no time to irritate or disturb the cells. The slow rate of absorption, however, subcutaneously and perhaps distention of the tissues kept the creosote globules in contact with the cells a longer time and brought about the suppuration. But, if this were the case, why did this not occur in the very first injection, instead of the fifth or sixth. Errors in technique can be eliminated, for the injections were given very carefully. Perhaps intramuscular injection would have been successful, but after this experience I did not dare try them. I have not entirely abandoned the question of subcutaneous injections after some further modification of this preparation.

Calculating the equivalent of the 5 c.c. injected in the rabbits on the basis of the comparative amounts of blood in the animal and man, a man weighing 130 to 150 pounds might take intravenously 140 to 160 c.c., some 60 to 90 minims of creosote. To be on the safe side and feel the way cautiously, 25 c.c. diluted with equal volume of .9 per cent. salt solution were given intravenously in a case of pulmonary consumption, in good condition, and apparently limited lesions at left lung apex, with no bad effects. In two other cases, however, the results of the injections were disconcerting.

These two cases, however, were very sick men; they had very extensive pulmonary involvement and dyspnea on the slightest exertion. Both cases exhibited after the injection of 25 c.c. at the rate of about two c.c. a minute, attacks of vomiting, rapid weak pulse, cold damp integument and some signs of collapse, which disappeared after administration of cardiac stimulants. It seems quite probable that the ill results in these two last cases were due to too great a concentration of the preparation and if, say 25 c.c. were diluted with 150 c.c. of physiological salt solution, given slowly and at the proper temperature there would be few, if any, disturbing results in cases of only moderate severity. Indeed, in conjunction with my friend, Dr. Carlin Philips, of Bellevue Hospital, I was prepared to give such diluted injections in a case of acute miliary tuberculosis (confirmed by autopsy) but the woman's veins were so deeply buried that it was out of the question.

These observations on the intravenous injections in man are not given with any idea of furnishing any results in the treatment of tuberculosis. These were merely trials to see if the injections could be given and tolerated. Whether, if they were given systematically and continuously in suitable cases the effect would have been beneficial, has not been determined. It might be worth trying.

We may now continue with the consideration of the calcium medication in experimental tuberculosis, since this creosote mixture contains a calcium salt as an integral part of its combination. Again the administration both intravenously and intraperitoneally every other day for weeks at a time in some twenty tuberculous guinea pigs and rabbits had no appreciable effect on the course of the tuberculosis nor in the character of the lesions. The calcium

medicated animals died just the same as their control and untreated companions. Nor did it appear that the treated animals were kept alive any longer than the controls.

Now let us contrast lime medication with lime assimilation in tuberculosis. The evidence of lime starvation in tuberculosis and its correction by lime assimilation is drawn from two sources.

The first source is clinical verification of lime starvation in human beings in their recovery from pulmonary tuberculosis ensured by lime assimilation. The second evidential ground is furnished by animal experiment in contrasting the factor of lime starvation artificially reproduced and reversed in their effects on the tubercular process. Let us take up the inductive evidence of experiment first. It is startling in its unequivocal precision and straightforwardness. In a word the experiment seems crucial.

Lime starved dogs, although given every other natural element of nutrition have their natural resistance and refractoriness to tuberculosis utterly swept away and die of the miliary type, some five or six weeks after the intravenous inoculation of two milligrams of bovine tubercle baccilli. But companion dogs given back their lime nutrition ten days after this inoculation doubled their weight and when killed fifty days later had arrested their miliary tubercles and were nearly barren of bacilli, whereas the continuously lime starved tuberculous dogs were literally teeming with them. Under the microscope the continuously lime-starved dog showed in the liver, for instance (which was involved by at least its own volume of tubercles) the ordinary mainly cheesy unarrested tubercle with its encircling zone of granulation tissue like cells. But in the companion dog, returned to his lime-containing food, although equally involved by the tubercles quantitatively, their quality and structure were altogether different and undergoing a different course of events—arrest, circumscription, and connective tissue retrogression. In this dog the tubercles were shrunken, their caseous masses had largely disappeared and they had spectacularly prominent walls of young fibroblasts and connective tissue.

Moreover, guinea pigs inoculated with the material of the arrested tuberculous dog showed an exceptional behavior. Bovine tubercle bacilli, although they may lose virulence in culture, are, provided their numbers are sufficient, uniformly fatal to the guinea pig when planted directly out of tissues. But these pigs are still alive, six months after the inoculation, and such of them as have been killed show a benign and healing type of tuberculosis. What happened here?

Not only did the dog with the return of lime assimilation dispose of myriads of bacilli, but it appears as if he managed to so modify the remainder that they were unable to work their customary havoc in the inoculated guinea pigs. The diminution of virulence of bacilli in their environment on artificial culture media is familiar, but a similar transformation in the living tissues as in this puppy is truly remarkable and a most significant commentary on and substantiation of competent calcium nutrition in tuberculosis. The nature of this transformation in the bacillus seems worthy of inquiry. Indeed after some years of study, so as to learn how to approach this inquiry, I hope to take part in its solution, for it involves the question of the ancestry and pedigree of the tubercle bacillus. Finally, scrutinizing the whole experiment from various angles of self-criticism it is difficult to escape the conviction that lime starvation and lime assimilation are the real issues behind the masks of vulnerability and resistance in tuberculosis.

The second domain of evidence in the verification of the calcium nutrition generalization from the clinical study and reversal of the primary phenomena of tuberculosis by its treatment and remedy in lime assimilation is unnecessary to review here. That is already on record in the study of Dr. Russell, a rare model, as I venture to think, of real scientific achievement and intellectual prowess in the larger domains of medicine. Even empiricism which through the centuries has built up a great and durable knowledge in medicine, especially in therapy, utterly failed to strike at the real issue of tuberculosis.

By the restitution of defective lime assimilation in the simple addition of hydrochloric acid to milk and egg, so that rennet activation may insure the nutritive intake of calcium in its casein or albumin combination Russell obtains 65 per cent. of arrest and healing of pulmonary tuberculosis. This refers to cases which have not as yet reached their procrustean beds. I have watched this treatment in his cases faithfully for nearly a year. In the course of the treatment an exudation makes its appearance with definite physical signs in one area or another of the lung, determined, it would seem, by the preponderance of the lesions. This exudate then retreats, undergoes resolution, and presumably walls off and encapsulates the lesions.

Moreover in private practice and independently I have again tested and applied this treatment, the corollary of the lime metabolism generalization. And I have watched this same thing happen. Under the systematic continued and persistent regime of calcium assimilation I have seen a number of my patients improve, undergo this exudation or partial consolidation in the lung, which then resolving would appear to contribute to the walling off and closing of the lesions. Hand in hand with this course of events the sputum clears up of tubercle bacilli which finally disappear and the patients are discharged with healed pulmonary tuberculosis. *In the face of this evidence, studied directly and conscientiously, I can no longer hesitate to believe that the great natural healing process in tuberculosis which rescues eight or nine-tenths of mankind, can be imitated and placed under human control under the guidance of a definite scientific principle.*

The beneficence and importance of this measure to the consumptive are too obvious, or at least they ought to be, to need elaborate commentaries.

Thus the contrast of calcium medication and lime assimilation in tuberculous animals is unequivocal and striking. In the one case we find no appreciable deterrent effects on the progress of the disease, while in the other disappearance of bacilli, arrest and retrogression of the lesions result. So it is also in the treatment and course of tuberculosis, especially pulmonary, in human beings. Empiricism has been on the verge of stumbling on the real cause of tuberculosis for a hundred years but it failed by being caught in the pitfall that lime medication could accomplish lime assimilation.

It is proper criticism to say that, having tried only one calcium salt—the hypophophite—it is precarious to make the general statement that all calcium salts are inefficient in supplying the want of lime nutrition. But there is another way of at least

getting at the probabilities of this generic inference, and this is by reasoning rather than undertaking the appalling amount of sheer laboratory work of testing the great array of all the calcium salts in their various combinations.

For in the first place all sorts of calcium medication from powdered bones to lime dust inhalations have already been tried in the rather blind and empirical attempts to find a remedy. In the second place, as we shall presently see, the notion of presenting the organism with crude lime to reduplicate the steps of the evolutionary formula of lime nutrition is rather naive.

What is the rationale of lime assimilation to which the analysis of this creosote calcium compound has finally led us? This is the essence of the whole generalization. It appears that evolution through all these thousands of years in the development of the mammalia has worked out the adaptation of lime nutrition in a particular fashion and with a nice adjustment. The foundation and starting point of this adjustment lies in the elaboration of our main and cardinal lime bearing food—milk and, after this, eggs.

In the mammalia it appears that to take integral part in cell function to give cells their capacity of repair, their full complement of nutrition, to contribute to what we call their vitality and vigor, lime must pass to the cells as a food supply. First of all the calcium must be in combination with casein, as in milk or some equivalent of casein, and then this combination must be acted upon in the stomach by rennet. In many of the mammals, the ungulates, for instance, the rennet is free and the formula is simplified. But in the highest of the mammalia, the carnivora, and men, another factor enters into the calcium-casein-rennet equation and this is the activation of the rennet by the secretion of hydrochloric acid or through the additional and compensatory activation by ingestion of acid food.

How insidious, then, may be the cultivation or habit of lime poverty? How well forty years ago the great clinicians insisted that the tuberculosis was ushered in by a "constitutional habit." For any interference with the sequence or combination of circumstances, as for instance insufficient hydrochloric acid or insufficient acid food to activate the rennet, disturbs the nutritive operation, upsets its delicacy of adjustment, and brings about one degree or another of lime starvation. It may be noteworthy to observe that the administration of calcium salts is a long way off from giving so much as a counterfeit of this formula, and the artificial and synthetic reduplication of this calcium-casein-rennet equation seems at present at least nowhere in sight.

The main and explicit types of lime starvation, of lime poverty, are scurvy, rickets and tuberculosis. How many other more subtly concealed maladies for which lime dearth is mainly or in part responsible remains to be seen under the acknowledgment and guidance of this generalization. In the case of tuberculosis it is more accurate to state that it is a form of lime starvation plus the tubercle bacillus.

Thus some eighty per cent. of humanity with its competent lime assimilation overcomes tubercle bacillus infection without as much trouble as cutting a wisdom tooth. Thus also evolution wipes out another fraction of humanity—unhappily their numbers are grievously large—unable to cope with the infection in their lime weakness. This process seems ruthless. In the end it is beneficent and imperative for the progress and fitness of the human race. Be sure of one thing: evolution will never bring any species down to the level of its unfit. It means extermination. So if man is to abide and persist, lime competency is one Shibboleth before which the unfit must go to the wall. Tuberculosis makes off with most of them.

The present selective process in the evolution of man is through the gauntlet of disease processes. Is it untimely to ask whether many of them are not self engendered, the inevitable consequence of our organization instead of the facile summing up and labeling of them with extrinsic causes?

Please do not misunderstand my position of calcium medication and lime nutrition. I do not exclude the possibility of some nutritive lime in-take in medication. On the contrary, I feel that there is something about the conjunction of this creosote and calcium combination not attained by either factor alone. It is probable that some of this lime medication does make its way, in a roundabout and indirect way to cellular nutritive anabolism. But in so doing it must obey the generalization, which can happen as follows: So important does this rennet seem for integrity of our organization, depending on lime assimilation, that compensatory rennet in small amounts and traces is found in the blood, and generally distributed throughout the body. Now, then, should the lime medication meet with some albumin in the body juices—some equivalent of casein and its congenors—and this in turn be acted upon by the free tissue rennet—the carrier as it were of lime for cellular intake—the lime assimilation formula could be followed and fulfilled.

What I do feel justified in saying, is that however valuable and commendable either creosote or calcium medication or both may be in the secondary phenomena of tuberculosis they do not and cannot hit the main track and trail of the disease process. And furthermore lime medication is only a poor Dromio and a feeble imitation of lime assimilation.

It is now in order to return to the first part of the paper—the observations in the treatment of the children.

We have the bedside notes of these entire fifty cases, but for brevity they are best given in tabular form. A few representative cases, however, may be given in summary. The cases have been divided into mild and severe types, referring not only to the character of the primary disease in general, but to the extent and degree of the respiratory tract symptoms in particular.

These children were as a rule, three years old or thereabouts and were given half-drachm or drachm doses (which is the equivalent of one or two minims of creosote) in milk, every two or three hours, beginning the first 24 or 48 hours appearance of cough or other respiratory tract symptoms. After this, the drug was administered according to need as indicated by the course of the symptoms. Were we now to undertake similar treatment in a new group of children, we should not wait for hints from the respiratory tract. We should be disposed to give the drug anyhow as a matter of routine. For it does no harm and may forestall these complications, or at least temper and mitigate their severity. We should also add dilute hydrochloric acid to the milk, the cardinal lime-bearing food, containing the creosote mixture activating the rennet to ensure lime assimilation restitution, offset by the fever and infection, and thereby apprehend the danger of tuberculous infection, or its outcropping, which is notorious after measles. The addition of dilute hydro-

Case	Name	Age Years	Admitted	Character of Disease	Complications	Marked Improvement	Discharged	General Remarks
1	Joseph P.	2	March 5, 1908	Mild	Severe cough. Coryza. Bronchitis	On third day	Four weeks later	Prolonged desquamation.
2	May Z.	3	April 25, 1908	Mild	None	After second day	Date omitted	Little or no cough until discharged.
3	Regina McC.	3	April 25, 1908	Mild	Severe cough. Card. sympt.	On 7th day	Date omitted	Cough ceased on 15th day.
4	Martin F.	2	June 12, 1908	Severe	Bronchopneumonia	On 4th day	Died June 21, 1908	Cough improved under treatment.
5	Annie F.	5	May 15, 1908	Severe	Severe croupy cough. Marked Laryngitis	On 8th day	June 21, 1908	On 14th day cough disappeared.
6	Sadie L.	4	May 25, 1908	Mild	Severe cough. Cardiac sympt.	On 7th day	July 4, 1908	On 10th day cough disappeared.
7	Sam R.	4	June 13, 1908	Mild	Double otitis media	On 7th day	July 11, 1908	
8	David F.	3½	May 28, 1908	Mild	Cardiac sympt. and bronchitis	On 4th day	July 7, 1908	On 8th day cough disappeared. Prolonged desquamation
9	Bennie B.	3	May 18, 1908	Severe	Marked bronchitis, double otitis media, slight dilatation and irregularity of heart	On 10th day	July 5, 1908	
10	Tillie S.	3	May 17, 1908	Mild	Moderate bronchitis and laryngitis, double otitis and prolonged vaginitis	On 7th day	July 11, 1908	
11	Ruth J.	3	May 20, 1908	Severe	Acute laryngitis, vaginitis of measles	On 6th day		Markedly croupy cough. May 25, May 28 patient very comfortable.
12	Jacob G.	7	May 15, 1908	Mild	Slight bronchitis and cough.	At once	July 12, 1908	Treatment discontinued on 3d day. Prolonged desquamation from scarlet fever.
13	Lillie D.	3	April 21, 1908	Severe	Marked bronchitis and laryngitis with croupy cough, bronchopneumonia, double otitis, vaginitis		June 14, 1908	Creosote with hypophosphite given in this case for 15 days in succession.
14	Sarah E.	4½	May 17, 1908	Severe	Cardiac sympt., vaginitis and suppurating glands following scarlet fever	On 7th day	July 12, 1908	Severe cough ceased on 3d day. Treatment discontinued.
15	Agnes DeC.	2	May 19, 1908	Mild		At once	June 14, 1908	Remedy lessened cough during lung involvement. Possibly hindering development of empyema.
16	Herbert H.	3	March 20, 1908	Very severe	Marked laryngitis with croup. Bronchopneumonia developed later	On 10th day	June 7, 1908	
17	Joseph K.	6	March 25, 1908	Severe	Pneumonia at the outset	April 8, 1908, 3 days later cough no longer troublesome	June 6, 1908	
18	George B.	4	March 10, 1908	Severe	Severe cough, coryza bronchitis and all cardinal symptoms. April 22, bronchopneumonia	In 48 hours	April 20, 1908	B. P., developed left lung March 22. Again C. H. q. 2 h. Slight colitis P. resolving March 3d. No vomiting on taking C. H., was kept up for 10 days.
19	Luke G.	4	Feby. 11, 1908	Mild	Koplik spots, sl. bronchitis and cough. Card. sympt.	Immediate	March 6, 1908	
20	Meta G.	7	June 22, 1908	Severe	Marked eruption w. coryza and bronchitis, marked laryngitis croupy cough	On 8th day	July 30, 1908	B. P. developed July 4. July 17 P. resolving. No ill effects from creosote with hypophosphites.
21	Isidor M.	3	March 8, 1908	Severe	Marked bronchitis and laryngitis. Croupy cough. Breathing with difficulty	On 4th day cough ceased	March 20, 1908	
22	Robert H.	9	May 17, 1908	Severe	Diffuse bronchitis, marked laryngitis	In 24 hours	June 23, 1908	Sibilant and sonorous rales.
23	May S.	5	July 5, 1908	Severe	Marked coryza, diffuse bronchitis and laryngitis	In 48 hours	July 25, 1908	July 7 child resting quietly.
24	Dorothy O.	9	June 11, 1908	Severe	Severe eruption, diffuse bronchitis and laryngitis. Cough severe	In 48 hours	July 16, 1908	In 72 hours cough disappeared entirely.
25	Sadie P.	4½	May 16, 1908	Mild	Slight bronchitis and laryngitis, eruption and well marked conjunctivitis	In 24 hours	June 22, 1908	Cough entirely disappeared in 24 hours.
26	Joseph G.	7	May 15, 1908	Mild	Slight bronchitis and Laryngitis	In 24 hours	July 12, 1908	Cough entirely disappeared in 24 hours.
27	William C.	1½	May 18, 1908	Severe	Bronchitis and laryngitis	In 36 hours	Died June 26	May 25, bronchopneumonia left lung, spread although cough was eased.
28	Lora L.	3	March 25, 1908	Severe	Bronchitis, laryngitis, coryza and conjunctivitis	In 48 hours	April 26, 1908	
29	Marion B.	3	Jan'ry 8, 1908	Severe	Bronchitis, coryza, conjunctivitis, laryngitis, croup	In 48 hours	May 25, 1908	Severe attack. Marked cardinal symptoms. March 18 operated on for mastoiditis. March 28, erysipelas of face.
30	Morris R.	12	Feb'ry 26, 1908	Mild		In 48 hours	Omitted date	
31	Jerry H.	8	April 10, 1908	Severe	Marked bronchitis, laryngitis, coryza and conjunctivitis	In 24 hours	May 8, 1908	Some difficulty in breathing. Face markedly swollen.
32	Ruth M.	3	May 13, 1908	Mild	Moderate bronchitis and laryngitis	Cough disappeared in 2 days	June 14, 1908	
33	Pauline S.	4	May 16, 1908	Severe	Marked bronchitis, laryngitis, coryza and conjunctivitis	In 48 hours Cough ceased on 7th day	Died June 9, 1908	May 28, Mastoiditis. June 2, sinus thrombosis, operated, metastatic abscesses knees and elbow joints.
34	Sadie S.	4	May 28, 1908	Severe	Severe cough, frequent prior to eruption, upon appearance of which it becomes worse	In 48 hours	July 4, 1908	
35	Julia C.	3	June 9, 1908	Severe	All symptoms aggravated Cough severe and troublesome	After 3 days almost entirely disappeared	July 16, 1908	
36	Sadie S.	3½	June 28, 1908	Severe	Bronchitis and frequent troublesome cough	In 48 hours	July 16, 1908	No colitis. No gastric disturbance.
37	Sam T.	2½	May 15, 1908	Severe	Severe bronchitis, very troublesome cough	In 24 hours Only slight cough after 48 hours	June 14, 1908	No gastric disturbance.
38	George H.	6	June 28, 1908	Mild	Slight catarrh and cough	Cough disappeared in 24 hours	July 4, 1908	

chloric acid does not interfere with the lime creosote emulsion. Among the twenty mild cases the following may serve as examples:

CASE I.—Joseph P. Age 2 years. Admitted March 3, 1908. Classical case of measles. Rather severe cough. Coryza. Bronchitis. Creosote and

Case	Name	Age	Admitted	Character of Disease	Condition	Marked Improvement	Discharged	General Remarks
39	Martin C.	1½	May 6, 1908	Severe	Well-marked [illegible] symptoms [illegible]	In 24 hours. Treatment continued. In 48 hours cough less troublesome and treatment continued 4 days longer.	Died May 29, 1908	May 15 bronchopneumonia set in with high temperature and severe coughing spells. C. H. 5m. 2 h. given, but in spite of that there was rapid involvement of the pleura with empyema. Patient developed sepsis and died May 29, 1908.
40	Alfreda O.	33	May 20, 1908	Mild.	Diffuse [illegible] laryngitis	In 48 hours. Cough disappeared 3 after days.	June 18, 1908	
41	Samuel A.	3	May 26, 1908	Severe	Severe laryngitis and catarrhal symptoms. Cough troublesome	In 48 hours. After 6 days cough entirely disappeared	June 20, 1908	
42	Walter C.	10	June 2, 1908	Mild.	Slight catarrhal symptoms and cough	Cough disappeared in 48 hours.	June 30, 1908	
43	Esther F.	2	June 4, 1908	Mild	Marked cough	In 4 days	July 16, 1908	Child comfortable from 4th day of admission. Restful nights. No laryngeal trouble, no vomiting.
44	Sam Z.	2	June 12, 1908	Severe	Severe croupy cough, bronchopneumonia, double otitis, colitis		July 16, 1908	Bronchopneumonia developed at end of first week.
45†	Isi B.	3	May 31, 1908	Severe	Severe cough and coryza	Died		July 10, developed bilateral bronchopneumonia with consolidation of entire left lung. Erysipelas developed. Case transferred to isolation ward. [illegible]
46	Paul R.	3½	June 23, 1908	Severe.	Marked bronchitis and croupy cough. Stenosis of the larynx. Hemorrhagic measles	After 5 days.	July 16, 1908	No disturbance of alimentary tract.
47	Barbara S.	4	May 15, 1908	Severe.	Severe cough, complicating otitis media	After 15 days cough disappeared.	Date omitted	
48	Dorothy O.	9	June 11, 1908	Severe	Severe cough. Bronchitis.	After 4 days 11 days later cough disappeared.	Date omitted	
49	Lauretta M.	4	June 20, 1908	Severe.	Severe cough and bronchitis	Cough ceased on 18th day.	Date omitted	June 24, bronchopneumonia left upper lobe. Dyspnea of pneumonia.
50	Abe Z.	2½	June 1, 1908	Mild.	Diffuse bronchitis and marked cough.		July 15, 1908	
51	Julius C.	3	June 6, 1908	Severe.	Marked bronchitis and cough with bronchopneumonia and colitis		July 16, 1908	
52	Michael B.	2	Jan'ry 1, 1908	Severe.	Diphtheria, intubation, pronounced symptoms of complicating bronchopneumonia		July 16, 1908	On extubation patient continued for short intervals with slight coughing spells. C. H. administered for 40 days. Gradual improvement and disappearance of cough.

Hypophosphites, drachm one every 2 hours. Cough improved after three days' treatment. Case discharged four weeks later after prolonged desquamation.

Case II.—Mary L. Age 3 years. Admitted April 25, 1908. All cardinal symptoms of measles. Cough improved after second day of treatment with the creosote and patient remained comfortable with little or no cough up to the time of discharge.

Case III.—Ruth McC. Age 3. Admitted May 13, 1908. All characteristic symptoms of measles. Cough rather severe and persistent. After seven days of the creosote administration cough improved, insignificant at the fifteenth day, and then ceased entirely.

Case XIX.—Lucie G. Age 4. Admitted Feb. 11, 1908. Koplik spots. All cardinal symptoms of measles. Cough. Bronchitis. Half drachm calcium creosote every two hours. Cough much improved in 48 hours, and held in check during the height of the disease. No complications. Discharged Mar. 6, 1908.

Case XLIII.—Esther F. Age 2. Admitted June 4, 1908. Measles. Marked cough on admission. Improvement in 4 days after creosote and hypophosphite administration; half teaspoonful every 2 hours. Child comfortable after that period. Bowels regular. Restful nights. No tendency toward any laryngeal trouble. No vomiting. Creosote administration kept up off and on for 25 days with no gastric disturbance. Discharged July 16, 1908.

Case XL.—Alfreda O. Age 33 years. Admitted May 20, 1908. Fairly severe attack of measles with diffuse laryngitis and bronchitis. Creosote lime emulsion one drachm every two hours. Improved cough in 48 hours. In three days' further treatment cough had disappeared. Discharged June 19, 1908.

Case V.—Annie F. Age 8 years. Admitted May 15, 1908. All cardinal symptoms. Severe cough, croupy at times. Marked laryngitis. C. H. (creosote hypophosphites) one drachm every two hours. Cough very troublesome for period of eight days, after which time there was marked improvement. By end of second week cough disappeared. No further complications. Discharged June 21, 1908.

Among the 32 severe cases, the following are illustrations:

Case IX.—Bennie B. Age 3. Admitted May 18, 1908. Creosote emulsion one drachm every two hours. Cough improved after first week, although bronchitis was marked on May 22. On May 25, general condition much improved. On May 28, small area of consolidation at right apex. Cough again became aggravated. Treatment continued with improvement and resolution. Double otitis media. Slight dilatation and irregularity of heart. No gastric disturbances incident to treatment. Discharged July 5, 1908.

Case XI.—Ruth J. Age 3 years. Admitted March 5, 1908. Severe cough. Markedly croupy. Acute laryngitis of measles. Improvement following creosote treatment in 24 hours. No further note of cough after this date, nor of gastric irritation. Vaginitis. Discharged June 30, 1908.

Case XII.—Lillie D. Age 3. Admitted April 21, 1908. Marked bronchitis, laryngitis and croupy cough. Creosote emulsion one drachm every two hours for seven days and then one drachm every four hours. Cough markedly improved, though there were paroxysms from time to time for ten days later. The creosote and hypophosphites was given for a period of fifteen days with no ill effects.

Case XIII.—George B. Age 4 years. Admitted March 19, 1908. Severe cough. Coryza and bronchitis. C. H., one drachm every two hours. Cough improved in 48 hours and no longer troublesome. March 23 developed bronchopneumonia left base. Cough troublesome at times. Again put on creosote emulsion and continued for 10 days. Condition improved. Slight colitis. No vomiting or gastric disturbances. *Pneumonia resolving on April* 12, and discharged April 20, 1908.

Case XX.—Meta G. Age 7 years. Admitted June 22, 1908. Severe case of measles. Coryza, bronchitis. Marked laryngitis and croupy cough. C. H., one drachm every two hours. Cough improved in eight days. Creosote kept up for 20 days. Cough disappeared, but again became troublesome and hacking, as bronchopneumonia developed on July 4. Creosote increased to two drachms every two hours. There was no ill effect, cough improved. July 17 bronchopneumonia resolving. Discharged July 10, 1908.

Case XXIV.—Dorothy O. Age 9 years. Admitted June 11, 1908. Measles. Severe eruption. Diffuse bronchitis and laryngitis. Child restless. Cough severe and very troublesome. The preparation one drachm every two hours worked promptly. In 48 hours the cough very slight and disappeared 24 hours later. No further complication. Discharged July 16.

Case LII.—Age 2 years. Admitted June 1, 1908. Diphtheria and measles. Intubated. Bronchopneumonia and severe paroxysms of coughing. On extubation patient still had slight coughing spells. Creosote was administered for 46 days in this case and it was encouraging to watch the improvement and the general gradual disappearance of the cough. Discharged July 16, 1908.

The textbooks are not at all unanimous about the administration of creosote in these affections of children. In Osler's system of medicine for instance, in the consideration of measles, no mention of creosote is made in the treatment of the respiratory affections. Expectorants, heroin, and codeine are recommended. Perhaps it has been assumed or experience with ordinary creosote has shown that gastric intolerance would interfere with its administration. Certainly from the abundant data this is not the case with this preparation in measles nor with similar affections in children and adults in general. And we are disposed to think from our own experience, that creosote is as valuable, if not more so, than these expectorants, codeine or other morphine derivatives, especially in children. The treatment should be continued in the severe cases for ten or fifteen days, for the cough is hard to check. For instance, in Cases VI, XLIII, and XLVIII the cough was controlled in four days or thereabouts, but the treatment was continued for several days longer.

Nothing extraordinary or new is claimed for the effects of creosote in these children. As for the mild cases it is a question whether they may not have been given undue prominence. For a very good form of treatment of this type is to leave the children reasonably in peace—except to watch for evils which may not occur—and they will get well. And yet it does no harm upon the slightest indication of the evil to give creosote as a prophylactic. The severe cases are quite another matter. A very conservative estimate is that ten per cent. of these have bronchopneumonia and ominous respiratory complications, and another conservative estimate is that five per cent. of these die of these complications. But two deaths occurred in our severe cases, one of them from an entirely outlying complication—otitis media—and the other of bronchopneumonia in spite of our medication. We may have intimated that the resolution of the bronchopneumonia occurred as a result of the medication. We do not know. Perhaps the lesions would have undergone resolution if left to themselves. But why leave to chance and hazard what we have good reason for thinking we can correct or mitigate by treatment?

OXALURIA DOLOROSA.

A CONTRIBUTION TO GENITOURINARY SURGERY.

By B. G. R. WILLIAMS, M.D.,

PARIS, ILLINOIS.

Several years ago I had the privilege of being called into consultation in a case which presented the cardinal symptoms of a renal or ureteral calculus. A specimen of the urine was submitted to me for examination. Although no microscopical concretions were present, the amount of hemorrhage was tremendous. This urine was highly acid and contained large quantities of calcium oxalate crystals. Pus and microorganisms were absent. The surgeon quickly decided that a renal stone was present either in the kidney pelvis or in the ureter, and insisted upon an immediate operation. The diagnosis proved to be incorrect.

To-day few surgeons would arrive at such a conclusion without further positive evidence. Nor may this hesitancy be explained by any definite instructions in the surgical texts, but rather by former embarrassing personal experiences. Surely there is a great paucity of literature upon the subject of oxaluria in general, but especially with reference to its presence as a cause or accompaniment of abdominal distress. I fail to understand why medical and surgical writers have neglected to give adequate space to this important pathological phenomenon. Though barely touching the subject, it seems to be conceded by many authorities, among whom are notably Musser[1] and Edsall,[2] that certain symptoms arising from the persistent passage of calcium oxalate crystals by the urinary stream may be very similar to or practically identical with those of ureteral calculi. How then may these two conditions be differentiated? Certainly the latter demands surgical interference, while the former falls into the realms of internal medicine.

Source and fate of the oxalates: Turning to the

physiological chemistry of oxalic acid and the part it plays in animal metabolism, we immediately get into deep water. Many authorities seem to be perplexed and in many instances differ strikingly in opinion. However, certain points may be hastily noted: A large amount of the oxalic acid excreted by the kidneys comes directly from the food. Thus certain fruits and vegetables, as grapes, apples, oranges, and tomatoes, contribute to this "oxalic ingestion," so that, as Delepine[5] has shown, much more oxalic acid in excreted during the summer than during the winter. But certain investigators [4, 5] have concluded that all the oxalic acid of the urine might be accounted for by the ingestion of the oxalates or by the fermentation of other substances in the alimentary tract leading to their formation. Klemperer[6] takes exception to the statement, holding that this organic acid may occur in a urine in which the diet is free from the oxalates and that the crystals of its calcium salt may occur in the urine of starving dogs. Similar proofs that ingestion and fermentation cannot account for all the oxalic acid in the urine have been offered by Salkowski and Leube[7] and Robin.[8] These latter opinions are doubtless correct; but whether or not there is a true oxalic diathesis scarcely concerns this communication, except in so far as therapeutic indications might arise. The actual presence in the urinary passages of the calcium oxalate as a crystalline deposit, rather than those processes resulting in its formation, must be held to account for every symptom noted in that condition which we may well term "oxaluria dolorosa."

At any rate, oxalic acid is excreted by the kidney as calcium oxalate, which is ordinarily held in solution by the diacid-sodium phosphate, and no crystals are observed in such a urine when freshly voided unless the ingestion has been great indeed. But if the urine is highly acid much of the oxalate is precipitated, the form of the crystal depending to a great extent, though not entirely, upon the degree of the acidity, or, in other words, the rapidity of the precipitation processes. If the acidity is not extreme, we would expect to find the envelope, dumbbell and hourglass forms of the oxalate. But if the acidity becomes tremendous the crystals are, as a rule, less perfectly formed, appearing as minute acicular structures of variable lengths and shapes, often, apparently, as broken bits of longer needles or as long double pyramids with sharp ends (Rieder[9]). Here and there may be seen a perfect envelope crystal. Such an appearance is invariably present in oxaluria dolorosa. In some of these cases the urine may be neutral or even alkaline, those influences which neutralize the diacid-sodium phosphate evidently causing the precipitation of the sharp crystals.

Nature of the lesion: A persistent occurrence of these needlelike structures along with those changes in the urine which cause their precipitation, soon brings on trouble. Eventually hematuria and ureteral pain begin and our attention becomes directed to the condition. From what follows it would appear that the nature of the irritation or injury to the mucous membrane lining the ureter is essentially mechanical, though I doubt if this could be strictly proven. Delepine[3] states that the occurrence of these needles in the freshly voided urine is usually associated with symptoms of irritation in the urinary passages. When the condition is persistent the degree of this injury is considerable. So much so, in fact, that Swinburn[10] in an analysis of twenty-six cases concludes that the urethra itself may suffer injury. Just how these crystals produce the irritation little concerns us. In rare instances they may coalesce to form sharp microscopic concretions or even visible gravel, but that the crystals of themselves may cause hematuria and severe abdominal distress I have proven to my own satisfaction by a careful and systematic examination of all the urine passed by the patient, and by the fact that, in one case at least, operation demonstrated no further findings of value. Again, there are therapeutic proofs which I shall take up later. Personally, I believe the irritation to be of a mechanical nature and identical with that which might be produced by "pulverized glass." Surely some of the physical properties of the former are identical with many of those of the latter. Ignoring the sharp appearance of the edges and points of these crystals, another experiment gives us astonishing evidence. Thus a specimen of the urine is held in the direct rays of the sun and set into motion by twirling the test tube. Each crystal, notwithstanding its microscopic smallness, catches the light, flashing minutely as it appears and disappears.

It has been claimed that the oxalate crystals of certain plants have been known to cause irritations of the skin and even dermatitis. The mechanical nature of this injury remains unproven but plausible, and many interesting points may be gained by an investigation of the subject. To this I shall give some space. Oxalic acid in crystalline as well as in a soluble form plays an important role in plant metabolism, though I cannot take time to consider the actual processes involved. In solution as the binoxalate of potash, it is found in large quantities in the order Oxalidaceæ (Kerner[11]). It is interesting to note that the insoluble crystals of calcium oxalate may occur in the cells of many plants, especially in the monocotyledons. Where these are found as perfect octahedrons, or so-called "envelope" forms, there seems to be no question but that they are incapable of injuring the animal membranes. But in other plants, notably the poisonous Araceæ, a different condition presents itself. Here the "raphides," which may occasionally be seen in harmless plants, occur in large amounts, and there seems but little doubt that they may cause dermatitis at least in certain persons (idiosyncrasies). The raphus or needle is a long and imperfectly crystallized bit of calcium oxalate. There is a modern tendency to apply this term[12] to all crystals, but for technical purposes, when speaking of "raphides" or "rhaphides," we mean needles or needlelike structures. Certain poisonous plants contain these acicular crystals, either singly or in fascicles, and it is to these forms that suspicion has been directed. Campbell[13] says that the tissues of the Araceæ usually contain large numbers of these raphides, to which has been attributed the extremely acrid taste of many of them. Further, that the *Dieffenbachia seguine*, a species of this order, is extremely poisonous. The juice of this plant is of a milky appearance and contains countless thousands of these microscopic needles. In the West Indies, the home of the plant, it has been termed the "dumb cane," because when taken into the mouth it causes the loss of speech. This is not due to any paralysis but to a local condition, as Chambers describes, the tongue immediately swelling and being accompanied by excruciating pain. One should bear in mind that the toxic agent is not a soluble substance but that the tongue has been

pierced, so to speak, by thousands of insoluble needles and that the injury is mechanical in the strictest sense of the word. Speech is regained in about seven days. Also the genus Arum of the order Araceæ numbers many poisonous plants. Some of these, because of their peculiar prickling action, are used as external irritants, for example, the *Amorphophallus campanulatus*. Our North American Indians found that by cooking these plants many of them, which in their natural state were poisonous, became quite edible (Chambers[14]). Still another genus, Arisæma, includes many poisonous species. Returning to our subject, it will be seen that the fragments of acicular crystals and the minute irregular forms of oxaluria dolorosa approach in appearance very closely the raphides. And it will be apparent how easily elements which may cause a dermatitis could injure a mucous membrane. The exceedingly long raphus, even if formed in the pelvis of the kidney, could not pass intact through the tortuous and highly muscular ureter.

Calculus versus oxaluria dolorosa: It would seem that a differentiation of these two conditions on symptomatology alone might prove to be a difficult and unsafe procedure. A true renal calculus causing symptoms by virtue of its location often demands surgical treatment even though its size might permit of its ultimate passage by the ureter. But operative intervention, when only crystals or occasional microscopic concretions are causative of the pain and hemorrhage, is neither indicated nor permissible. In the first place, the presence of these crystalline deposits in a urine highly acid or alkaline should place the surgeon upon his guard, and a sample freshly voided should be examined to make sure that these observations are correct. True, a calculus may also be present. The red blood cells in oxaluria dolorosa are often well preserved. The patient voids his urine frequently. The hemorrhage often proceeds with great rapidity and is doubtless from a large surface. But in uncomplicated calculus there is usually but an oozing. In case tuberculosis complicates the calculus, the amount of hemorrhage may be increased. But such blood is very likely to be laky, and a careful microscopical study will show the presence of many "ghosts." Pus, a common complication of renal calculus, is rarely present in oxaluria dolorosa. I have observed it in one case. The irritation is a moving one, and germs do not easily obtain a footing such as is offered in the rough and unwashed caverns of the stationary stone. Upon the other hand, such white cells as may be present are characterized by the clearness of their nuclei. In addition to an attempt (this often expresses well the procedure) to palpate and identify a renal or ureteral calculus through an abdominal wall rigid with pain, I desire to lay special emphasis upon the diagnostic importance of the skiagraph. This statement may seem quite out of place here, but from what will follow I am inclined to repeat it again and again until there is no excuse for misunderstanding. Here surely the skiagraph should not fail us. When oxaluria is present and pronounced it follows that the stone, if present, must contain much of this substance. The oxalate of lime stones cause shadows quite as dense as bone or even the most impermeable metal and are certainly easily detected. In the hands of a competent x-ray diagnostician the negative findings are quite as reliable as the positive ones. In other words, I would say "no stone if there is no shadow." The exception, I dare say, is rarely met.

Oxaluria simplex versus oxaluria dolorosa: In this communication I am reserving the term "oxaluria" only for those cases in which calcium oxalate crystals are present in appreciable numbers in the freshly voided urine. This may prove to be a too narrow interpretation, but nevertheless absolutely necessary at present in order that confusion may be avoided. Even though symptoms are absent I have no doubt that any urine which when freshly voided contains these crystals is not a normal urine. And if such a condition becomes permanently established it will certainly cause trouble in the urinary passages. An occasional exception might be observed where large amounts of certain fruits and vegetables are being eaten or following acute gastrointestinal disturbances. But even here most of the oxalate is in solution and either escapes observation or is diagnosticated from uranalyses with standing samples. Indeed, true "oxalic diatheses," if such are really ever present, should be diagnosticated, not by the presence of the crystals, since these are precipitated by local conditions, but rather by quantitative titrations of the soluble salt. It follows, parenthetically, that such estimations are subject to serious limitations if the diet is not carefully analyzed. But where, for certain reasons known or not apparent, oxalates are present in large amounts and the acidity of the urine is high, we are likely to find crystals of calcium oxalate in the freshly voided sample. That this precipitation of crystals even within the upper urinary passages may be considerable without causing symptoms, must be recognized. But when the condition becomes established and persists for long periods of time, pain and hematuria eventually ensue. In simple oxaluria, pain and other symptoms are lacking. In this condition we are most likely to find the more perfectly formed crystals. The urine may be markedly acid, occasionally several hundred degrees. Such oxalurias are usually transient, and this fact alone may explain the absence of local symptoms, for it is quite probable that the perfectly formed octahedral crystals may cause some degree of irritation.

Clinical crystallography: In the freshly voided urine of the normal individual any oxalates which are present are usually in solution and are therefore invisible to the microscopist. The crystals which may be found in a "standing" urine when fermentation has begun are usually perfectly formed and consist of octahedral and dumbbell forms. In the freshly voided urine of oxaluria simplex or following oxalic acid poisoning the same varieties may be noted. In the freshly voided urine of oxaluria dolorosa the findings are somewhat different. Perfect crystals are usually present and catch the eye, giving the first clue as to the identity of the deposit. But a careful examination usually reveals the presence of many imperfectly crystallized, acicular, and irregular forms. Occasionally a long needle may be observed, but usually the crystals have either failed to form or have been crushed by the powerful muscular walls of the ureter. Double pyramids with long axes and acute angles may occasionally be noted. At times, though not usually, we see an attempt at coalescence or the formation of microscopic concretions.

The uranalysis: So far as practical purposes are concerned this has been considered thoroughly enough, but it may not be unwise to review and emphasize some of the principal points: (1) *Simple oxaluria*: Reaction normal or variable. Condition usually temporary. Not easily differentiated from a specimen of standing urine except by a study of the urinary reaction, since in either case the crystals

are usually well formed. No blood. Very few desquamated epithelial cells. Always examine a fresh specimen before attempting a diagnosis. (2) *Vicarious oxaluria*: Noted in diabetes mellitus where the fluctuations in the amount of oxalic acid appear to be inversely proportional to the amount of glucose. Crystals, if present, are usually perfectly formed. This condition cannot be diagnosticated without the aid of the chemical estimation of oxalic acid. (3) *Painful oxaluria*: Freshly voided specimen usually highly acid, though it may be neutral or even alkaline in certain cases, rarely shows a normal reaction. Crystals appear sharp when held in the light. Perfect crystals of envelope or dumbbell shapes may be noted and serve to identify the nature of the deposit. Further search, however, will bring out the fact that many of the crystals are imperfectly formed, exhibiting the properties described above. Often large quantities of desquamated cells, especially of the tailed and multinucleated epithelial elements. Pus sometimes, though not often, present. Such white cells as are present tend to be well preserved. Red cells often present in large numbers and are well preserved. No tubercle bacilli and rarely any other varieties of microorganisms are noted. Skiagraphs negative. (4) *Calculus*: Reaction variable, rarely highly acid. Freshly voided urine may or may not show crystalline oxalates. Amount of blood variable, but often only an oozing and urine appears smoky rather than a bright red. Pus and microorganisms often present. Tubercle bacilli not uncommon. If oxalate crystals are persistently present in the urine, skiagraph should be positive.

Treatment of oxaluria dolorosa: Uncomplicated oxaluria dolorosa usually responds promptly to simple but rational therapeutics, but persists and grows worse where empirical methods are attempted. While the treatment is not operative, a surgeon is usually consulted. Thus it might be well to point out the chief indications and methods of treatment. (1) *Dietetic*: Prohibit the use of all foods which may contain oxalic acid or be converted into this substance, especially oranges, apples, grapes, tomatoes, rhubarb, sorrel, carrots, cabbages, string beans, garlic, asparagus, celery, sugars, and starches. (2) *Antacid*: In those cases associated with a high urinary acidity. This promises good results only when carried out intelligently. It is commonly instituted by leaving a solution of potassium acetate at the bedside with instructions to take *ad lib.*; hence the poor results. Those beneficial changes noted upon reducing the excessive acidity often immediately disappear when the urine becomes neutral or alkaline. It must be recalled that a certain slight acidity is imperative for the solution of the calcium oxalate crystals. It becomes a difficult matter to maintain the urinary reaction at a point where a specimen from a twenty-four hours' sample shows an acidity of 30 to 50 degrees, but when once the diet is fixed and the dosage of the alkali is calculated, such is not impossible. Discountenance the taking of acids of any sort only when prescribed to bring up the urinary reaction. On the other hand, do not permit the taking of waters containing carbon dioxide. In case the physician has not the time or opportunity to keep tab on the degree of acidity and the case is a severe and chronic one, the patient may be induced to do this and become expert at the calculations. His path is much straighter than that even of the diabetic, and he soon learns that he must never deviate from it. I recall one case of this nature who had passed about three years of continual agony. During this time he had made a round of all the doctors and had taken practically every form of treatment, good and bad. A man in this condition becomes desperate and is willing to attempt any rational treatment, even though it may not appear quite as wonderful as those rapid benefits promised by irregulars. Decinormal sodium hydrate is employed in the titrations with phenolphthalein as an indicator, according to methods found in works on medical chemistry. (3) *Acid Salts*: Reasoning doubtless that oxalate salts are normally held in solution by diacid-sodium phosphate, Maguire[15] advises the administration of this substance in large quantities by the mouth. In a case of oxaluria, where the reaction is alkaline or neutral, this method might be successful. Its author cites a case which apparently proves his contention. However, the details of the uranalysis do not seem to be clearly recorded and are open to question. It is exceedingly interesting to note that Maguire holds the idea that only a stone could have given rise to the symptoms which he observed and would have us believe that he was able to effect its solution in the ureter. But he sounds the keynote to a more plausible explanation when he states that the *x*-ray picture was negative. (4) *Miscellaneous*: Regulation of bowels, symptomatic measures, etc.

THE MORTALITY OF INDIFFERENCE.

By C. N. HASKELL, M. D.,

BRIDGEPORT, CONN.

INSTRUCTOR AND CHIEF OF CLINIC, DEPARTMENT OF NEUROLOGY, NEW YORK POSTGRADUATE MEDICAL SCHOOL AND HOSPITAL.

THERE is an extremely interesting and apparently obscure condition which presents so many phases of importance and general interest that I beg the liberty to call the attention of the profession to it and to report some cases that seem worthy of notice. Notwithstanding its obscurity, and the many perplexing difficulties attending its recognition, it can in no sense be regarded as an uncommon disease. It is so frequently and so persistently overlooked, and, remaining unrecognized for considerable periods of time, is attended with such high mortality, that one feels justified in commenting upon it in terms that cannot readily be misunderstood.

CASE I.—This case is one which appeared at the New York Post Graduate Medical College and Hos-

pital, and came to the Neurological Department in the service of Prof. Graeme M. Hammond, to be treated for neurasthenia. The patient is 24 years of age, single, a bookkeeper, and born in this country. Her father, who was alcoholic to some degree, died of pneumonia at 52. Her mother is alive and well. She has two brothers older and a sister younger than herself, and save for children's diseases they have always been well and strong. A younger brother died at the age of four from "brain fever." Further than this her family history is not of much interest. She had measles at 4, whooping cough at 8 and diphtheria at 10. Her growth and development have been normal and her life has been uneventful.

She complains that she is restless at night, awakes tired in the morning and continues so throughout the day. Her appetite is very poor and she is frequently nauseated. She is troubled with headaches almost daily, which are diffused and dull in character. She is very nervous and it is with difficulty that she controls her emotions. She is forgetful, irritable, and introspective. She has abnormal fears, ringing in the ears, numbness in her face, hands, and feet. All these symptoms combined with insomnia have made her feel that she may be going insane. Her pupils are dilated and she has a fine tremor of the hands. Her reflexes are all well within the normal limit. Otherwise her neurological findings are quite unimportant. This case, then, would seem, even on careful observation, to be one of neurasthenia, with a slight predominance of mental symptoms (psychasthenia). No profound mental abnormality can be demonstrated.

The patient was examined by a careful and painstaking member of our staff, and no neurological detail was overlooked. Furthermore, she had visited other clinics and she had a piece of paper on which were written the words "psychasthenia, neurasthenia, anxiety neurosis, and hysteria," representing the various diagnoses that have been made in her case. A private physician thought that she had malaria, and still another guessed gastritis. Should we, then, as neurologists, or general practitioners of medicine, be content with the diagnosis of psychastenia, or neurasthenia? Is there a probability that her symptoms may be due to gastritis or malaria?

The following cases were seen in private practice:

Case II.—A merchant, 56 years old, with family history of no importance, had a severe attack of grippe twenty years ago. Nine years ago there was discovered sugar in his urine, and since then he has been on a diabetic diet. For the past year he has been very nervous and has had no ambition. He has had a short, nagging cough for which his family physician has frequently prescribed, but no physical examination has ever seemed necessary. His symptoms have been ascribed to his diabetes plus a probable malarial infection. On consulting another physician recently it was determined that he was suffering from a nervous breakdown, and he was advised to play golf, take long walks, ride horseback, and take Turkish baths two or three times a week. Again a physical examination did not seem at all essential to arrive at a proper diagnosis and outline this strenuous form of treatment.

Case III.—A boy, 19. No feature of his family history or previous illnesses seems to have any bearing upon his present condition. Eight months ago he was taken suddenly ill with a chill. He was treated at home for several days for supposed malarial infection, the remedy being a teaspoonful of Warburg's tincture three times a day. Then a doctor saw him at his office and pronounced the case as one of walking typhoid. According to the patient's story his examination revealed the fact that his tongue was coated, his bowels moved daily, he felt feverish to the touch, and examination of his chest through two shirts and a vest was negative. The Widal test did not seem necessary or pertinent. After the fever had continued without abatement for six months a chiropractic doctor was consulted. He made no headway in breaking up the typhoid fever, although several dislocations of the spinal column were successfully reduced. The boy's lungs were normal except for the baneful influence of pressure on the nerves caused by the vertebral dislocations.

Further careful inquiry into Case I reveals the fact that this young lady has lost twenty pounds of flesh during the past six months; that her menses have become irregular, scanty, and painful, and that she has a "nervous" cough, which she has been told comes from her stomach. She perspires some at night. Physical examination revealed no neurological or mental pathology, as has been stated before. Her temperature at 4 P. M. was 100.3° F.; pulse 120, and respirations, 26. Abdominal viscera negative. A systolic murmur at the base of the heart on the left confirmed a hemoglobin index of 60 (Dare). A cavity of some size was found in the lower portion of the left upper lobe in front, while the lower left was full of moist subcrepitant râles. The right apex was infiltrated. The sputum contained tubercle bacilli.

Case II showed extensive involvement of both lungs except the right upper lobe. A cavity formation in the upper left had given rise to frequent bloody expectoration. Infiltration was complete in the lower and middle right. Sputum loaded with tubercle bacilli. Temperature at 5 P. M., 101° F.; pulse, 120, and respirations, 33. The urine, which was not excessive in amount, contained one-half per cent. of sugar and five per cent. of albumin, with a few hyaline casts. His blood pressure was 210 (Janeway). Certainly a poor candidate for golf and horseback riding. There was nothing else of importance in this case.

In Case III there was nothing of interest except the lung findings. The lower left lobe had broken down considerably, and the apex of the same side was infiltrated. The history and physical signs were suggestive of a tuberculous bronchopneumonia. The right lung was free from disease. Temperature at 2 P. M., 103° F.; pulse, 130, and respirations, 36.

Here, then, are three unfortunate individuals who, through the carelessness or ignorance of those in whom they have reposed their confidence, have, probably, lost the only chances they had to get well. The title of this article was intentionally made as ambiguous as it could be, for the double purpose of attracting attention and inciting interest in a condition which is, in my opinion, all important. The three cases which I have related above are fair examples of dozens which I have recorded, and I may say that hardly a day passes without observing a case of pulmonary tuberculosis which has previously escaped detection.

Still another case interesting from a different point of view is the following:

Case IV.—A factory foreman of 40 complained of headaches, loss of appetite, tired feeling, and insomnia. He had lost twenty-five pounds of flesh in

six weeks. Family and personal history were unimportant save for the fact that a brother five years younger had died of consumption two years previously. The patient spent considerable time with the brother, whose sputum was not properly cared for. Examination revealed a temperature of 99.4 F. at 3 P.M., pulse, 100, respirations, 20. The right apex presented semi-dry subcrepitant râles, both front and back, and a few below the clavicle internally. Whispered voice sounds were exaggerated in the left apex, the expiratory murmur was prolonged, and the lateral percussion note from the base of the neck to the acromion was contracted. Otherwise the physical findings were negative. He was frankly informed of his condition and instructed to take his temperature three times a day and return in a week for observation. He was also advised to go to a sanatorium if rest and other measures at home did not prove beneficial. His employer, in the goodness of his heart, sent him to his own physician, a good surgeon, who could detect no abnormal sounds in the man's chest. He did not return to me.

If pulmonary tuberculosis were an uncommon and really obscure disease, some excuse might be offered for such oversights. On the contrary, it stands second in the list of diseases that destroy life. Some one dies from it every three minutes, and statistics show that every third persons is or has been infected with it. Textbooks and medical journals are replete with articles giving the profession the necessary information regarding its diagnosis and treatment. Millions of dollars and a great deal of energy are spent each year in the nearly hopeless task of preventing its spread and in caring for those afflicted with it. The problem of its eradication lies in its early recognition in the individual by the physician, and consequently the responsibility rests largely with the medical profession. I venture to say that where one case of pulmonary tuberculosis is recognized in its incipiency, at least one hundred escape detection.

There is no disease so frequently overlooked as the one under consideration, a most unfortunate circumstance when it is considered that it is extremely insidious in its onset, and, when beyond timely recognition, fatal in its termination. We all know the real reasons for these serious errors in diagnosis. A busy practitioner in a neighboring city recently told me frankly that he did not know what he heard when he listened to a patient's chest. Within a few miles of a teaching center like New York, such a lack of technical knowledge is inexcusable, inasmuch as the lives of many depend upon his accomplishments as a diagnostician. There are many others of the same sort. More culpable still is the man who knows but will not take the time or trouble to make the necessary examinations. He assumes an attitude which carries with it the idea that he is all-wise and that such details as are involved in careful examinations are quite unnecessary.

Modern methods, however, are slowly but surely educating the public to see that there is nothing mysterious or occult in the physician's powers of discernment or his healing art. The lay mind is beginning to appreciate that there is no soothsaying or second-sight foolishness in the diagnosis of disease, and our clients are already beginning to demand that they shall be thoroughly examined. Ultimate failure awaits the man who is too busy or too indifferent to examine his patients.

Until quite recently the methods of teaching physical examinations in the colleges have been at fault, and, what is more important, teachers have taken too much for granted in the receptivity of their pupils, with the result that many graduates are absolutely incompetent to observe correctly certain conditions that should be made very clear to them.

There is certainly no scarcity of literature on the subject of tuberculosis, but it must be admitted that most of it is too technical and uninteresting to occupy the attention of the average practitioner of medicine. What is really needed to awaken more interest in the subject is the establishment of local and county society clinics with competitive work of some sort that will make it very desirable for each member of such societies to demonstrate his ability to recognize the second most fatal disease that we have to encounter.

More plain talk, or some plain talk on the part of those who think they know something about the subject would possibly awaken some latent interest that would otherwise lie dormant.

Fifteen years ago I wrote an article on "The Early Diagnosis of Pulmonary Tuberculosis," and another one about three years ago with the same title, and I am now constrained to make some remarks on the subject that will be more easily construed and less likely to be forgotten.* You need not be neurologists to diagnose nervous disease, gastrologists to detect gastritis, or expert phthisiologists to discover pulmonary tuberculosis; you only need to be thorough and systematic in your methods of examination, honest in forming your opinions and in expressing them, ready to acknowledge your ignorance, if need be, and earnest in your desire to learn the truth.

The constitutional symptoms of the disease in question are fairly well depicted in the history of Case I. Contagion is a very important factor and should be carefully investigated. Invariably insist that every person that you intend to examine, whether male or female, old or young, rich or poor, shall entirely remove the clothing to the waist. Inspect the chest for retraction of the apices, lagging of the affected side, restricted movement at the base or apex, and bulging of the intercostal spaces due to the presence of fluid in the pleural cavity. Percuss the chest for areas of dullness or flatness and note the percussion resonance above the clavicle between the base of the neck and the acromion. Palpation may reveal some degree of variation of vocal fremitus and pulmonary resonance. Inspection, palpation, and percussion are valuable corroborative methods to employ, but are not nearly so valuable as auscultation. The chest cannot be successfully auscultated without the use of a stethoscope or phonendoscope especially adapted to the various irregularities of its contour. Every portion of the chest from apex to base, in front and behind, should be auscultated inch by inch. Respirations, either forced or natural, augmented by a short quick cough, will usually reveal any abnormal sounds. Cough sounds are exaggerated breath sounds and are subject to the same variations and it should be remembered that coughing will often reveal certain râles which cannot be detected in any other way. The voice sounds are changed in character when slight consolidation has taken place and the whispered voice is appreciated more accurately than the spoken voice.

The adventitious sounds or râles are by far the

*The Early Diagnosis of Pulmonary Tuberculous Disease (Proceedings Connecticut Medical Society, 1897), *New York Medical Journal*, June 26, 1909.

most important consideration in the detection of early pulmonary tuberculosis. These are semi-dry or slightly moist and sticky, and vary from a finely crepitant râle to a sonorous sound. The more moist and coarse they are the farther the disease has progressed, so that if one were confined strictly to early or incipient cases, the râles must needs be of the finest variety. If you find any râles that are sharply localized, give them especial attention.

Make careful notes of your findings and if you are not confident of your ability to draw conclusions immediately, instruct your patients to return later and with the aid of your books give your cases careful consideration. Do not lose sight of the fact that somebody's life may depend upon your skill and honesty—more especially upon your honesty. Give the patient the benefit of any doubt about the diagnosis. If you are going to make a mistake, do it on the safe side for the patient and disregard yourself in the matter. It is much safer and better for the patient that you should tell him that he has consumption when he hasn't it, even though it frightens him badly and drives him to another doctor, than to tell him he is all right when he is developing a disease which will eventually prove fatal. If you realize that you are not competent to interpret correctly the sounds you hear, take the next train to the nearest teaching center and confide your shortcomings to a good instructor. Be honest with yourself and your teacher and refrain from saying that you understand this or that sign when you really do nothing of the sort. Continue your studies until you have learned enough to make of yourself not only a safe member of society, but a real help to your fellowmen. Stay until you can recognize the majority of cases of pulmonary tuberculosis that come under your observation before they are detected by the lay friends of the patients. If you are unwilling or unable to complete your education in the diagnosis of this most common disease, send your patients to some one who is more discerning, and thus give those who have so innocently and ignorantly entrusted their lives to your care the only chance they may have to live. The few dollars that you may lose by a frank acknowledgment of your ignorance is nothing as compared with a human life, and it is safe to say that your honesty will be rewarded.

A word about the treatment of these patients. They have all been put to bed in the open air to rest until their active symptoms shall have subsided. They will receive as much nourishing food as they can digest; their various bodily functions will receive proper attention, and they will be encouraged in every way to keep up the fight for their lives.

THE BASIC CAUSE OF FLATFOOT.

By JAMES R. MITCHELL, A.B., M.D.,

FORT WORTH, TEXAS.

LECTURER IN CHEMISTRY, FORT WORTH MEDICAL COLLEGE.

The higher the intellectual development of an animal, the more pronounced the differentiation between its upper and lower extremities. The zenith in this evolution is attained in man, whose arms and legs are highly specialized. Each arm tapers toward the hand, which is peculiarly adapted for nimble action. Each leg is anatomically developed for locomotion, without regard for tedious dexterity. The ingeniously contrived foot establishes man's truly stately posture and endows his carriage with strength and elasticity.

Unfortunately, however, statistics indicate that in civilization the foot is failing in its duty as a support. Flatfoot has been steadily on the increase until now it affects to some degree one-half the adult population. The United States Army rejects more men for flatfoot than for any other single cause. In fact, it constitutes forty per cent. of all causes. Of 123 army candidates recently examined and classified, 22 had normal feet, 23 had slight arch defect, 40 suffered foot strain, and 32 suffered acute foot strain. Our Government would cease building any type of bridge did 26 per cent. of such structures duplicate this complete collapse! Nature must soon relegate every one of us back to "all fours" if we cannot correct the causes of this downfall. Fifty years hence our progeny may have to creep and wriggle into their aeroplanes instead of entering them with triumphant, manly stride. Pride in the graceful instep of a high-arched foot denotes a patriotic pride in racial superiority. The high instep of the Arab signifies a complete adaptation to the erect posture, while the foot of the negro—"so flat that the arch makes a hole in the ground"—is a stigma of inferiority.

The premonitory signs of flatfoot yield important clues concerning the cause. The patient notices pain and stiffness in the calves of his legs, much worse in the morning on arising. Often the pain lasts but a half hour, and disappears entirely after a short morning walk. Such a pain is often misdiagnosed and mistreated as rheumatism, when in reality but a symptom of the broken arches. If the doctor examines the foot he is unable to flex it to more than a right angle to the long axis of the tibia. Both the pain and the resistance depend upon a rigid gastrocnemius—nature's attempt to put the foot to rest by muscle spasticity. An outline of the foot on greased paper confirms the diagnosis of a broken arch. An *x*-ray picture may show the bones to be slightly displaced.

A long search through the text-books has failed to provide me with a logical reason why flatfoot should be so prevalent. The authors seem to have guessed at the causes, instead of having reasoned from the facts. I will take up each assigned cause separately and point out its apparent fallacy.

Misshapen Shoes That Bind and Compress.—This cause must act but rarely. A fusilade of blisters, calluses, and corns would certainly assail the foot long before the bones were wrenched out of place. Children, who from babyhood have never worn shoes, are flatfooted. I have been forced to the conclusion that shoes of any kind, or of no kind, have very little concern with the condition.

Walking on Solid Pavement.—This cause must be purely contributory, otherwise all mountainous races would be severely afflicted; such is not the case.

Weakening of Tendons.—This suggestion implies that the tendons are loosened from their bony attachments. Later we will see that the true cause of flatfoot is the true cause of the weakened tendinous attachments. This is a concurrent effect, not a cause.

Inclination to Let the Feet Turn Inward.—This is another way of saying that a natural mode of walking induces flatfoot. To walk correctly, the foot must turn in. It is the economical method of obtaining the maximum power of the big toe.

Weight of Patient.—The originator of this cause evidently does not love a fat man. He probably never saw the vaudeville performer who, day after

day, held five people on his arms and shoulders. Seven hundred pounds did not damage his arches, although he had been doing such stunts for five years when I saw him.

"Slovenly Habits of Walking."—This excuse provides a refuge from brainwork. It is a slovenly, unsupported statement. It ignores the fact that the ranks of the flatfooted army are recruited from every walk of life. The dignified judge and the illustrious general may stand upon the same disorderly footing as the shiftless loafer and the idle vagrant.

The causes assigned may hasten the effect, but none is the basic cause of its production. They are accessory causes after the fact, or accelerating causes, if you prefer that name. A study of these accelerating causes leaves an unsatisfied feeling that much has been left unsaid. All the accredited explanations fall flatter than the foot they attempt to explain.

Dr. Taylor's widely accepted explanation of flatfoot assumes the basic cause to be a continuous contraction of the gastrocnemius muscle. He submits the diagram shown herewith.

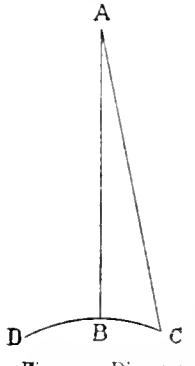

Fig. — Diagrammatic explanation of the production of flat foot. AB, represents the long bones of the leg; AC, represents the gastrocnemius muscle; DC, represents the long arch from the tuberosity of the calcaneus to the ball of the great toe.

It requires but little imagination to appreciate that, if the point D be fixed, a persistent shortening of AC must result in a flattening of DC. But this theory neglects the explanation of what in the first place induced the contraction of the gastrocnemius, whether the origin is nervous, spontaneous, or otherwise. It assigns little importance to the plantar fascia, stretching toughly from D to C, which must completely nullify the action of the gastrocnemius were that muscle the essential factor. Such a condition as this theory portrays has no other analogy in the body. Can you duplicate elsewhere the action of an active muscle,—not of an inactive muscle, nor of scar tissue, understand, but of an active muscle,—causing a similar deformity? I believe that the promulgator of this theory puts the cart before the horse. I believe that, in the universal relationship existing between the spasticity of the gastrocnemius muscle and flatfoot, the flatfoot always causes the rigidity of the muscle, just as in the relationship between the rigid rectus and the appendix, the fault always begins with the appendix. In no sense could a rigid rectus be blamed as the cause of appendicitis, but should always be considered as nature's instrument for putting the belly wall to rest. Similarly, nature in her desire to limit the motion of the weakening foot attempts restraint by stiffening the gastrocnemius muscle.

Let us now draw an analogy from the experience of the architect. Suppose the arch of a stone bridge has given way. Would not the architect seek out some defect inherent in the material of the bridge? He might regard time, misuse, and the strain of traffic as factors contributing to accelerate the weakening of the material, but he would conduct a careful examination to disclose some cracking of the cement, or rusting of girders, or crumbling of stone, or other structural weakness that prevented the bridge from sustaining its formerly safe load. Like the arch of a bridge, the arch of the foot would certainly collapse were the rigid composition of the bones in any way weakened. The strength of the arch is bred in the bone.

My purpose in submitting this analogy is to enable the reader at once to appreciate my contention that the basic cause of flatfoot is a slow absorption of calcium salts from the bones of the foot. I believe that the facts which I will present justify the conclusion that every flatfoot is another lump of evidence in proof that our nation is suffering a lime starvation. I could exhibit, as a concrete illustration of this theory, a bone so softened by the abstraction of its lime salts with hydrochloric acid that it has been readily tied into a knot. Bone is connective tissue infiltrated with lime salts. Bone that has lost its mineral can be no stronger than connective tissue.

Bone is essentially a dense structure containing relatively insoluble lime salts cemented with a mortar of collagen. When the lime salts are removed, the strength of the bone is lost. All lime-containing structures of the body are subject to abstraction of their minerals according to the whims and necessities of the blood. This loss of lime is evidenced from the brain and nerves in tetany; from the teeth in artificial lime starvation on experimental animals; from the bones in osteomalacia. In truth, the blood is protected first.

The blood is the oldest tissue of the body. With nature first come is first served. As Ringer pointed out more than a quarter of a century ago, the blood needs calcium in the proportion 1:10,000 to maintain the heart-beat. If the blood gets sufficient lime from the food to replace the amount lost daily in the urine and other excretions, the tissues remain intact. If the lime in the daily food supply is insufficient, the blood has no scruples about attacking the teeth, the nerves, or the bones to snatch the needed lime to tide over a stringency. The blood comes first. The heart-beat is more important than the rock-ribbed bone.

Flatfoot, like bowlegs, develops gradually; there is never any sudden collapse. The process resembles the action of water in wearing away a stone. Yet one may object to this theory of mineral absorption by inquiring why the foot should be involved, and not the knee nor the hand. To some extent heredity must determine the site, just as when a rat is fed upon a calcium-free diet its nerves and teeth are affected more severely than its bones. For the most part, however, simple physical laws govern the site of absorption. Gravity directs a relatively larger amount of blood with greater force to the foot than to any other part of the body. This would subject the foot to increased absorption of salts. Further, the muscles of the legs, with intermittent activity, impel a vigorous venous current, which in turn induces an active circulation through the bones of the foot. The more active the circulation of the blood, the more active its powers of absorption,—just as the quicker the rate of water dropping, the faster is the rock worn away. As all absorption varies directly as the motion, so all calcium absorption must vary directly as the motion. No wonder nature puts tension upon the gastrocnemius in an attempt to limit the motion of the foot! It is the same patent granted to the rectus abdominalis to limit the spread of peritonitis. Decrease of motion implies decrease of absorption, which in turn means an end put to the drain upon the mineral resources by the savage blood circulating in the Haversian canals. If the

mineral absorption is not controlled, the accelerating causes combine to render the collapse of the arch complete.

I look upon flatfoot as but one more symptom of our national lime starvation. The causes of this mineral famine are self-evident. The American diet is well supplied with protein, carbohydrate, and acid food-stuffs, but sadly deficient in the mineral. Our children all too often are nursed with condensed milk. As they develop we feed them on cereals, all naturally poor in minerals, including wheat artificially bleached which we call flour, and alleged rice so highly polished of its mineral content that it is fit only to be ground up as face powder. We provide the youthful generation with vegetables, many of which have been raised upon played-out alluvial soil; even such minerals as may have been present were dissolved out and thrown away with the water after cooking. The universal habit of hasty eating takes away fair opportunity for the digestive juices to dissociate and combine with the minerals presented for use.

We allow young men—and sad to relate young women, too—to drink alcohol at an age when their bodies still need milk. Those who grow up in cities drink flood water, stored in reservoirs away from all contaminating contact with Mother Earth, and for that very reason the water is denied the portion of mineral salts which Mother Earth would gladly give did opportunity present. What a cold satire that these loved ones are given a slab of marble—with its abundance of lime—only after they are dead!

If the basic cause of flatfoot be lime absorption, then its consideration teaches us that a cure in the late stage is impossible. But if flatfoot cannot be cured, we can devise simple means for its prevention. Such a method would require a diet rich in lime salts, as contained in milk, eggs, fruits and vegetables; the avoidance of decalcifying acid food, and the drinking of water known to contain the physiological minerals. The mineral balance of the blood determines our equilibrium when on our feet. Dietetic prevention must replace our rubber heels and makeshift arches. An arch reinforced with metallic calcium scorns the assistance of aluminum plates.

The seven bones of the arch are bonded into a close union for mutual help toward the material uplift of mankind. It is a union whose members receive the small wages coined from a few specks of calcium, a union whose downtrodden members seek no relief from duty unless goaded to mutiny by the "arch-fiend"—a demineralized diet. The concrete foundation for the maintenance of this inflexible spirit must be laid deep in each bone. The strength of the arch is bred in the bone.

The Dangers of Pertussis and Its Relation to Tuberculosis.—Saint-Philippe believes that whooping cough often lays the foundation for tuberculosis, chronic bronchitis, and emphysema. Abortive cases of pertussis or those without a whoop constitute one-sixth of all cases of the disease. The diagnosis should be made from the obstinate spasmodic cough with vomiting, the profuse expectoration, the discharge from the eyes and nose, and the congested face. Examination of the sputum reveals the bacillus of Bordet and Gangou, the causative microorganism, and the blood shows leucocytosis. Early diagnosis and proper treatment may enable one to prevent the serious complications, bronchopneumonia, and prolonged bronchitis. The disease is seldom directly fatal, but frequently children die from the sequelæ. The coexistence of measles and pertussis renders the latter much more than ordinarily fatal.—*Journal de Médicine de Paris.*

HOW MAY WE BETTER THE CONDITION OF THE GROWING CHILD?

By E. MATHER SILL, M.D.,

NEW YORK.

ATTENDING PHYSICIAN IN DISEASES OF CHILDREN AT THE GOOD SAMARITAN DISPENSARY; LECTURER IN DISEASES OF CHILDREN AT THE NEW YORK POLYCLINIC HOSPITAL AND MEDICAL SCHOOL.

EVERYONE who has had wide experience must admit that improper and unscientific feeding of children from birth to maturity is one of the most fruitful causes, both directly and indirectly, of disease, disability, incapacity for work, both mental and physical, with loss of energy, susceptibility to contract, and inability to withstand, disease.

The problem of nourishment which is so vital to the children of the poor, since the condition of our future population and thereby the welfare of the nation is dependent upon the way in which her children are nourished, should command the interest of all.

Only recently I have made a careful study of 210 malnourished children under ten years of age, to ascertain as nearly as possible the cause or causes of their physical condition, and to determine how that condition could be avoided, and what line of treatment was best to bring these children back to a normal state. My investigations showed that in the great majority of cases insufficient and improper food was largely responsible for their condition; there were other contributing causes as well, but this one appeared to be paramount. In making a study of the diet of these 210 ill-nourished children we found the following breakfasts were given: Tea or coffee, 105; cocoa or milk and bread, 30; milk or tea and egg, 10; coffee and oatmeal, 4; nothing, 1. It is well known that breakfast is the important meal for the growing child, and the record in these cases showed how totally inadequate this meal was, and in consequence many must have been so hungry in school that they could not concentrate their minds on study. These children could be given a nourishing meal at school for a trifling sum as is done in many of the schools with success in England, Scotland, and France.

Undernourished children contract disease much more easily than properly nourished children, and when contracted, it is much more severe and prolonged. Such children have so little reserve force to fall back upon that when they have to undergo a severe illness or operation they are much more apt to succumb.

Ill-nourished children are especially subject to catarrhal affections of the nose and throat and to bronchitis; they also are very susceptible to cold, and easily affected by it. Many are subject to rheumatism, articular and muscular, and rheumatic sore throat; also not a few have chorea and rheumatism of the heart.

All ill-nourished children are easily fatigued both mentally and physically, and have not the capacity for work that is seen in well-nourished children. Many of them have a tired, worn, old, inattentive look, complain of feeling tired, and cannot concentrate their attention for any length of time, and their gaze is constantly wandering.

They are pale and anemic, with thin, flabby muscles; their brains, as well as their bodies, are starved for want of nourishment, and fail to react to ordinary methods of teaching. Many of them are put down in the schools as dullards, or backward children. In these cases good nourishing food is all

that is needed and far more necessary for the stomach than books to feed the mind. It is an impossibility to concentrate the mind when hungry or to study on an empty stomach.

Is it not absurd to force these little half starved things to attend school as our compulsory school laws do force them to do? Is it fair to suppose that a hungry child, wasted and weakened, with the attendant conditions of lassitude, irritability, nervousness, and pallor, the result of prolonged underfeeding and bad housing, can study for five hours with scarcely any intermission?

In our investigations of these 210 families we found that the average number of rooms, and many of them inside rooms, per family was three, with an average air space of 3000 cubic feet. The average number in each family was six. This allows only 600 cubic feet of air space for each person, or one-half what is required for health.

It was found that 62 per cent. kept their windows closed at night as well as during the day. Fifty per cent. of the children ate candy, etc., between meals; 13 per cent. were in a grade at school with younger children; 80 per cent. were in bed at 9 o'clock or later, while they were all under ten years of age and should have been in bed by 7 or 8 o'clock at the latest.

Most of these children were bathed very infrequently. A large percentage had decayed teeth, and obstructed breathing through the nose as a result of large tonsils or adenoid growths.

Many of them had no desire for good nourishing food, because they had become so accustomed to the tea and bread, or coffee and bread, diet. When we find by a conservative estimate that there are a million and a half of these undernourished children in the United States is it not appalling?

Proper nutrition of the body is a subject that has always been of great importance, yet up to a comparatively recent date has received no scientific study. It is only when we begin to look at the composition of foods that we realize how complicated they are, and it is then that we learn that the chemical substances of which the body is made up are very much the same as the foods which go to nourish it.

We find the chemical elements in the foods used by man are the same as those found in the body, and these elements form a great variety of compounds, the most important of which are protein, fat, carbohydrates, mineral matter, and water. These compounds in the food are to nourish the body, supply it with heat and energy, to repair the tissues of the body, to form new bone, blood, muscle, nerve, tendon, cartilage, and other tissues and produce growth.

It has been found that 60 per cent. of the body weight of the average man is water; protein about 18 per cent.; mineral matter forms 5 or 6 per cent.; fat, 15 per cent., but the proportion varies greatly with food, exercise, age, and other conditions. Carbohydrates form less than one per cent. of the body weight.

Each of these several compounds in the food has its special office to perform in the economy and metabolism of the body; they either build tissue or yield energy. Protein, fat, or carbohydrates, any of them can be burned in the body to produce heat or energy. This, however, is a less usual and less important function for the protein, its principal function being to build new tissue, and for this purpose it is the most important ingredient in the food, since it is the most important part of nearly all the tissues of the body. Mineral matter is necessary but in smaller quantities. The fats and carbohydrates are required to form heat and muscular energy, this being their chief function. It has been found that about 0.9 per cent. of fat in the ordinary mixed diet comes from the animal foods, and about 0.9 per cent. of carbohydrates from the vegetable foods, while protein is obtained chiefly from meat, fish, and milk among animal foods and from cereals and legumes, such as peas, beans, and lentils, among vegetable foods.

Knowledge of the composition and requirements of the body and the composition of foods and the amount of different compounds in the body, the amount of percentage of the different compounds in each food, and the function of each of these compounds in the food when taken into the system enables us to construct intelligently and scientifically proper diets for various ages, occupations, and conditions. Careful chemical analyses of foods and clinical experience in the feeding of hundreds of children has shown that the following dietary schedule and articles of food are best adapted to the average growing child:

One-half hour for breakfast, 7 to 8 A. M.: Glass of milk, baked apple or orange. Cereals: Oatmeal, cracked wheat, farina, hominy, etc.: two to three tablespoonfuls of one of these cereals, with milk and cream. Eggs: one to three, according to the age of the child, either soft boiled, scrambled, poached, or in the shape of an omelet; or a lamb chop or small piece of steak, or fish for variety occasionally; one to three slices of bread, ⅜ of an inch thick, or a roll, with abundance of butter.

10 A. M.: An apple, a banana, a couple of graham crackers, or a small glass of milk.

One hour for dinner, 12:30 to 1:30 P.M.: Soup, bread, and butter. Meats: rare steak, rare roast beef, mutton or chicken (fish may be given once a week). From ⅛ to ¼ of a pound of meat or fish should be given, according to the age and capacity of the child. Baked or boiled potatoes, with butter and salt, or stewed with milk, and a green vegetable such as spinach, carrots, string beans, green peas, cauliflower, squash; a purée of dried soy beans or dried peas may be given two or three times a week at this meal, or baked beans may be given (one to two tablespoonfuls) and this will in a measure take the place of meat. A glass of milk. Hominy or rice may be given three or four times a week (two to three tablesponfuls). A simple dessert such as rice pudding, bread pudding, custard, blancmange, ice cream.

At 4 P. M.: An apple, peach, or pear may be given if the child is hungry. Half an hour may be given for supper from 6 to 7 P. M.: Bread and butter and a glass of milk, or bread and milk, milk with one of the cereals, bread and butter with jelly, fruit juice or syrup, a small piece of cold meat, or omelet, or scrambled eggs: plain cake, stewed prunes, or apple sauce.

Requirements of the growing child. For the proper development and growth of a child nature demands that certain fixed and unchangeable rules be followed, and when these rules are disobeyed development and growth are impaired and often, as a result, disease follows.

In order that a young animal may grow steadily and develop into a large and healthy specimen of its kind it must have plenty of good nourishing food with a high percentage of protein suitable to its age; but if it does not receive this food at regular

intervals it becomes stunted and, although later it may be healthy and fat, it never attains the size of one which has had plenty of the right kind of food from birth. So it is with the child if improperly nourished while young, it becomes stunted and dwarfed. Children are so active and use up so much food in the shape of energy in that way, besides the food they need to develop the body, that they require a highly nutritious diet, containing a high percentage of protein, and this is especially important where the child is malnourished. It is up to the twelfth year of age that we see most of the cases of malnutrition, and it is up to this age that the greatest demands are thrown upon the child, since this is the period of rapid development and changes in all the tissues of the body, and on this account it is a period of particular susceptibility to disease. A child up to this age requires long and regular hours of sleep, and under the age of twelve years every child should be in bed by 7 or 8 P.M. Children under 7 or 8 years, especially if undernourished, should have a nap of an hour or two during the middle of the day. The growing child to be well must not only be well nourished, but must be regularly fed, be properly clothed, and have plenty of fresh air. Since a large amount of fresh air is necessary to oxiginate the food that is required for growth, four or five hours out of doors every day are essential. When the weather is too bad for this an indoor airing may be given by opening all the windows in the play room, dressing the child in its outdoor wraps, and allowing it to play there. Sleeping rooms must be well ventilated at night by opening the windows from the top at least six inches. All the talk about night air obtained in this manner being injurious is a fallacy.

Children should have certain hours for play in the open air in parks or playgrounds, not in the dusty streets, the only place that so many seem to be able to play now, and certain hours for study. Long hours in ill-ventilated school rooms for young children do great harm by undermining the health of the child, which is far more important than anything it can be taught in school. Cleanliness is also an important factor in the well being and health of every child, and a tub bath should be given at least once a week in winter and oftener in summer. Children are entirely dependent for their care, feeding, clothing, sleep, care of teeth, bathing, play, etc., upon their family, therefore, by instructing the American people along these lines the child will be benefited and learn the principles of nourishment, health, and hygiene. Teach the parents the importance and value to the young child of well cooked, nourishing food given at regular intervals, of cleanliness, proper clothing, play in the open out of the streets, long hours of sleep in well ventilated rooms, care of the teeth, early medical attention when needed, medical supervision. Encourage the idea of taking children to the country, for trips and vacations, and allow them to get as close as possible to nature and run wild like little Indians. Let them see the many joys and attractions the country has to offer them. Let them learn from nature about the trees, the birds, the insects, and the animals. Let them go barefooted and play the healthful outdoor games.

Parents are responsible for their children while young. They can insure in a large measure their children's health, happiness, and success in after life by following out these crucial demands for health and growth of the child. We should give the little children a fair chance by teaching these principles and working to have them exercise what every child in the land has a right to demand. Then there will be no fear but that our children will grow hearty and strong like the little animals that they are and then the race will be improved and strengthened physically, mentally, and morally as time goes on.

104 West Seventy-sixth Street.

Dangers Due to the Use of Menthol.—R. Leroux states that menthol used in treatment of nasal conditions is not only injurious, and dangerous, but also sometimes fatal. He cites cases in which the use of a small amount of mentholated oil in the anterior nares for an acute coryza in infants has brought on the most alarming symptoms of dyspnea, ending in suffocation. The reflexes are excited by this drug before it is absorbed by the walls of the nasal cavities It causes inhibitory spasm which may end in death. This drug when used for acute troubles also causes much pain, acute conjunctivitis, pseudoerysipelas of the face, pharyngeal cough, reflex otalgia, and ringing in the ears. Labial and nasal erythema may result in chronic cases and thickening of the nasal mucosa causing obstruction. The author believes that this drug should be used with the greatest caution especially in children.—*La Presse Médicale.*

Renal Functions in the Course of Nephritis of Childhood.—P. Nobécourt and P. Merklen distinguish several types of nephritis according to the condition of the kidneys with regard to permeability to chlorides and nitrates. In cases where the chlorides are not eliminated there occur edema and anasarca; in those in which nitrogen is not eliminated there occur digestive symptoms. This is true both in acute and chronic nephritis in children. In the chloremic form there may occur pharyngolaryngeal edema, pulmonary edema, hydrothorax, digestive troubles, including vomiting and diarrhea, headache, eclampsia, coma, Cheyene-Stokes respiration, and visual troubles. In the azotemic or uremic form there is no edema but there are loss of appetite, vomiting, torpor, pruritus, etc. The authors distinguish a simple albuminous form; a chloremic form with scanty urine containing albumin and casts; an azotemic form, with modifications of arterial tension and cardiovascular symptoms; and a combined form with symptoms of both of the other varieties. In the simple form there is no development of uremic symptoms, nor is there a marked change in weight. In the chloremic form, the chlorides being treated, the urea is eliminated normally. As to prognosis, with normal permeability one need not fear accidents; with retention of chlorides alone there are only the phenomena due to edema; with the combined form there are the most intense symptoms indicating grave renal disease or diffuse lesions. The appearance of arterial hypertension and dilatation of the heart is of bad prognostic value. Simple albuminous nephritis may nevertheless cause anemia and cachexia if of long standing. If retention of chlorides continues the prognosis is bad. These cases are illustrated by the pale, cachectic children who succumb to intercurrent diseases. As to treatment, in simple albuminous forms the use of salt and albuminous substance is harmless. In these cases a mild diet, varied with vegetable soup, is of value. In the chloremic form one should give water only for a few days, with lactose. The addition of milk containing salts is not indicated. When the renal function improves a milk diet is given and later meat, eggs, and bread are administered. Lactose and theobromine should be used as diuretics. Milk is the food of choice in nephritis.—*Archives de Médecine des Enfants.*

New York, May 11, 1912.

THE IMMORTALITY OF THE CELLS AND TISSUES.

MANY biologists have for a long time held that potential immortality is one of the properties of protoplasm. The unicellular organism endowed with the capacity of indefinite subdivision, is able to perpetuate itself in its own offspring. Instead of senile decay, it undergoes, with each conjugation, a sort of rejuvenation, and if the conditions of its environment are favorable, its existence may be prolonged without limitation. In his "Essays on Heredity," August Weissmann refers to this inherent immortality of the cell. Even in the multicellular organism the power of immortality has not been sacrificed entirely, for this is still retained in the reproductive cells. Death is the result of natural selection. Endowed originally with an infinite capacity to subdivide, the cells of the body, exclusive of the reproductive cells that survive in the offspring, have acquired a finite existence. The former cells, and necessarily the aggregation that constitutes the individual body, have been doomed to death as the result of the struggle for existence between the individual cells as well as between the different animals. The cessation of life is an adaptation to the conditions imposed by the crowding of cells and animals, with the consequent reduction of the means of subsistence. But the cells and tissues of the body never forget their birthright. The capacity to an indefinitely continued existence which has been stilled by the complex needs of the organism may be again awakened. The riotous multiplication of the cells seen in cancer exemplifies this return to the primitive condition of an unchecked existence.

Recent laboratory investigations have provided a method of demonstrating the fact that the life of the tissues may be conserved even after these have been removed from the body. The work of Harrison, Carrel, and Burrows in the artificial cultivation of tissues is already well known. But Carrel has gone further. He has succeeded in developing a method (*Journal of Experimental Medicine*, May 1, 1912) by means of which the active life of a tissue outside of the body may apparently be prolonged indefinitely. By washing cultures of connective tissue in Ringer's solution and then placing them in a new medium, the growth was made more rapid, and, by repeated washings and passages, the occurrence of senility was prevented and the duration of life was greatly prolonged. Some cultures were in this manner kept alive for as long as sixty days. Carrel's technique is based upon the supposition that senility and death are the result of the accumulation of catabolic substances and exhaustion of the medium. In its latest development his method consisted of passing the tissue cultures alternately from plasma to serum at the temperature of the organism. Some of the cultures were living at the beginning of the third month of their life *in vitro*.

The morphological characters of the tissues grown outside of the organism have been carefully studied and have been found to vary according to the technique employed in the cultivation of these tissues. Of greater interest, however, were the dynamic characters acquired by the cultures. The rate of growth was influenced by the nature of the medium, its osmotic tension, the way in which the plasma was cut, the amount of old plasma left around the cells, the form of the culture, and the frequency of its passages. It seems that the older a culture was, the quicker it grew. Generally the cultures remained very small in spite of their constant growth, and frequently they diminished in size as the result of mechanical injury, concentration of the medium, and microbic infection.

The possibility of preserving the functional capacity of a tissue *in vitro* for a long time was demonstrated by Carrel in the case of fragments of heart taken from the fetus of the chick. Such fragments were found to pulsate rhythmically at the beginning of the third month of life outside of the organism. A piece of heart muscle that had been cultivated on January 17 and that had ceased pulsating one week later, was kept alive by a series of eleven washings and passages until February 28. After its twelfth passage the culture ceased growing. Then the tissue was dissected and the old plasma completely extirpated. A small central fragment of the culture removed, washed, and placed in a new medium, began on March 1 to pulsate at a rate that varied between 60 and 84 per minute. Three days later the pulsations stopped, but were again restored by another passage. In this manner, after successive passages, the functional power of the heart muscle was each time resuscitated. On March 19 the pulsations were irregular.

On the basis of these experiments Carrel concludes that "experiments made with these or with more perfect techniques and followed over long periods of time may lead to the solution of the problem of permanent life of tissues *in vitro*, and give important information on the characters acquired by tissues liberated from the control of the organism from which they were derived."

The power of resuscitating the mammalian heart after somatic death was demonstrated in the most spectacular manner over ten years ago by Kuliabko of St. Petersburg, who succeeded in restoring for a period of two hours the pulsations to a human heart that had been removed at autopsy two days before, and that had been kept in a refrigerator. This experiment was shortly afterwards repeated by

Hering and by numerous other physiologists. At the present day, under the wizardry of modern biological methods, these wonders are surpassed and at the same time there is opened up a world of infinite possibilities in the study of the vital functions of the cells when these are removed from their complex associations in the intact organism.

INTESTINAL AUTOINTOXICATION.

Headache, indigestion, indefinite pains, apathy, loss of appetite and weight, poor circulation, offensive breath, and muddy complexion form a syndrome for the relief of which the physician is very frequently consulted. On inquiry he finds it to be associated with chronic constipation and lays the blame on autointoxication. Arteriosclerosis may, according to Metchnikoff, be a remote sequel of this condition and the life of the individual may be appreciably shortened because of it. Its seriousness and frequency both demand for it a careful consideration.

A. Distaso (*Centralbl. f. Bakt. etc.*, Abt. I, Orig., Bd. 62, H. 6, p. 433), seeks the explanation in the bacterial flora of the large intestine. He divides the organisms of the colon into two large groups, the non-indologenes and the indologenes, and among the latter finds those which, acting upon the end products of protein digestion as found in the intestine, elaborate those toxins which, when absorbed, produce the above symptom-complex. A smear from the stool of a normal breast-fed infant will show an enormous preponderance of Gram-positive organisms the majority of which will prove to be *B. bifidus*. This organism produces substances which stimulate intestinal peristalsis and as a result the stools of such an infant are soft. If now the child be put upon cow's milk, a smear will be largely Gram-negative, the colon bacillus predominates, the stools become formed and harder, and constipation may appear.

Now it is true that in the normal human adult, the great majority of the organisms in the stool, notably the *B. coli*, belong to the indologenes group and therefore constitute an ever-present threat against the health of the individual. But nothing happens until stasis appears. Then the entire picture changes. The colon like the appendix appears to be one of the degenerating organs and therefore especially susceptible to pathological changes. Putrefaction increases, large quantities of toxins are produced and absorbed. The increase in the contents of the colon stretches its walls and induces muscular atrophy. Their weight drags the organ out of place and distorts it so that stagnation is favored and a vicious circle established. Gradually the character of the flora changes. A smear will show a predominance of Gram-positive bacteria many of which are cocci. The absolute number of organisms is decreased and there are many spores present.

The large intestine appears to serve the sole purpose of furnishing a place in which the residue from digestion is partially dried and stored until it accumulates in sufficient quantity to be removed. The old idea that the bacteria complete the protein digestion begun by the body ferments and that they are necessary for life has been very generally rejected. Indeed recently M. Cohendy (*Annales de l'Institut Pasteur*, T. xxvi., p. 106) has worked wtih chicks which he hatched from disinfected eggs and kept under aseptic conditions and found that they developed fully as well as control animals and appeared to be normal in every way. Arbuthnot Lane then devised exsection of the large intestine as a method of treatment for autointoxication and after sufficient animal experimentation applied it to man.

Distaso had the opportunity to follow some thirty-six of Lane's cases for three or more years and found that the patients remained in good health and gained in weight and activity. The stools of these individuals are very constantly soft or even fluid and a smear from one shows the organisms to be almost wholly Gram-positive consisting largely of *B. bifidus* and *B. acetogenes-β*, both members of the non-indologenes group. This evidence certainly stems to place the blame largely with the indologenes bacteria and to demonstrate the uselessness of the large intestine. Still the operation is not a simple one and Metchnikoff claims that quite analogous changes in the intestinal flora follow the exhibition of *B. lacticus*—a somewhat simpler procedure. It is to be hoped that Distaso will carry out his expressed intention to pursue his investigations along this line.

THERAPEUTIC ECK'S FISTULA.

Eck's fistula has been known since 1877 as an experimental resource for studying the physiology of the liver. The intervention was long a severe one, largely because of the collateral injuries inflicted on important neighboring organs. Recently improvements in technique have greatly reduced the operative mortality. Among these is the immunization of the animals against the autodigestion of tissues which results from injury to the pancreas. It is said that the operation was once performed on the human subject, under what circumstances we are not informed. The death of the patient which occurred on the following day may or may not have been attributable wholly to the intervention. Under any sort of physiological equilibrium an Eck's fistula in man is hardly conceivable. The operation consists merely in anastomosing the vena cava and portal vein after which the latter is ligated. It is otherwise, however, if the portal circulation is already hopelessly obstructed; for in such a case an attempt to convey the nutrient portal blood directly into the general circulation should lead to a prolongation of life, provided the liver has not been wholly isolated. That the operation has never come into use in cirrhosis of the liver must be set down straightway to the introduction of the Talma-Drummond operation in 1898, which gave the cirrhotic liver an increased supply of blood through omentopexy.

At a very recent session of the Berlin Medical Society (*Berliner klinische Wochenschrift*, March 25, 1912) Rosenstein spoke on the ideas of Franke expressed to the German Surgical Congress, of 1911, on the possibility of treating cirrhosis of the liver with the establishment of an Eck's fistula. The technique has been perfected on the cadaver and

on dogs, but thus far Franke has found no case suitable for the operation. In discussing this point Bier stated that during the past year he had begun the operation twice but was unable to complete it once because of severe hemorrhage and again because of extensive thickening of the peritoneum. He knew of no successful case thus far at the hands of any other operator. Therefore the patient whom he presented to the Society was the first to be operated on with complete success. This was a woman aged 60 with cirrhosis and ascites. The two veins had been anastomosed and the intervention had been well tolerated. About four months had since elapsed, and thus far evidences of improvement are still somewhat in abeyance. Bier had started out with the full intention of doing a Talma operation and changed it on the spur of the moment. The intervention appears to have been difficult and tedious, marred with interruptions, but the patient's life seems not to have been menaced. The operation has now been shown to be practicable and it will be for the future to say if it is worth while. The patient will doubtless be shown before medical societies, so that the question of improvement will be settled at first hand. Meanwhile it may be doubted whether pending the verdict, the intervention will be repeated.

RECENT VIEWS OF DIET FOR DIABETICS.

The present age is one of revolution in regard to the dietetics of diabetes. Authorities vie with each other in recommending special carbohydrate plans. There is an oatmeal diet, a potato diet, there are flour diets, vegetable diets, and at the present rate we should soon be having a sugar diet. It is becoming the custom to abuse meat and to forbid alcohol even in minimal amounts. To understand the completeness of this revolution it is sufficient to glance through the bills of fare devised by that pioneer in diabetic feeding, Bouchardat, whose work was the chief, if not the sole authority, a generation ago. The men who advocate the newer plans of feeding comprise some of our soundest clinicians, although it is almost needless to state that such men do not go to the extremes of the diet faddists.

At a recent meeting of the Medical Society of Leipzig (*Muenchener medizinische Wochenschrift*, March 5) Rolly spoke of the results of some experiments which appeared to show that flesh albumins increased glycosuria, while vegetable albumins, if anything, diminished it. The former he pronounced cell-irritants. Bornstein claimed that with each increase in sugar production the nervous system suffered. The diabetic was a neurasthenic and, like all others of his kind, could not tolerate alcohol even in small quantities. He claimed that this substance stupefied the body cells, or that metabolism was slower, evidently implying that the alcohol was not oxidized. The results of calorimetry and animal experiment he seemed inclined to discredit. Of some value is his suggestion based on Lampe's findings to test for lecithin albumin in diabetes.

The remarks in discussion by von Strümpell should be of interest. This eminent clinician deprecates the tendency to measure the patient's actual condition by the amount of sugar excreted. It is true that when this reaches a certain height we begin to see furuncles appear, and that we can determine a tolerance point to carbohydrate feeding. Nevertheless, he has known patients to eliminate two or three per cent. of sugar in the urine for ten years and yet be in relatively good health. We must indeed keep down the glycemia, but we must also keep up strength and efficiency. Hence he would give a diabetic all the benefit which can come to him through physicotherapy—air, light, water, electric baths, incandescent light baths, and massage. To treat by diet only is not to treat at all. We must treat the patient, not his glycosuria. Rolly summed up in a few axioms: Mild cases bear protein well, severe ones ill. Alcohol withdrawal is unnecessary. Mild cases of diabetes benefit by moderate exercise, severe cases do not.

THE SERUM TREATMENT OF PERNICIOUS VOMITING OF PREGNANCY.

That the severe vomiting frequently occurring in pregnant women is the result of a toxemia is a fact firmly established upon clinical and pathological observation. Although the nature of this toxemia is still veiled in obscurity, it is probable that the maternal organism reacts to the partly foreign cells of its fetal parasite by the formation of antibodies. Upon the presence of these substances depends the possibility of making a serum diagnosis of pregnancy recently reported and referred to in these columns. About one year ago Mayer and Linser reported a case in which a dermatosis of pregnancy was rapidly cured by means of hypodermic injections of blood serum obtained from a healthy pregnant woman. In July, 1911, Le Lorier applied this method with success in the treatment of pernicious vomiting of pregnancy, utilizing the blood serum of a healthy pregnant woman near term. G. Fieux and A. Dantin, reporting their results in the *Annales de Gynécologie et d'Obstetrique*, March, 1912, state that they have also demonstrated the efficiency of this method of treatment, employing, however, the blood serum of the second or third month of pregnancy. Their case was one of the most pronounced types of gestational vomiting, in which the systemic intoxication was revealed by the presence of acetone and albumin in the urine and also by the diminished excretion of urea. The patient had reached a state of extreme prostration and emaciation, when she received a hypodermic injection of three to four cubic centimeters of the blood serum. There was an almost immediate response; the vomiting diminished, the urine increased in volume, and the general condition of the patient improved. But in a short time the patient relapsed to her former condition. A second injection of twelve centimeters of the blood serum obtained from a woman in the third month of pregnancy was followed by a rapid and permanent disappearance of the vomiting and the other constitutional symptoms. Although definite conclusions cannot be drawn from the report of one case, nevertheless when this is considered in connection with that reported by Le Lorier, and with the case of dermatosis of pregnancy that responded in a similar manner to this method of treatment, one is inclined to perceive in serum therapy a new field of usefulness when applied to the toxemias of pregnancy. Possibly the eclampsia, the choreic, and the hemorrhagic tendencies of pregnancy may respond in a similar manner.

News of the Week.

Death Rate in New York.—For the twelfth successive week the death rate in New York City has been lower in 1912 than in 1911, the "record" year. For the week ending April 27 was 15.42, against 16.55 for the week ending April 29, 1911. This represents a decrease of 112 in the total number of deaths. In only three of the seventeen weeks of 1912 has the rate been higher than in the corresponding week of 1911. For the entire period the rate for the respective years is: 15.80 for 1912 and 17.13 for 1911. A recent number of the *Bulletin* of the Health Department points out that the death rate for 1911 in New York was just one-half what it was when the Metropolitan Board of Health was organized in 1866. In that year the rate per thousand was 30, while last year it was 13. The first health act relating to the city and State of New York was passed, the *Bulletin* says, in 1784, and was purely a quarantine act. Thirteen years later the first Board of Health, consisting of a health officer and seven health commissioners, was appointed by the State. In 1798 an outbreak of yellow fever which caused 2,080 deaths in a few weeks in a population of only 55,000 led to the enactment of a comprehensive health law, and the reporting of infectious diseases was required. In 1827 the Board of Health became a city instead of a state body, but the sanitary condition of the city remained deplorable from a modern viewpoint, until an investigation by an association of citizens led to the appointment of the Metropolitan Board of Health, which held its first meeting on March 3, 1866. In 1870 this was dissolved in turn, and a city Board of Health, consisting of four health commissioners, four police commissioners, the Health Officer of the Port, the Mayor, was formed. In 1873 the Board was again reconstituted, consisting of two health commissioners, the president of the police force and the officer of the port. On the formation of the greater city the Board of Health was again altered, consisting of the Commissioner of Health, the Commissioner of Police and the Health Officer of the Port, which is its present personnel.

Army Medical Corps.—Preliminary examinations for the appointment of first lieutenants in the Army Medical Corps will be held on July 15 and September 3, 1912. The essential requirements for admission to the examination are that the applicant shall be a citizen of the United States, betwen 22 and 30 years, a graduate of a medical school, of good moral character and habits, and with at least one year of hospital training after graduation. Full information concerning the examinations can be procured upon application to the "Surgeon General, U. S. Army, Washington, D. C."

Expert Medical Testimony.—Believing that there should be some statutory regulation of expert medical testimony in court, the New Haven (Connecticut) County Bar Association has appointed a committee to confer with the members of the State Medical Association. The Medical Association also at their annual meeting went on record as favoring co-operation between the legal and medical fraternities for the purpose of securing such legislation.

Street Dangers.—During the month of April forty-two persons were killed and 183 injured in accidents due to vehicular traffic in the streets of New York City. Of those killed fourteen were children under sixteen years. Automobiles killed nineteen persons as compared with eleven for the same month of 1911; trolley cars ten as against eleven and wagons thirteen as against twenty-four.

Centenarian Dead.—Said to be 102 years of age and probably the oldest person in New Jersey, Mrs. Mary Thackara died recently, having suffered from her first illness only six months ago.

Montclair Sanatorium.—The Tuberculosis Preventive and Relief Association of Montclair, N. J., is again attempting to establish a tuberculosis sanatorium in the town, a project which in the past has been successfully opposed. The State Board of Health, which has the power of issuing the necessary permit, will shortly hold a public hearing in reference to the application.

British Tuberculosis Committee.—The committee of expert publicists appointed last February by the Chancellor of the Exchequer under the chairmanship of Mr. Waldorf Astor, has issued an interim report outlining a scheme for the prevention, detection, and cure of tuberculosis. The report urges the establishment of dispensaries for diagnosis, and of sanatoria, farm colonies, and open air schools for treatment, proposing that the funds provided by the Insurance Act be used in addition to the sum provided by the Finance Act of 1911. These combined funds will make a total of almost $12,000,000 available for the first year. The committee believes that about 300 dispensaries will be necessary throughout the United Kingdom, and that there should be sanatoria sufficient to provide one bed for every 5,000 of population.

Polyclinic Hospital.—On the 1st of May the Polyclinic Hospital of New York moved into its new building on West 50th Street. The hospital has a capacity of 300 beds. Three gasoline auto ambulances will be used to cover the district bounded by 42d Street, Central Park West, 92d Street, and the Hudson River, which has been assigned to the hospital.

Hospital Saturday and Sunday Association.—The largest amount collected in the history of the society, $95,000, was recently apportioned among forty-four non-municipal hospitals in New York. The distribution according to the rules of the association was based on the number of days of free treatment given to the poor regardless of race or creed for which the hospital had received no payment either from the patient or from the city.

To Enlarge the Columbus Hospital.—The Sisters of the Sacred Heart, who maintain the Columbus Hospital on the east side of New York, are planning to increase the hospital facilities by the addition of a wing to the present building, which after twenty years of use is now quite inadequate. The Pope has sent his approval of the work, which is largely carried on among the Italian residents in the city.

Concession to Antivaccinationists.—The Board of Education of Montclair, N. J., has agreed with some one hundred and fifty parents of school children who believe that vaccination is dangerous, that these children may attend school although not thus protected, the parents to withdraw any such child upon notice from the Board that there is special danger in the community from smallpox, "until such time as in the judgment of the Board the danger is entirely past." It may be questioned whether the judgment shown by the Board thus far is so good that it may in the future be relied upon.

Gifts to Charities.—By the will of Mr. Benjamin Guggenheim of New York, who lost his life in the sinking of the *Titanic* on April 15, Mt. Sinai Hospital receives $10,000, and St. John's Guild Floating Hospital, $5,000. By the will of the late Dr. Francis Bacon of New Haven, $100,000 is bequeathed to the New Haven County Antituberculosis Society, $10,000 to the Connecticut Children's Aid Society, and $5,000 to the New Haven General Hospital. The residue of the estate is left to Yale University, to be used as a scholarship fund for the aid of needy undergraduate students. The will of the late Dr. John H. Musser of Philadelphia provides for the endowment of a series of lectures at the College of Physicians in that city, to be known as the "Benjamin Musser Lectures on Clinical Medicine" in honor of his father, and under certain conditions also provides for the endowment of a fellowship in the John H. Musser department of research medicine in the University of Pennsylvania. In the opening clause of his will Dr. Musser desired that after an autopsy his brain should be given to the Anthropometric Society of the Wistar Institute of Philadelphia, of which he was a member. The will of the late Augustus W. Openhym of New York creates a fund of $275,000, of which upon the death of his wife one-third each is to go to Mt. Sinai Hospital and the German Hospital for the maintenance of free wards, while the remaining third is left to Columbia University for the establishment of the Openhym Fund for research work into the cause, prevention, and cure of cancer, or, if this work becomes unnecessary, for medical and surgical research into other diseases. The Harvard University Medical School has received a fund of $10,000 from Mrs. W. M. Underhill, the income of which is to be devoted to investigation into diseases and disturbances of function of the nervous system. By the will of the late Eliza Downey of Philadelphia, more than one-half of the testatrix's estate, amounting to $5,100, is bequeathed to the Methodist Hospital.

Dr. Joseph D. Bryant has removed to 48 West 59th Street.

Prof. Ludwig Pick, who is coming to this country to deliver the Cartwright Lectures of the Alumni Association of the College of Physicians and Surgeons in November, is prosector of the Friedrichshain Hospital and pathologist of Professor Landau's Clinic in Berlin. He has written many articles on gynecological subjects and has also made notable studies of cancer in the thyroid of salmon, of ochronosis, etc. He is one of the best known morphologists in Germany.

Dr. William S. Breakey, professor of dermatology and syphilology in the Department of Medicine and Surgery of the University of Michigan, has tendered his resignation to take effect at the end of the college year, when he will have completed forty-four years of continuous service.

Coroner Albert F. Schwannecke of the Borough of the Bronx, New York, died at his home on April 30 from the effects of injuries received while making an official investigation on the previous day. Coroner Schwannecke was fifty years of age, and was serving his second term as coroner.

Dr. A. J. Rongy has been appointed attending gynecologist to the Lebanon Hospital, New York.

Dr. Mark I. Knapp of this city read a paper before the Philadelphia Clinical Society on May 6, on "Diagnosis by Inspection," demonstrating his method in several cases.

Jefferson Medical College.—Dr. Orville Norwitz has resigned as professor of genitourinary disease after an incumbency of more than 20 years. He has been elected emeritus professor. Dr. James W. Holland, who recently resigned as dean and professor of medical chemistry and toxicology, has likewise been elected emeritus professor. Neither vacancy has yet been filled.

The Ninth International Red Cross Congress was opened in Washington Tuesday of this week. The session was held in Pan-American Hall, Senator Elihu Root presiding in the absence of President Taft, the titular head of the American Red Cross.

Alabama State Medical Association.—At the annual meeting of the society held in Birmingham the following officers were elected: *President,* Dr. H. T. Inge, Mobile; *Secretary,* Dr. J. N. Baker, Montgomery; *Treasurer,* Dr. H. G. Perry, Dothan. The next meeting will be held in Mobile.

Litchfield County (Mass.) Medical Society.—At the annual meeting held in Winsted on April 23, the following officers were elected: *President,* R. S. Goodwin, Thomaston; *Vice-President,* Dr. F. S. *Skiff,* Falls Village; *Secretary-Treasurer,* Dr. Robert Hazen, Thomaston.

Worcester North District (Mass.) Medical Society.—The following officers were elected at the annual meeting held on April 23 at Fitchburg: *President,* Dr. Edward J. Tully; *Vice-President,* Dr. Walter F. Sawyer; *Secretary,* Dr. Curtis H. Jennings; *Treasurer,* Dr. F. H. Thompson, Jr., all of Fitchburg.

New Haven County (Conn.) Medical Association.—At the annual meeting on April 25 the following officers were elected: *President,* Dr. Louis M. Gompertz, New Haven; *Vice-President,* Dr. Thomas M. Bull, Naugatuck; *Clerk,* Dr. Willis H. Hartshorn, New Haven.

Sixth District (N. C.) Medical Society.—The following officers were elected at the annual meeting held on April 25: *President,* Dr. F. R. Harris, Henderson; *Vice-President,* Dr. C. S. Mangum, Chapel Hill; *Secretary,* Dr. C. A. Woodward, Durham.

Eastern Illinois Homeopathic Medical Society.—At the annual election the following officers were chosen: *President,* Dr. W. H. Lycan, Charleston; *Vice-President,* Dr. C. J. Bresee, Mattoon; *Secretary,* Dr. M. H. Whitlock, Charleston; *Treasurer,* Dr. E. E. Richardson, Mattoon.

Berkshire District (Mass.) Medical Society.—At the annual meeting on April 25, held in Pittsfield, the following officers were elected: *President,* Dr. I. S. F. Dodd; *Vice-President,* Dr. John B. Thomes; *Secretary,* Dr. O. L. Bartlett; *Treasurer,* Dr. J. D. Howe.

Stearns-Benton Counties (Minn.) Medical Society.—At the annual meeting on April 19, held at St. Cloud, officers were elected as follows: *President,* Dr. J. H. Beaty, St. Cloud; *Vice-President,* Dr. C. F. Brigham, St. Cloud; *Secretary-Treasurer,* Dr. J. C. Boehm, St. Cloud.

Obituary Notes.—Dr. HERBERT COOPER ROGERS of Brooklyn, N. Y., a graduate of Bellevue Hospital Medical College in 1878, assistant surgeon to the Long Island College Hospital, and associate surgeon to the Bushwick Hospital, and a member of the American Medical Association, the New York State and Kings County Medical Societies, and the Associated Physicians of Long Island, died at his home of pneumonia on April 29, aged 55 years.

Dr. Milton T. Reeder died at Millersville, Pa., on April 24, at the age of 65 years. He was graduated from Bellevue Hospital Medical College in the class of 1880. He was active in Masonic circles, vice-president of the Millersville National Bank and secretary of the Lancaster County Medical Society.

Dr. Samuel F. Kessler of St. Joseph, Mo., a graduate of the Jefferson Medical College of Philadelphia in 1889, and a member of the Missouri State and Buchanan County Medical Societies, died at his home suddenly on April 10, aged 49 years.

Dr. Norman F. Terry of Springfield, Mo., a graduate of the Miami Medical College of Cincinnati, Ohio, in 1870, and a member of the American Medical Association and the Missouri State and Greene County Medical Societies, died at his home of paralysis suddenly on April 17, aged 59 years.

Dr. Alfred L. Saylor of Sherwood, Ore., a graduate of the Rush Medical College, Chicago, in 1880, and Surgeon-General of the Oregon State Militia for eight years, died at the Good Samaritan Hospital on April 8, aged 62 years.

Dr. Samuel J. McCurry of Anniston, Ala., a graduate of the Atlanta Medical College, Georgia, in 1880, and a member of the Alabama State and County Medical Societies, died at his home of Bright's disease on April 13, aged 52 years.

Dr. Herman Westphal of Butte, Mont., a graduate of the College of Physicians and Surgeons of Baltimore in 1898, died on April 15, aged 43 years.

Dr. Augustus Peck Clarke of Cambridge, Mass., a graduate of the Harvard University Medical School in 1862, a veteran of the Civil War, professor of gynecology and dean of the College of Physicians and Surgeons of Boston from 1894 to 1900, and a member of the American Medical Association, of which he was a vice-president in 1895, the Massachusetts State and Middlesex County Medical Societies, and the American Association of Obstetricians and Gynecologists, died at his home on April 22, aged 70 years.

Dr. James E. Smith of Mt. Carmel, Ill., a graduate of the Eclectic Medical School of Cincinnati in 1878, died at his home after a long illness on April 10, aged 74 years.

Dr. E. F. Floyd of Lone Oak, Texas, a graduate of the Hospital College of Medicine, Louisville, Ky., in 1883, and a member of the American Medical Association and the Texas State and Hunt County Medical Societies, died at his home of pneumonia on April 18, aged 53 years.

Dr. Martha Ripley of Minneapolis, Minn., a graduate of the Boston University School of Medicine in 1883, died at her home on April 18, aged 69 years.

Correspondence.

CHRISTIAN SCIENCE AND CHRISTIAN CHARITY.

To the Editor of the Medical Record:

Sir:—A recent description of the *Titanic* disaster (*New York Times*, April 20, 1912), by Mr. Lawrence Beesley, closes with an account of the effect of his Christian Science belief on his thought and conduct during that tragedy. As this is so typical of one phase of this cult it will serve to emphasize a point to which I have tried to call especial attention,* namely, the indifference to suffering and danger in others that frequently accompanies the much boasted quietude of mind and lack of apprehension that is cultivated by this sect.

As soon as the writer realized the danger, before going on deck he "read quietly and then went upstairs with a knowledge that fear was almost entirely eliminated and that opportunity to escape from the peril that threatened was a right we ought all to be able to claim." This peace of mind enabled him to "stand quietly on the deck" until he was able to "get a place in a boat" and thus escape from the sinking ship. During the awful interval after the collision the heroes—the real men who had not been pacified by Mrs. Eddy's soothing preachments—were struggling to get the women into the lifeboats and keep order. They saved others, but did not save themselves. After this last splendid service they went down with the ship. It seems like blasphemy to talk of eliminating fear with a consequent "opportunity to escape" in the presence of such sacrificial deeds

Many physicians have noted that this quietude of mind in the presence of great calamity is really a sort of callousness to suffering that this belief often begets. The peace that paralyzes efforts for others in desperate need is not a thing of which to boast. Here lies the great danger to the world of this cult. A poise and quietude that makes no effort to relieve real suffering or save others may be a good product of Eddyism, but it should drop the name "Christian." "By their fruits ye shall know them."

Henry Dwight Chapin, M.D.

*"Christian Science in Operation." Medical Record, December 23, 1911.

SUGGESTIONS REGARDING THE SOUTHWESTERN EPIDEMIC OF CEREBROSPINAL MENINGITIS.

To the Editor of the Medical Record:

Sir:—During March I was in Texas and had an opportunity to study the epidemic of cerebrospinal meningitis which, during the last few months, has seemingly gained such a foothold in the Southwest. The first point which impressed me was the fact that the epidemic was not nearly so well in hand as press reports and the statements of those who had come in an advisory capacity to assist in controlling it would seem to imply. I learned that there was a considerable increase in the number of patients in the Dallas City Hospital, the number at the time of my visit being 82, with 8 new admitted on one day and 2 to 4 on other days. There were between 60 and 70 cases in the hospital "when the epidemic was officially declared over." It seems that business was considered to a degree which was detrimental to the work of controlling what has proved to be a very serious proposition. Undoubtedly the advent of a representative of Dr. Flexner, with the skill to which distance seems to have lent enchantment, had a salutary effect, especially in welding opposing factions of physicians together, and there is no doubt that the use of the Flexner serum has, in a very encouraging degree, controlled the progress of the disease. However, from an outsider's viewpoint, it is plain that much has yet to be done to solve the riddle of the control of this disease.

From several quarters I learned that the use of the serum was of no avail, and doubtless, judging from the literature on this subject, its use was not pushed. Still I am sure that hundreds of cases, which otherwise would have died, were saved by the administration of the Flexner serum, and to an unbiased investigator it could not fail to impress

itself that in this remedy has been found an extremely valuable curative measure.

By far the most important matter which impressed itself upon my mind was the inadequate prophylactic measures that were generally in use at the time of the epidemic, or, more correctly, at the time when public sentiment regarding the seriousness of the epidemic was at its height, and the people, urged on by the newspapers and the medical profession, were taking more than ordinary pains to disinfect the nasopharynx. Of course, for economic reasons, quarantine was by no means as thorough as it should have been, and while the serum was used a number of times for prophylactic purposes, a few cases of anaphylaxis that occurred were so dangerous that there was apparently as great a fear of the injection as there was of the disease.

Experience with antimeningococcus serum has emphasized four points: It is not as harmless as diphtheria antitoxin; its administration is not nearly as simple a matter as the injection of other antitoxic sera; its prophylactic administration is not as well understood as its therapeutic use, and occasionally it causes anaphylaxis of an alarming character. To me it was strange that the prophylactic use of bacterial vaccines was not in general use. This, coupled with the fact that Dr. A. E. Thayer of Baylor Medical School, probably the most capable bacteriologist in the State, had made a successful vaccine and emphasized its value, and, too, that in this very State a spectacular circumstance closely related to this had taken place within a year—I refer to the encampment of more than 12,000 soldiers of the U. S. Army and their immunization by means of antityphoid inoculation. I was surprised that it had not occurred to physicians that what was possible with typhoid, cholera, scarlet fever, and other infectious diseases, was likely of equal possibility with the one in question. There seems no doubt in my mind that by omitting to use inoculations of killed cultures of *Diplococcus intracellularis* the profession has overlooked a possible means of stamping out the epidemic, and, in addition, is depriving the medical profession of information which would be of immense value, and which will not be as easily secured again.

Another point worthy of emphasis deserves mention here. Very little, if anything, has been learned regarding the diagnosis of incipient cases of cerebrospinal meningitis. In this connection I quote from page 24 of P. H. R. No. 69, "Epidemic Cerebrospinal Meningitis," by W. H. Frost, U. S. P. H. & M. H. S., published January 26, by the United States Government: "To undertake to make bacteriological examinations sufficient to discover all the carriers in a community of any considerable size is obviously impracticable; if it were possible it would consume so much time that the infection would have ample opportunity to spread in the meantime. . . . The most recent bacteriologic studies, as well as past experience, indicate that cerebrospinal meningitis, when once it has become epidemic, is not controllable by any known means of practical application." Doctor Thayer, who has spent much time in investigating this matter, interested me greatly by a casual reference to a personal experience with this method in the control of this infection. Both he and his assistant found pure cultures in their own nasal secretions, and it occurred to them that part of a malaise from which they were suffering was due to toxins produced by this particular germ, which was abundantly proved by their personal feelings twenty four to thirty-six hours after an injection of vaccine, and a very important point was brought out which cannot be emphasized too strongly—it was not possible to secure further cultures of the meningococcus from their nasal secretions, and the same characteristic "dry throat and nose" with disappearance of the meningococci has been observed after many protective injections.

It may be possible to initiate a test similar in character to the von Pirquet tuberculosis test or the Widal test for typhoid fever, or the Bordet-Gengou reaction. Of course, this is purely suggestive, and far more simple than the bacterial study of the nasopharyngeal flora, or containing far more possibilities for good than "simply waiting until you get it or don't." It is admittedly entirely possible that no test of this character can be worked up, but it would seem that here was an excellent opportunity to prove this negatively. When it is evidently possible to control the infection in the nose with an injection of killed meningococci, why is it not reasonable to make this a prophylactic measure of general usefulness, and should not its possible value be definitely proved or not? And if it is found that the use of meningococcus vaccine as a prophylactic kills the organism in carriers, will it not serve two very important ends—the immunization of the patient and the prevention of the spread of the disease?

In conclusion let me emphasize: (1) That more attention be paid to prophylaxis of this disease than had up to the time of my visit apparently been paid; (2) that the use of meningococcus vaccine in prophylactic work deserves an extensive and thorough trial; (3) that there is an opportunity to establish a reaction test in cerebrospinal meningitis.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

KING EDWARD'S HOSPITAL FUND—ROYAL COMMISSION ON TUBERCULOSIS—NYSTAGMUS—INSURANCE ACT DIFFICULTIES AND OPPOSITION—OBITUARY.

LONDON, April 19, 1912.

YESTERDAY at the annual meeting of Governors of King Edward's Hospital Fund, Lord Rothschild, the honorary treasurer, reported that the present value of the investments was £1,604,004, showing a net increase of 1.4 per cent. The trust securities showed a diminution of their original value of 5.6 per cent., while the non-trust securities showed an increase of 5.4 per cent. The Speaker of the House of Commons occupied the chair and stated that the munificent donor of £50,000 to the London hospitals, the major part entrusted to the administration of this fund, who had wished for a time to remain anonymous, was Sir Ernest Cassell, who gave it in memory of his daughter. He also stated that the committee on the out-patient system had made considerable progress with the study of the voluminous evidence collected, and its report might be looked for at no very distant date.

The final report of the Royal Commission on Human and Animal Tuberculosis made rather an opportune appearance just before the opening of the seventh International Congress on Tuberculosis, which, as of course you know, is now sitting in Rome. It is stated here that 4,000 delegates are in

attendance there, but you will have direct information about it, and it does not concern a London correspondent. Our Royal Commission, however, may claim mention again. The present volume of its work is a solid contribution of about 350 pages, illustrated by sixteen colored plates, and records the comparative bacteriological and histological investigations made by Dr. Arthur Eastwood. He has worked with viruses obtained from cases of spontaneous disease in human beings, animals, and birds, as well as with specimens from experimentally infected animals. The investigation is of the greatest interest and will receive the careful consideration of all interested. It is not possible to describe at length the conclusions to be drawn from the report, but these examples may suffice to show those of Dr. Eastwood. He found tubercle bacilli of human origin and of animals were identical culturally, microscopically, and in their effects on the tissues of experimental animals. So, too, bacilli from any human tissues were identical with those in the bodies of cattle and swine. Some of human origin grew more luxuriously and did less histological damage in the organs of experimental animals than those commonly obtained from cattle and swine. The characteristics of a virus were remarkably stable in protracted experiments, and so support the view that changes in a particular virus do not rapidly or readily take place in the human body. But he found there were some viruses that held an intermediate position between those of human and animal origin, so that all strains could not be grouped in two stable classes. Nevertheless, all mammalian viruses differ only in degree, not in kind. But avian viruses, he found, differed from mammalian types in kind as well as in degree.

During our coal trouble it seemed opportune that miner's nystagmus should obtain renewed attention, and it came before the public in rather a direct manner. Sir A. B. Markham, M. P., himself a coal owner, wrote to the Home Secretary to direct his attention to the theory of Dr. Court that the disease is due to the insufficient light given by the safety lamps in use and that increased illumination is the preventive. This theory has been urged by Dr. Court for some twenty years as the result of investigations in different mines. He found that men working with naked lights suffered to an insignificant extent in comparison with those using safety lamps, the light from the latter being so much more defective. Defective light, he maintains, is the chief, if not the only, cause of the strain on the eyes which leads to nystagmus, which will disappear under efficient illumination. Surely it should not be difficult to supply this, and it seems surprising that some mine owner has not installed a complete system, for of late the question has assumed a pecuniary aspect, for compensation has been awarded to sufferers on the opinion of experts, who held that one attack predisposed to more, and so to permanent injury. If this opinion should prevail the compensation demanded from employers will be enormous. Dr. Court repudiates this view. He has forty years' experience in the coal mining industry and he advocates a full independent inquiry.

The opposing theory, still held by many, attributes the disease to the strain of the extrinsic eye muscles, particularly the elevators, on which much stress falls when the miner is at work in a position requiring him to look upward. The fatigue might thus be compared with that giving rise to writer's cramp. If this view were correct we ought to find nystagmus common in other mines, but it is practically only found in coal mines. In his reply to Sir A. Markham, the Home Secretary says Dr. Court's suggestions were brought to the notice of Dr. Haldane, who, with Dr. Llewellyn, has brought the subject before the Royal Society. The theory proposed by Dr. Llewellyn, who has made extensive inquiries among miners in coal and other mines, is that the disease depends on imperfect centripetal impulses, resulting in loss of the intricate connection between the governing centers of the associated movements of the eyes. He found hypermetropia or astigmatism in 93 per cent. of the cases he examined, suggesting that there might be some predisposition to the disease, as only a small percentage of miners are attacked by it. He admitted further that accident, shock, or general ill health might predispose to it. Moreover, he found Dr. Court's statements as to insufficient illumination confirmed by the fact that in naked lighted mines the disease is almost unknown. Dr. Haldane suggested to the Home Secretary that it would be a "good thing if Dr. Court and Dr. Llewellyn were to get into communication with each other. This might lead to a fuller discussion and a more complete exchange of views."

The Insurance Act is still exciting a good deal of discontent among the Friendly societies. On Monday a new organization calling itself the "Amend-the-Act League" opened an office in Westminster, and invited all parties and all classes to rally to its assistance. On Tuesday Mr. Worthington Evans, M.P., attended a meeting at the East End of about 4,000 persons on the lines the Amend-the-Act League intends to work. He was received with great enthusiasm. Another public meeting is to be held on the 23d, at which delegates from eighty-five constituencies in and around London have promised to be present and Mr. W. H. Forster is to preside. Other meetings are being arranged for the chief provincial towns. A penny "Amend-the-Act" stamp is being freely sold, as to which the officials says "it is better to lick a stamp once to get a right sort of insurance than to lick them always for an act that is deficient."

The Friendly Societies in Surrey have formed a United Council to watch over and promote the interests of men in their county who are affected by the act, and who are estimated to number from 50,000 to 60,000.

The Scottish Medical Insurance Council has been formed and meetings held in the Royal College of Surgeons of Edinburgh. They propose to consolidate medical opinion and maintain the interests of the profession in Scotland as affected by the act. It was determined that the insurance areas should be the units of the organization; that in each committees should be elected by the resident practitioners and should not enter into relations with insurance authorities without the sanction of the executive. A resolution of dissatisfaction was passed that the profession had not been properly consulted at any stage as to a measure introduced ostensibly in the interests of the public health. The meeting affirmed its adherence to the six points about which so much has been written, adding a seventh, viz., that "disciplinary powers be vested in some properly constituted medical body." The proposal was further approved that if these seven principles be not incorporated in the regulations of the commissioners, the executive should at once prepare a scheme for a medical service to be carried on by the profession in Scotland.

At the annual meeting of the Hospital Saturday Fund, Sir T. Vezey Strong, presiding, spoke of the difficulties they would have to face when the State insurance system was established. He held strongly by the voluntary principle which had always been supported by the English people and which was best for patients. Sir Saville Crossley was equally emphatic for the voluntary plan and against red tape government management and the increase of rates which would assuredly follow. Mr. Alvey urged that provision ought to be made for payment to hospitals for work done on behalf of insured persons, and it must be done in a way that should not interfere with the voluntary system.

Dr. William Ogle, lately superintendent of the Statistical Department of the General Register Office, has died at the age of 84. He was an Oxford graduate, A.M., M.D., became a member of the Royal College of Physicians in 1859, and was elected fellow in 1860. He was on the medical staff of St. George's Hospital for several years and a lecturer on physiology. He had been an examiner at Oxford, a medical officer of health in Hertfordshire, and held other important posts. He translated Kerner's "Flowers and Their Unbidden Guests," and was the author of numerous official reports issued by the Registrar General, besides contributions to medical societies, their transactions, and the *Journal* of the Statistical Society. He also edited some of Aristotle's works.

Sir Thomas Rennie, who spent many years in the Far East as medical officer to British consulates, maritime customs, and native hospitals, died on the 11th inst. at Aberdeen, where he was educated, graduating there M.B., C.M., 1872, and M.D., 1875.

Professor Edward Divers, F.R.S., who died last week at the age of 75, spent many years in Japan as Professor of Chemistry in the University of Tokyo and Principal of the Engineering College. Before accepting the invitation to Japan he was a lecturer at the Middlesex Hospital on Medical Jurisprudence. He was M.D. of Queens College, Galway.

Surgeon Colonel W. C. Robinson has died. He received his first commission in 1860 when he was L.R.C.P.I., and served in the Abyssinian expedition, 1867-8, for which he was awarded the medal. He retired in 1895.

OUR BERLIN LETTER.

(From our Regular Correspondent.)

SURGERY OF THE LUNGS—ACUTE AND CHRONIC PULMONARY SUPPURATIONS—SURGERY OF PULMONARY TUBERCULOSIS AND OF BRONCHIECTASIS—ARTIFICIAL PNEUMOTHORAX—INDICATIONS FOR PNEUMOTOMY—TRAUMATIC WOUNDS OF THE LUNG.

BERLIN, March 1, 1912.

THE present status of surgery of the lungs was the subject of a symposium recently held before the Medical Society of Berlin. The speakers were H. Fränkel and W. Körte. The former discussed the subject from the medical viewpoint, while the latter discussed the surgical aspects. Fränkel dealt with the theme under two headings, one including non-tuberculous pulmonary suppurations, and the other including only tuberculous processes. There are two factors that have contributed to the present high development of pulmonary surgery, namely, the improvement in the technique of pneumotomy, and the method of *x*-ray examination. By means of extensive resections the operative field can now be widely laid open,—thus affording not only greater perfection in operative work, but also a greater facility in diagnosis. Of the suppurative process in the lungs one may distinguish between the acute and chronic and the unilateral and bilateral forms. The acute suppurations are mainly of metapneumonic origin, and are caused by embolism or aspiration. These cases mostly resolve spontaneously. If this does not take place in three or four weeks operative interference is demanded. The danger consists in the development of septicemia and of inflammatory exudates that develop in the neighborhood of the gangrenous areas in the lung. Moreover, the latter may extend to the pleura or may cause metastatic abscesses in other parts of the body. In all instances of unilateral pulmonary gangrene operation should be performed as early as possible. The largest statistics relating to this condition have been published by Lenhartz. These deal with 120 cases which were operated upon with a cure in 73 per cent. There were 28 cases which came under the observation of Fränkel and which were operated upon by Körte. Of these 67 per cent. were cured; 21 of the cases were acute. That more cases came under the observation of Lenhartz in Hamburg than were observed in Berlin is probably due to the fact that the habits of alcoholism and tobacco-chewing indulged in by seafaring men predispose them to pulmonary suppurations. In the acute cases that are easily diagnosed, *x*-ray examination is of the greatest value. The examination, however, must be frequently repeated, for the cavities, according to their degree of fullness or emptiness, give quite different radiographic pictures. The *x*-ray examinations should be made in different positions, and under the briefest exposure, in order to eliminate the movements of respiration. Of greater difficulty is the diagnosis of chronic cases, for in these there are no longer circumscribed foci but infiltrates that give shadows involving the entire lung. According to Forlanini these cases should be treated by inducing an artificial pneumothorax. But the speaker did not believe that this method was adapted for all cases.

Among the bronchiectases there are to be distinguished acute and chronic, and circumscribed and diffuse forms. These cases are mostly the end-results of bronchopneumonia, and in warm and dry climates these cases are easily cured. If the cases are not cured, and tend to become diffuse, then the performance of artificial pneumothorax and resection of ribs must be considered as the proper operative measures. If there are pleural adhesions the latter procedure alone should be resorted to. Unfortunately the operative results already published are not favorable.

Artificial pneumothorax has been largely resorted to in the past few years in the treatment of pulmonary tuberculosis. If there are no adhesions the method is without danger. Since, however, adhesions are frequently present, and since the operation can be employed only when the disease exists on one side, the field of adaptability of this operation is a limited one. A manometer must always be employed, and to tear the adhesions with force is a serious surgical blunder. The method fulfills two requirements: the immobilization of the lung and the favoring of the development of connective tissue. In many cases improvement is also observed on the non-operated side. If artificial pneumothorax fails, then the resection of ribs is indicated.

This operation is particularly demanded in cases of recurrent hemorrhage and in all cases of tuberculosis with empyema.

In opening his address Korte referred to the great aids to pulmonary surgery which have resulted from the *x*-rays and the use of the differential pressure cabinet. Of course, before the introduction of these resources all the operations had been performed, but these are now far safer. Of the three methods, namely, the use of the negative pressure cabinet, according to Sauerbruch, the use of Brauer's positive pressure apparatus, or the employment of Kuhn's method of intratracheal intubation, the method of Brauer appears to be the one that has gained greatest recognition. With reference to diagnosis it has been Körte's experience that pulmonary abscess and pulmonary gangrene cannot be distinguished from each other. A diffuse gangrene such as sometimes follows an influenzal pneumonia is not suitable for operation. In his cases there were found at operation total adhesions in eight instances, and partial adhesions in 32 instances, both varieties constituting 50 per cent. of the cases. The presence of adhesions is no contraindication to pneumotomy. The operation may be carried out under local anesthesia, but in all cases a large thoracic opening should be provided. The use of morphine and scopolamine is superior to general anesthesia. The thermocautery is not superior to the knife, for the former is not capable of stopping the deeper hemorrhages. Within recent years the operation has been unsuccessfully employed in the treatment of bronchiectases. The ligation of a branch of the pulmonary artery may be considered in this connection. Direct healing by the process in the lung is not to be expected from this procedure. In a number of cases a favorable result has been obtained in consequence of the shrinkage of the lung resulting from the operation.

As to the dangers associated with surgery of the lungs, those connected with the movements of the lungs and of the mediastinal structures, and with reflex inhibition of respiration, the former may be avoided by the employment of differential pressure, while to prevent the latter there is at present no efficient means known.

The indications for operation in wounds of the lung are intrathoracic bleeding and traumatic pneumothorax. The speaker's losses in operations of this kind were comparatively small, considering the fact that the patients' lives were in jeopardy. Of the 30 cases operated upon for empyema there were 9 fatalities. In 140 cases the result of the operation was so favorable that the lung immediately resumed its respiratory function.

Care and Control of the Alcoholic.—A. Lambert states that one can best classify alcoholics into three classes: The first class consists of those suffering from industrial alcoholism, who begin taking the alcohol in moderate doses to enable them better to perform either muscular or mental work. This form soon leads to increasing doses and tends always to chronic alcoholism with its accompanying mental deterioration. The second class includes the convivial drinkers who drink to increase the joys of life, and while this invariably tends to attacks of drunkenness it does not so often tend to chronic alcoholism, but in any given individual it may turn into excessive steady drinking and then naturally to chronic alcoholism. The third class consists of those individuals who drink to blot out the recollection of sorrow or of trouble; of those who cannot face the harshness of their existence or of those who, congenitally weak mentally, cannot stand the strain of their environment, and who naturally turn to some narcotic for relief. The convivial drinkers, while they frequently show a greater amount of drunkenness than those of the other classes, yet show a less amount of chronic alcoholism. Briefly stated, the treatment found of value by the author in the treatment of alcoholism consists in the hourly dosage of a mixture of belladonna, hyoscyamus, and xanthoxylum. This mixture is given every hour, day and night, for about fifty hours. There is also given about every twelve hours a vigorous catharsis by means of compound cathartic pills and blue mass. At the end of the treatment, when it is evident that there are abundant bilious stools, castor oil is given to clean out thoroughly the intestinal tract, and the reconstruction treatment by means of tonics is begun. During this treatment it is essential that each patient be treated as a separate individual. How the mixture of belladonna, hyoscyamus, and xanthoxylum acts the author does not know. If any one of the ingredients is left out the reaction of the cessation of desire is not as clear-cut as when the three are mixed together. The dosage necessary is judged by the physiological action of the belladonna.

Nervous and Mental Disorders in the Schools.—A. W. Fairbanks states that the prevention of these disorders requires the following pedagogic reforms: (1) The abolition of all competitive work. (2) The absolute abolition of either moral or material rewards for excellence in school work or attendance. (3) The elimination of special examinations, the passing of which is held essential as a requisite for promotion. (4) The making of promotion solely dependent upon the capacity shown by the individual child in its ordinary routine daily work, such promotion to occur whenever the child indicates its capacity for such advancement. (5) The elimination, as far as possible, of a fixed standard, either of grade or of graduation, to which children are expected to conform at definite periodical intervals, or at definite and arbitrarily fixed ages. (6) The elimination of report cards sent to parents, weekly or monthly, or at any other time. (7) The abolition of condemnatory or adulatory certificates and the substitution therefor of personal contact with the parents and the home. (8) In certain cases the institution of special instruction by special teachers in very small classes. (9) The abolition of afternoon sessions for all grades below the fifth, or the entire devotion of the afternoon session to educative play without restraint. (10) The assignment of the easiest studies for the afternoon sessions for all grades from the fifth upward. (11) The reduction of the time during which the concentration of the attention of the pupils is required for any one subject. (12) The abolition of home lessons requiring mere abstract reasoning or routine memory.

Blood Transfusion for Hemorrhagic Disease of the Newborn.—B. Vincent reports a series of four cases of this condition in order to emphasize the striking result of blood transfusion in this disease and to describe a variation in the technique which shortens and simplifies the operation in infants. In the author's first three cases the donor's radial artery was connected by a glass tube with the infant's femoral vein, as this vessel seemed to be the

most accessible vein of sufficient size in a baby. The operations were carried out successfully, but it was found that certain difficulties in the operation were due to the awkward position of the femoral vein, its depth, and the numerous branches. This experience led the author to search for a more superficial large vein. The examination of many infants demonstrated that the external jugular vein is more easily located and larger than the other superficial veins in a baby. The author has used this vessel in the past four cases and has found that it is as large as the femoral vein in an infant, or larger, and has no troublesome branches. Its position just beneath the skin makes the exposure of the vein and the insertion of the glass tube a comparatively simple matter. If the tube is about 12 centimeters long it will extend beyond the infant's head and the donor's artery can be easily connected to the upper end. By this method the blood is transmitted almost directly into the infant's heart.

Correction of Lateral Curvature of the Spine.—E. G. Abbott states that the two fundamental principles underlying the correction of such deformities are: (1) overcorrection, for if motion is not established in all directions to the extreme of normal motion the treatment is only palliative and not curative, and (2) fixation in the overcorrected position, until the parts are so thoroughly stretched and changed in their shape that the deformity will not return. That it has heretofore been impossible to correct the deformity of fixed lateral curvature is due to the fact that it has been impossible to apply these principles. It is then evident that to effect a cure the spine must be flexed and drawn to one side by force exerted in the direction opposite to that of the fixed curve; and that together with this the low shoulder and depressed ribs must be elevated and forced into a position posterior to that of the high shoulder and bulging ribs, *i.e.* the patient must be placed in a position which is exactly opposite to that of the original deformity, and this with the spine flexed. By this method not only is the spine overcorrected, but the integral parts of the deformity pass through the same arc which they traversed when the deformity developed. A frame made of gas pipe and a hammock are employed for the purpose of making the necessary corrections and of applying the plaster jacket. The technique is described in detail.

Abbott's Method of Correcting Fixed Lateral Curvature.—D. D. Ashley states that Abbott's method is concerned only with the so-called "structural" or fixed curve—the curve that the patient cannot voluntarily overcome. The postural, functional, and habitual curvatures are not considered in this treatment, these still being treated by exercises. It is not a cure for all conditions and forms of scoliosis. It is especially applicable in the acquired forms when not too rigid, severe, and complicated by structural changes of bony ankylosis, although several cases in which the *x*-ray revealed apparent ankylosis have yielded successfully to this treatment. The correction of a deformity of the body must mean the ability of the surgeon to make an overcorrection, as in bowlegs, knockknees, clubfeet, and wryneck. Abbott's conception is based upon the theory of a rotating forward of the concave side and that in correction the bodies must move to the concave side and backward, as the deformity was produced by flexion and side bending toward the convex side, the correction and overcorrection must take place in the same position of flexion and side bending to the other side. To attain this effect Abbott flexes the spine with pressure over the lower ribs, with side bending, the arm of the depressed side being brought high up and forward and the arm of the convex side being brought well down and backward. The frame and hammock hold the patient in this position of extreme flexion, while the plaster of Paris jacket is being applied. Usually four fenestræ are cut out, the largest behind to permit farther flexion and free rotation of the concave side backward, and two in front, commencing at base of breasts and extending from five to eight inches; these to adjust pressure pads. Another is generally made on the side of the convexity better to control any crushing or bending of the ribs, which is to be avoided.

Rotary Lateral Curvature.—C. Ogilvy describes the exercises devised by Klapp as an accessory in the treatment of this condition. These creeping and corrective exercises relax the muscles of the spine and improve the general condition of the patient, but do not result in holding any true correction of the bone deformity. To do this a spinal brace is essential in addition to these exercises. Speaking generally, results sought for are: (1) The correction of the standing postural deformity of shoulders forward and abdomen protuberant with an accentuated lumbar lordosis. (2) The correction of the lateral deviation of the spine, associated with the leaning of the body in the same direction. (3) The correction of the rotation of the vertebræ with the associated malposition of the ribs.

Present Status of Surgery for Cancer of the Breast.—By E. S. Judd. (See MEDICAL RECORD, February 3, 1912, page 249.)

Journal of the American Medical Association.

April 27, 1912.

Angioneurotic Edema.—H. I. Wiel presents the history of several cases of angioneurotic edema associated with gastrointestinal symptoms and complicating other disorders, tuberculosis, cholelithiasis, gonorrhea, etc., and most of them in persons of decidedly neurotic habit. As usual the condition tended to recur and was rather resistant to treatment, remedies effective in one case often failing in others, or in different attacks in the same individual. The applications that were found of greatest use externally were compresses, respectively, of aluminum acetate, argyrol (20 per cent.), boric acid, and calamine lotion

Most writers on the subject have regarded the angioneuroses as a disease, and this may be the case in some instances. In the cases he reports the author states that it seems clear that the angioneurotic edema was not the disease itself, but an accompaniment and complication of various other disorders, all characterized by some sort of gastrointestinal disturbance. In that light it might be considered, as it has been by some, the outcome of some intestinal toxemia. It is possible that by working along the lines of anaphylaxis one may approach something definite as regards this point. In the meantime the recognition of these cases is of considerable importance, especially when they approach the surgical domain.

Neuropathic Inheritance.—A. J. Rosanoff discusses the application of the Mendelian theory to neuropathic inheritance in the human subject. Expectation in accordance with the Mendelian theory is stated as follows: (1) Both parents being neuropathic, all children will be neuropathic. (2) One parent being normal, but with neuropathic taint from one grandparent, and the other parent being neuropathic, half the children will be normal, but capable of transmitting the neuropathic constitution to their progeny, and half will be neuropathic. (3) One parent being normal and of pure normal ancestry, and the other parent being neuropathic, all the children will be normal, but capable of transmitting the neuropathic constitution to their progeny. (4) Both parents being normal, but each with the neuropathic taint from one grandparent, one-fourth of the children will be normal and not capable of transmitting the neuropathic constitution to their progeny, one-half will be normal, but capable of transmitting the neuropathic constitution, and the remaining one-fourth will be neuropathic. (5) Both parents being normal, one of pure normal ancestry and the other with the neuropathic taint from one grandparent, all the children will be normal; half of them will not be capable and half will be capable of transmitting the neuropathic constitution to their progeny. (6) Both parents being normal and of pure normal ancestry, all the children will be normal and not capable of transmitting the neuropathic constitution to their progeny.

Periurethral Complications of Strictures.—M. Silverberg concludes that the periurethral complications of stricture are of an infectious nature. Inflammation may be acute, leading to a circumscribed abscess, or hyperacute, leading to a phlegmon rapidly involving the perineum, scrotum, and abdominal wall. In the latter event the presence of urine is of secondary significance. Inflammation may be chronic and is then characterized by a progressive development of new connective tissue, possessing little resistance to infection, and therefore frequently the seat of limited suppuration.

Myocardial Degeneration.—E. F. Ingals states that the most important symptoms of this condition are irritability of temper, melancholia, loss of memory, precordial pain, palpitation, dyspnea, diminished physical and mental endurance, pulse alterations and slight edema of the ankles. These are attended by more or less change in the physical signs, which however are not distinctive until late in the disease. Often the process goes on without symptoms until an attack of angina pectoris or fainting appears, but in most cases there are some antecedent symptoms within two or three years. There are no signs enabling one to distinguish definitely between the various forms of the disease.

Vaccine Treatment of Acne.—O. Smiley presents a tabulated report of 100 cases of acne vulgaris treated by autogenous vaccines. Accessory treatment was also given to modify the viscosity of the blood if necessary; general tonics and mild laxatives were also employed. Calcium lactate was used in preference to sodium citrate. Liberal quantities of soap and water were also employed. In 86 per cent. of the cases the organism was a *Staphylococcus albus;* in 10 per cent., *S. albus* and *aureus;* in 3 per cent., *S. aureus* alone, and in only one case were the *S. aureus* and *citreus* found together. The size of the initial dose ranged from 100,000,000 to 150,000,000, and was increased by one-eighth to one-fourth of the initial dose until improvement appeared, and was then held stationary or modified by the degree of the negative phase. The largest doses were given when the *aureus* existed either alone or with the *albus*.

Skin Eruptions.—H. G. Adamson discusses the significance of the patterns and distributions of skin eruptions. These distributions may be determined by local physical agents, as in the case of the trade eczemas upon the hands and fingers. As regards eruptions of microbic origin it is noted that their site may often depend upon the facility with which infection takes place in certain positions, as in the case of lupus vulgaris upon the cheek. The lymphatic circulation is never responsible for the wide distribution of eruptions. In sporotrichosis the nodules appear along the course of the inflamed lymphatics. The vascular distribution of microorganisms is exemplified in the eruptions of secondary syphilis, the rose rash of typhoid fever, and in some infective erythemas and purpuras. The influence of the nervous system upon the distribution of skin eruptions is seen in herpes zoster, in alopecia following section of a nerve, in hyperidrosis limited to an area corresponding to that of a particular nerve distribution. Raynaud's disease and some allied minor affections are of vasomotor nerve origin.

Radium Emanation in Mineral Waters.—T. P. Lowe, quoting from Sir Willliam Ramsay's recent report on the radioactivity of the waters of Bath, states that radium is a very unstable element, continually changing into another body, also elementary. During this change it parts with helium, each atom of radium furnishing one atom of helium. Having shot out its particle of helium, the atom radium is no longer radium, but a gas to which Ramsay has given the name of niton, but which was first known by the cumbrous name of radium emanation. The potency of radium depends upon its niton. Neon is also supposed to be one of the products of radium, but possibly further investigations may show it to be one of the results of the disintegration of some other radium-like element which has not yet been discovered. The radioactivity of all mineral waters exists only at the source, and such waters rapidly lose this quality. Nevertheless, it is possible by artificial means to render them permanently radioactive. W. H. B. Atkins and F. C. Harrison state that radium produces the following therapeutic results: (1) Greatly increased diuresis and excretion of uric acid; (2) largely increased carbonic acid exhalation, from 20 to 60 per cent.; (3) lowered blood pressure, especially in arteriosclerosis; (4) decreased blood viscosity; (5) great improvement of gastric and duodenal digestion; (6) marked solvent action on gouty deposits; (7) the dislocation of uric acid and its salts into carbon dioxide and ammonia; (8) inhibition of inflammation and relief of pains in rheumatism; (9) increase of sexual vitality; (10) considerable influence over sympathetic nerve affections; and (11) marked results in diabetes, albuminuria, and glycosuria. All of these results the author has been able to confirm from personal

observation in Bath, and he would add the rapid disappearance of indican from the urine.

Vaccines in Rheumatoid Arthritis.—F. J. Horder states that it is illogical to conceive of the use of vaccines as covering the whole treatment of this complex disease. Individual cases show great variations and require different treatment even in principle. The proper examination of the case entails two separate investigations: (1) a critical analysis of the symptoms and signs, as referable to changes in joints, muscles, nerve tissues, blood, and general nutrition; and (2) an examination which has for its special object the discovery of one or more foci of infection. In this second part of the examination careful attention is paid to the mouth, the fauces, the nose, nasopharynx, and nasal accessory sinuses, the respiratory tract, the small and large intestine, the urinary tract and the uterus. If any infective focus is found efficient drainage is necessary. One may then proceed cautiously to raise by specific means the level of the patient's immunity against the residual infection going on at the site of the original invasion or against secondary foci in the body which cannot be dealt with directly. The means available are: (1) immune sera, by which it may be possible to supply temporarily a degree of passive immunity; and (2) vaccines, by which it is hoped to stimulate the patient to a more permanently useful degree of active immunity. If the case is acute or subacute and the evidences of intoxication are a noticeable feature of the case, the preliminary use of immune serum is indicated. In the more chronic cases, which are much more common, resort may be had forthwith to autogenous vaccines. In actual practice the microorganism most often incriminated as the infective element in the disease is a type of streptococcus, not *Streptococcus pyogenes*, but *Streptococcus salivarius* or *Streptococcus fecalis—i.e.* streptococci of relatively low virulence, not tending to suppuration and traceable, as the names are intended to suggest, to the mouth or intestine. Other microorganisms are much less common; the gonococcus, pneumococcus, and *Bacillus coli* almost exhaust the series, as at present established by reliable observations. Perhaps *Staphylococcus aureus vel albus*, *Bacillus influenzæ*, and certain diphtheroids may be included in the list. The initial dose of vaccine should always be small.

The Recurrence of Adenoids.—T. Guthrie states that the most important factor in the recurrence is the age of the child. In children under four years of age there is decided risk of recurrence; between the ages of four and seven the chances of recurrence are slight, and after the age of seven they are practically nil, always provided that the operation has been complete. Apart from the influence of age, it is certain that recurrence is much favored by an attack, within a short time of the operation, of one of the specific fevers, especially measles or whooping-cough. Again, according to C. Parker, in children who are the subjects of congenital syphilis recurrence seems to be the rule rather than the exception unless the general condition is carefully treated. Lastly, recurrence is probably favored by the presence of untreated anterior nasal obstruction, especially hypertrophic inferior turbinals, and is therefore apt to be met with in patients with high arched palates and narrow nasal cavities in whom removal of the adenoid does not lead to the establishment of free nasal respiration. All of these conditions have the feature in common that they tend to excite or maintain a state of chronic postnasal catarrh, which should, therefore, wherever it is present, receive appropriate treatment if the risk of recurrence is to be reduced to a minimum. In conclusion, it is remarked that a true recurrence of adenoid vegetations is a somewhat rare event even in the case of young children, and the fear of it affords no valid argument against operation.

Tuberculization and Detuberculization.—R. W. Philip states that tuberculosis is a vicious by-product of an incomplete and ill-informed civilization. The hope for the solution of the tuberculosis problem, bristling as it does with difficulties of many sorts, lies in the application of an organized plan sufficiently wide to cover all the ground. Such a plan is outlined by the author as follows: In the foreground it appears clear that for every considerable community there must exist a center which shall concern itself in the widest possible way with the facts of tuberculosis as it exists in the area. Here every aspect of tuberculization will be dealt with and every line of detuberculization will be conceived and realized. Toward the center inquiries from all sides regarding tuberculosis should be directed. To the center patients in all stages of tuberculosis should be invited and likewise persons who may be anxious lest they be tuberculous. This great collecting center constitutes the seat of diagnosis and classification of the varying types of disease. The collecting center comes in turn to be a "clearing house." Each case will receive appropriate guidance and direction, whether at the center itself or at one of several residential institutions with which it should stand in organic relationship. For example, patients for whom there still remains hope of recovery will be passed to the sanatorium with its great possibilities of treatment and education. Another group, in whom tuberculosis has already played havoc, so that hope of recovery has disappeared, will be transferred to the hospital for advanced cases. Others, who may have already been treated successfully in a hospital or sanatorium and to whom return to ordinary work might mean physical relapse and corresponding economic waste, will be drafted to the farm colony for prolonged supervision under favorable conditions and simultaneous education on lines of therapeutic and economic value. The tuberculous school child will be transfererd to a special tuberculosis school in close relationship with the center itself or with the sanatorium or farm colony, so that during the process of recovery from tuberculosis mental development may not be unnecessarily interrupted. When the time comes for patients to be discharged from these several institutions they should be referred once more to the center for such medical superintendence and after-care as will ensure that the recovery, in whole or in part, which has been achieved shall be maintained.

Osteitis Deformans.—T. W. Parry reports a case of this condition occurring in a woman aged 63 years. The duration of the disease was four and one-half years. It began following shortly after an operation for appendicitis. The first manifestations were a bowing of the legs and a marked shortening of the stature. One day while the patient was stooping the left femur suddenly fractured. There was now no doubt of the diagnosis; the femora were much enlarged and bowed forward and outward, and the tibiæ were also bowed in the same direction, but not nearly so proportionately enlarged. When the patient lay on her back with her heels together the knees were widely separated and there was an arch under the

center of the right femur under which one could pass one's hand. The cranial bones were not enlarged as one would have expected, but the lower maxilla was thickened and protuberant at the chin. Death took place five weeks afterward, apparently from a failing heart.

Unsuitable Neck Clothing.—W. G. Walford states that any pressure on the neck acts most insidiously; the neck is cone-shaped and a collar or band that may be perfectly loose at the middle of the neck, say over the cricoid, may be tight enough to exert some pressure when it drops into its working position, more especially in a slope-shouldered person. Again, a collar may seem roomy, but may, when a person is reading, get pressed by the chin onto important organs. Next, the habitual wearing of neck clothing not sufficiently large arrests the full development of the neck, with its numerous organs for communication between brain and body. This is of great importance during the period of growth. Also in advancing life when the neck muscles are wasting and losing their tone, the vessels and nerves beneath become more exposed and sensitive to pressure. Many cases of vertigo, which may or may not be associated with vomiting, yield immediately to the remedy of loosening or enlarging the collar. The undersized neck is particularly noticeable in phthisis; the author believes that the cause of this undersized neck is the use of tight neckwear by fast growing young people. The lymphatics are easily obstructed by neck pressure. In heart cases it is particularly important that the neck clothing should be loose.

Tincture of Digitalis.—A. Goodall concludes from his investigations that nearly 50 per cent. of samples of digitalis made by manufacturing chemists of repute showed a departure from the average standard of potency. The limits of this variation were from 275 per cent. over strength to 40 per cent. under strength. In other words, the effect of a dose of 10 minims might be that of 37½ minims or of 6 minims. Tincture of digitalis probably retains its full activity for one year, but after that period deterioration of its potency to an important extent is likely to take place.

Muenchener medizinische Wochenschrift.

April 16, 1912.

Error in Sex.—Ringel reports the case of a supposed boy with hypospadias and bilateral cryptorchism, who was otherwise well developed. The hypospadias would be classed as penoscrotal. The testicles were in the inguinal canal. Although patient was but six years old there was considerable hair on the mons veneris. The raphe of the scrotum was plainly visible. Operation was undertaken to cure the hypospadias and then displace the testicles down into the scrotum. The first check was found in inability to isolate and mobilize the urethra, so that operation was abandoned. Two subsequent attempts also failed. It was then decided to operate only upon the testicles. When the latter were exposed, however, they were found to be prolapsed ovaries. Rectal exploration also showed the presence of a uterus. The plan of operation was now radically altered. The "scrotum" was split and search made for a rudimentary vagina, but it was decided to go no further for the time being. Two weeks later an exploratory laparotomy showed that the entire internal genitals were normally feminine. An attempt was now made to open up a vaginal passage from above downwards. A cul-de-sac with the blind end below was found and opened up externally, and a strip of gauze left in, and the labia majora subjected to a plastic reconstruction. Labia minora were absent. At a later period the hypertrophic pseudopenis was extirpated. The vagina had undergone some obstructive cicatrization and was again restored. The patient thereupon assumed a female name and attire.

Nature of Scleroderma.—Kolle after exhaustive studies on a patient with this affection arrived at the following conclusions concerning the genesis of the latter in the particular case involved. Either a traumatism or a toxinemia is capable of injuring the sympathetic, especially in a predisposed subject. A sympathetic neurosis is set up, which is expressed largely in terms of trophic alterations in the bloodvessels of the skin. The same sympathetic neurosis also makes its presence felt in the lymphatic glands, and the changes set up are felt in the integument as edema, pigmentation, etc. The suspended function of the lymph nodes may perhaps be neutralized by giving extracts from these bodies, which are evidently intended to disintoxicate certain substances which pass through them. From this viewpoint the mesenteric lymph nodes have great significance. The author gave his patient mesenteric gland substance and the general improvement in the patient's physical state is set down not to any curative efficacy but to neutralization of some of the effects of the malady.

The Apparent Immunity of Certain Subjects to Methyl Alcohol.—Foerster as a result of studying some of the immune subjects in a petty episode of wood alcohol poisoning arrived at the conclusion that those who do hard labor and perspire freely are much less likely to suffer than those under the opposite conditions. Thus at a Hungarian wedding those who danced the most appeared to be least poisoned.

Deutsche medizinische Wochenschrift.

April 18, 1912.

Pathology and Treatment of Cardiac Asthma.—Rosin speaks of the nocturnal onset, the mechanical oppression which serves as a sort of aura to the paroxysm, the high degree of orthopnea, the fact that the case seldom comes to physical examination on account of the labored breathing and restlessness. The exact mechanism of the attacks is not known. The condition is symptomatic of many affections—arteriosclerosis, especially of the coronary arteries, embolism in the same and in the pulmonary vessels, myocarditis, aneurysm, nicotinism. It is likely to be confounded with spastic bronchial asthma and in extreme degrees of the latter diagnosis may be all but impossible at first. The history of the attacks and the exclusion of certain causal factors in cardiac asthma, with the presence or absence of emphysema will make for a proper differential diagnosis. Renal asthma may require differentiation although both forms may occur under identical circumstances. The two conditions, however, are radically distinct for uremic asthma is due to circulating toxins while cardiac asthma is the result largely of mechanical conditions. There should be no confusion with nervous asthma. The best remedies for the attacks appear to be camphor and caffeine, given by intramuscular injection. If the emergency is sufficiently acute some digitalis derivative should be injected intravenously. Morphine injection is often used as a synergist. An icebag should be placed over the heart as a physical stimulant and venesection will at the same time relieve the strain on the organ. The patient should be propped upright and inhale oxygen.

Studies of a Case of Myxedema in a Child.—Loewy and Sommerfeld have made a long series of investigations on a seven year old child which weighed less than nineteen pounds, and was no larger than the average yearling child. Four studies of metabolism were carried out, and the results are to be published in a separate paper. The results were not those demanded by theory and the records of others but the patient had already had thyroid therapy, although seemingly with negative outcome. The authors have as yet reached no definite conclusions and the chief result of their work appears to be that doubt is thrown on some of the current teachings concerning the affection.

Insurance Medicine.

Medical Aspects of Life Insurance.—In a second lecture on this subject, given on March 1, 1912, in London Sir Richard Douglas Powell deals with the three capacities in which the physician comes into practical contact with life insurance work: as the family adviser of the proposer for life assurance, as a referee for expert examination of the proposer, and as medical adviser to the assurance company. As for the ethical propriety of the medical attendant giving intimate information respecting the present health and past disease and habits of the patient, Powell thinks the course is plain. If he refuses to give a report his refusal would prejudice the case of his client with the insurance company. If he decides to furnish the report he is bound to do so fully and to answer all questions with perfect frankness. Any important fact with regard to the proposer's health intentionally withheld would, if discovered at a later period, seriously imperil the validity of the contract for insurance.

With respect to the mode of examination of an applicant for life assurance, it is pointed out that in medicine generally one comes to regard the defects of people from a relief and repair point of view and look to the prognosis as regards the immediate future. In life insurance work the immediate future is out of account; one has to regard the ultimate end and the sum total of the viability of the individual and to estimate it from a pecuniary point of view. When doing this, however, one must not allow oneself to be obsessed by such demands upon one's perspicacity. They must not lead one to "wear a worried look" nor to assume an unduly Sherlock Holmes-like attitude of preternatural sagacity when a poor and often very nervous applicant for insurance has to be examined. There is nothing more to be done than leisurely and courteously to go into the case on the customary clinical lines to make the applicant easy by a straightforward, matter-of-fact manner, and to take special pains with nervous people to wait upon minor points until they become calm. One should never be or appear to be in a hurry. Referring to the influence of heredity with relation to life insurance, the author describes the constitution of a man as his build, the integrity or otherwise of the tissues of which each part of his body is made up, and the wholesomeness or otherwise of the juices with which they are bathed; the sum of his vital force, his cell-quickening power, which must bear the call of judicious expenditure for a long or but a brief period of time.

Hereditary influence has an important bearing upon the detail of this construction. The first point is that good long-lived family history, especially with longevity in the parents and grandparents, and a general good record of viability of the immediate relatives, is of favorable augury for the insurer and will often serve to countervail some defects in his personal medical history. And the converse holds good. Racial viability and disposition to disease require passing notice. Jews are more liable to diabetes and perhaps less to tuberculosis and alcoholism than some other races. Of European countries, if we may trust the parity of relative statistics, England and Wales hold a middle place in the viability of their population between Norway, where it is higher, and France, where it is lower.

Discussing diseases of the nervous system the author thinks that, with regard to melancholia, Sir George Savage's dictum is fundamentally true, that "every melancholic is a potential suicide," and although a confirmed melancholic would not be considered for life insurance, it is well in cases in which there is a marked neurotic history pointing to instability of the nervous system or actual insanity in the family that the applicant's personal history be closely scrutinized for any evidence of nervous depression or breakdown and that he be considered as to his social relations, business conditions, and personal habits. It is sometimes of importance to insure the life of a person who is confined in an asylum with delusional insanity. Chronic cases of this form of insanity may be accepted for insurance when there is every probability of their remaining under certificates in a well administered asylum. However, contrary to a somewhat popular belief, the average viability of the insane is low; their resistance to degenerative and infective diseases is much impaired; they readily succumb to tuberculosis, Bright's disease, and terminal infections. Sir William Gower's suggestion is, perhaps, as practical and near the mark as possible, viz., in the most favorable cases on grounds of insanity alone, to reckon for the duration of life as two-thirds of the average for the age by the addition of a number of years equal to half the normal expectation. The question of tuberculosis is considered at length and tuberculosis in connection with gland enlargements in particular. In opposition to the expressed opinion of a large number of careful observers the experience of Powell leads him strongly to the view that an abnormally large proportion of persons who have had surgical tuberculosis, whether in lymphatic glands, bones, or skin, become later the subjects of pulmonary tuberculosis. It is, therefore, impossible to regard any person who has or has had glandular tubercle or tuberculosis in the closed forms, be it joint disease, spinal caries or other bone disease, fistula or pleurisy, as presenting other than a blemished life.—*The Practitioner*, March, 1912.

Insurance Against Tuberculosis.—The Finnish insurance company "Fennia" proposes to introduce tuberculosis insurance for a small extra premium. The company expects to build a small sanatorium and proposes to treat applicants insured with it in this sanatorium in case of development of pulmonary disease. The sanatorium is to be enlarged, if necessary, and if room be still lacking, the company binds itself to procure equivalent treatment in private sanatoria. It expects also to help patients who prefer to have treatment carried out at their homes.—*Zeitschrift für die gesammte Versicherungs-Wissenschaft*, March 1, 1912.

Motherhood Insurance.—A government bill introduced in Sweden toward the end of 1911 proposes to establish compulsory insurance of all working women, to give them indemnity for time lost in case of pregnancy and childbirth. The insured women are to be supported for a certain time before and after delivery and also during the nursing period. All working women between the ages of 15 and 51 are included. The premium is to be paid partly by the women themselves, partly by the employers. If the sum collected is not sufficient, state help is provided for.—*Zeitschrift für die gesammte Versicherungs-Wissenschaft*, March 1, 1912.

Insurance on the "Titanic" Victims.—According to the *Insurance Press*, the insurance paid on the lives lost in the *Titanic* amounted to $1,881,111, of which nearly half a million was accident insurance.

Proceedings of the American Society for Psychical Research. Section "B" of the American Institute for Scientific Research. Vol. V. Part 1. April, 1911. Contents: A Case of Hysteria. By Drs. W. H. Hamilton and J. S. Smyth (Pseudonyms); and James H. Hyslop, Editor and Secretary of the Society. Price $6 (paper).

This large book is entirely devoted to the study and analysis of a group of phenomena exhibited by a young girl of phthisical type, with hysterical stigmata, while in the so-called trance state. Associated with Prof. Hyslop in this study are a surgeon and an oculist, both "doubting Thomases," respecting any manifestation of a supernormal agency. The foster mother of the hysteric, a spiritualist, was also present at the seances. Some of the incidents in the subject's experience are the orthodox physical phenomena, such as raps, rope tying, levitation, and tambourine flinging; while others are more unique, such as "trance whistling," simultaneous singing, the starting and stopping of a phonograph, etc. Eusapia Palladino is outdone by the exhibition of automatic speech, automatic writing, and clairvoyant visions, by "Miss Burton," whose psychic powers were first made known by raps on the headboard of her bed as she slept, when she was but a child. All evidences of conscious fraud on the part of the medium are eliminated in the study. "She could not whistle and she could not sing, in her normal state." In the "trance state" she could do both expertly. "Hysteria or subconscious phenomena of some sort," Prof. Hyslop remarks, "seem to lie at the basis of all mediumistic phenomena, whether of the genuine or non-genuine type. This fact indicates that we should expect to find simulation of the inexplicable in all of it, and that we have no right to employ the standards of normal psychology in estimating the nature of the facts which we are expected to explain. In determining the question of fraud, which means conscious effort to deceive, we should always recognize the duty of prior investigation of hysterical conditions." The various situations and actions of Miss Burton, described by the investigators, are interpreted by them as "hysterical simulation with occasional vistas of the supernormal." The sex findings by a Freud psychoanalysis are not to be found in the book, although the patient, or medium, was examined by a neurologist. The book is of especial interest to the psychologist; but it is also of interest to the general reader, and to the physician on account of the recognition of hysteria as furnishing a partial explanation, at least, of the phenomena exhibited. A drawing and eleven flash-light photographs, taken during experiments, accompany the text. The experiments were apparently conducted with care and attention to detail.

Second Review of Some of the Recent Advances in Tropical Medicine. Being a Supplement to The Fourth Report of the Wellcome Tropical Research Laboratories at the Gordon Memorial College, Khartoum. By Andrew Balfour, M.D., B.Sc., F.R.C.P. Edin., D. H. P. Camb., Director, and Captain R. G. Archibald, M.B., R.A.M.C., Attached E.A., Pathologist and Bacteriologist, in Collaboration with Captain M. B. Fry, M.R.C.S., L.R.C.P., R.A.M.C., Attached E.A., Protozoologist and Assistant Bacteriologist, and Captain W. R. O'Farrell, L.R.C.P. and S.I., R.A.M.C. Price $3.75. Published for Department of Education, Soudan Government, Khartoum, by Baillière, Tindall & Cox, London, Depot for United States, Toga Publishing Co., New York City, 1911.

The work that is being done by the Wellcome Research Laboratories in the Soudan is of immense importance to the development not only of this particular country but of all tropical regions, and its publications constitute a most valuable addition to the literature of tropical medicine, and, indeed, of all branches of science relating to man and nature in the hot lands. The present volume is a review of progress in tropical medicine between the date of the publication of the First Review, issued as a supplement to the Third Report in 1908, to June, 1911. The subjects covered are the following: Air, Ankylostomiasis, Anthrax, Bacteriology, Beriberi, Beverages, Blackwater Fever, Chickenpox, Chigger, Cholera, Climate, Clothing, Dengue, Diarrhea, Disinfection, Dropsy, Dust, Dysentery, Elephantiasis, Enteric Fever, Feces, Fevers, Filariasis, Filters, Flies, Food, Food Poisoning, Goundou, Guinea Worm, Hematozoa, Heat Stroke, Hydatid, Hydrophobia, Influenza, Insects, Leishmaniasis, Leprosy, Liver Abscess, Malaria, Malta Fever, Measles, Milk, Mosquitos, Mycetoma, Myiasis, Ophthalmia, Oriental Sore, Parasites, Paratyphoid Fever, Pellagra, Phlebotomus Fever, Piroplasmosis, Plague, Pneumonia, Preservatives, Protozoa, Refuse Disposal, Schistosomiasis, Scorpion Sting, Scurvy, Sewage, Skin Diseases, Sleeping Sickness, Smallpox, Snake Bite, Spirochætosis, Sprue, Staining, Syphilis, Technique, Tetanus, Ticks, Tropical Medicine, Trypanosomiasis, Tsetse Flies, Tuberculosis, Typhus Fever, Vaccination, Vermin, Verruga, Veterinary Diseases, Water, Whooping-Cough, Yaws, Yellow Fever.

All the advances in these subjects are noted, with copious bibliographical references, so that one without access to the literature may inform himself of all that is new in the domain of tropical medicine; while the student of any subject, with access to a library, will find in this work an invaluable index-guide to the original sources. The white man's burden, on the medical side, is wonderfully lightened by this painstaking research of Dr. Balfour and his accomplished aids.

K Vchéniu o Jelúdochno-kishéchnem Samootravlenyi (The Doctrine regarding Gastroenterie Autointoxication). By B. Korenchevsky. Moscow, 1909.

Korenchevsky's dissertation has "gastrointestinal autointoxication" for a subject, and consists of a critical review of the literature and the report of numerous experiments on the toxicity of the gastrointestinal contents of animals. It forms a formidable volume of some 400 pages, and because of its résumé of literature will save a great deal of time to any Russian reader interested in the subject of autointoxication. The author's experimental data seem to support Metchnikoff's statement that the putrefactive bateria of the gastrointestinal tract form a source of autointoxication in man as well as in animals.

Old Time Makers of Medicine. The story of the Students and Teachers of the Sciences Related to Medicine During the Middle Ages. By James J. Walsh, K.C.St.G., M.D., Ph.D., LL.D., Litt.D., Sc.D. Dean and Professor of Nervous Diseases and of the History of Medicine at the Fordham University School of Medicine; Professor of Physiological Psychology at the Cathedral College, New York. Price $2.00. New York: Fordham University Press, 1911.

For reasons which it is difficult to understand and which perhaps have to do with the fact that research in any field is always easiest along lines already partly investigated by previous workers a curious custom is observed by most writers on medical history. It appears to have become an accepted convention to devote chapter on chapter to the early Greek physicians and then to proceed without delay to a discussion of the great medical personages of the last few centuries. The gap of a thousand odd years or so between the decadence of the Roman Empire and the Renaissance is quite generally dismissed as being a period of scientific sterility that contributed nothing to progress, and therefore unworthy of detailed description. It is Dr. Walsh's purpose to show how little this attitude is justified, and the present delightful volume is intended to arouse interest in this particular epoch of medical history which in fact is second to none in significance. Anesthesia, antisepsis, prosthetic dentistry, careful study of the pulse and respiration, efficient sanitary regulations, the use of the ligature, all were foreshadowed or even in actual use during the mediæval centuries, and some important advances, such as in the medical education of women were made to a point which has not again been reached until the most recent times. Dr. Walsh's well-known art as a medical historian was never applied to better purpose or in more agreeable fashion than in this volume on what to most readers will be quite unfamiliar lore. Some of the chapter headings taken at random will give a little idea of the interest of the book: Great Physicians in Early Christian Times; Great Jewish Physicians; The Medical School at Salerno; Mediæval Women Physicians; Great Surgeons of the Mediæval Universities; Mediæval Dentistry; Cusanus and the First Suggestion of Laboratory Methods in Medicine; Basil Valentine, Last of the Alchemists, First of the Chemists, etc. The description of the great university at Salerno, in its day the leading seat of learning in the world, is excellent, though the author hardly emphasizes sufficiently the dramatic quality of its eclipse which was so complete that at present not even the site of its buildings can be pointed out, and even in the magnificent collection of manuscripts of the nearby monastery at Cava, the repository of all the local records, the present writer on the occasion of a recent visit was unable to find a single document bearing directly on the affairs of the university. Enough has been said to indicate the importance of Dr. Walsh's book, but properly to appreciate its value the volume itself must be studied.

PRACTICAL ELECTROTHERAPEUTICS AND X-RAY THERAPY. With chapters on phototherapy, x-ray in eye surgery, x-ray in dentistry, and medicolegal aspect of the x-ray. By J. M. MARTIN, M.D., Professor of Electrotherapeutics and x-ray methods in the Medical Department of Baylor University, in the Medical Department of Southwestern University, and in the State Dental College, Dallas, Texas; Member of the Texas State Medical Association, American Medical Association, American Roentgen X-ray Society, etc. Containing 219 illustrations. Price $4.00. St. Louis: C. V. Mosby Company, 1912.

So far as the practical value of the work is concerned Dr. Martin's volume is a distinct success. It gives in simple and clear language an explanation of the various procedures in the diagnosis and treatment of disease by x-rays, and the apparatus suitable for each class of work. On the other hand, the theoretical parts of the book are curiously obscure and involved. We have seldom, for instance, read a more unintelligible explanation of the "electron theory" than is contained in Dr. Martin's "introduction." It is a pity that the good impression created by the rest of the book should be marred by this fault, and we hope that in future editions Dr. Martin either leaves theory out altogether or has it presented more satisfactorily. The book is well printed, abundantly and usefully illustrated, and forms a good guide in the practice of electro- and x-ray diagnosis and therapy.

ARTHRITIS. A Study of the Inflammatory Diseases of Joints. By PETER DANIEL, F.R.C.S. Senior Surgeon Metropolitan Hospital; Surgeon to the Gordon Hospital; Assistant Surgeon, late Pathologist, Charing Cross Hospital. Edited by JAMES CANTLIE, M.A., M.B., C.M. Aberd., F.R.C.S. Eng., Surgeon Seamen's Hospital Society; Lecturer on Surgery, London School of Tropical Medicine. Price $4.00. New York: William Wood and Company, 1911.

THIS is the third volume of the Medicochirurgical Series and is devoted to the study of the inflammatory affections of the joints. Dr. Daniel has avoided making the book a mere résumé of literature, indeed gives hardly any references, but has endeavored to make it an expression of his personal views on the important subject it considers. His views, too, are frequently unorthodox enough to surprise the reader, but he brings a wealth of experience to their support; the book therefore is very stimulating, however unsatisfactory it may be for an undergraduate student.

The subject matter includes such headings as synovitis, sprains, gout, Still's disease, hemophilic joints, tuberculosis of the various joints, etc., etc. The pathological appearances are illustrated by numerous *x*-ray photographs and line drawings, most of which are very clear and useful. A few, however, are altogether too diagrammatic, as, for example, a picture of a "miliary tubercle" on p. 240, which looks more like a projection drawing of a golf ball with a "black dot" center than anything in pathological anatomy. Dr. Daniel's statements are frequently too dogmatic, but dogmatism and independent views seem to be the very *raison d'être* of the book and cannot therefore be quarreled with too strenuously. Treatment is fully described, various orthopedic procedures being very well presented.

The volume is a very handy one, and should prove valuable to the practical worker in joint diseases. The reviewer is inclined to question the propriety of putting only the editor's name on the cover of the book, the real author's name being found on the title page inside the book. This practice is certainly misleading to one who is looking over a library shelf in search of the author's work.

THE SURGICAL CLINICS OF JOHN B. MURPHY, M.D., at Mercy Hospital, Chicago. Volume I, No. 1. Octavo of 133 pages, illustrated. Published bi-monthly. Price per year, paper, $8.00; cloth, $12.00. Philadelphia and London: W. B. Saunders Company, 1912.

IN response to the demand for strictly clinical teaching, Dr. J. B. Murphy, of Chicago, has consented to the publication of a series of his "clinical talks" at the Mercy Hospital in Chicago, which are intended for physicians and not medical students. These clinics are stated to be reported verbatim, exactly as they are given, and are therefore claimed to retain all the lecturer's individuality. It is proposed to issue this work in six bi-monthly installments. The plan includes the history of each case, followed by comments on the technique of the operator, the diagnosis, and the methods of arriving at the same and all the points involved in the living pathology in the particular type of case. The present number includes clinical accounts of cases of carcinoma of the breast, lipoma of the shoulder, varicocele, nerve anastomosis, salvarsan injections, cystadenoma of the breast, pelvic tumor, fracture of the patella, blood clot in the bladder, Charcot's disease, epithelioma of the nose, duodenal ulcer, hydrops, hemangioma of the leg, and fistula *in ano*. Although more or less of an innovation in this country, these clinics of well-known physicians have been largely published abroad, particularly in Germany, and although the manner of presentation is naturally lost in a published article, there are many readers to whom the books will undoubtedly appeal.

INFECTIONS OF THE HAND. A Guide to the Surgical Treatment of Acute and Chronic Suppurative Processes in the Fingers, Hand, and Forearm. By ALLEN B. KANAVEL, M.D., Assistant Professor of Surgery, Northwestern University Medical School; Attending Surgeon, Wesley and Post-Graduate Hospitals, Chicago. Illustrated with 133 engravings. Philadelphia and New York: Lea & Febiger, 1912.

IN taking up this extended work of over 400 pages one is tempted to inquire the reason for such an elaborate monograph on a subject which in the ordinary text-books of surgery is usually dismissed in a single chapter. The author claims and with justice that such an important organ ought to be thoroughly understood as regards the class of injuries to which it is most frequently subjected and he presents a series of experimental and anatomical investigations upon which his surgical deductions are based. The author divides manual infections into a number of classes, depending on the nature of the infection and the result which it produces. The acute forms may be classified under simple localized processes and graver infections, including tenosynovitis and fascial space abscesses, acute lymphangitis, and their complications and sequellæ. Kanavel's scheme of treatment is based on the differential diagnosis, even where the graver types are present, for, although all three varieties may develop in a single case, yet only one type will usually be found. If they are combined the symptoms and signs of each are present and each will demand a separate and distinctive form of treatment, for, in opening a synovial sheath infection, we do not by any means drain the fascial spaces or vice versa. Again, unless a clear understanding is had of fascial space infection, and ordinarily we do not determine whether or not it is present in an acute tenosynovitis, we might so make our incision in the synovial sheath that the fascial spaces would become infected unnecessarily, and in a patient who depends upon his hands for his livelihood such an error becomes criminal carelessness. Again, while the lymphangitis may become a tenosynovitis or a fascial space infection, in a great majority of cases it remains a clinical and pathological entity and the mistake frequently made of assuming this relationship and treating it accordingly has been responsible for grave errors and consequences. The author claims that the differentiation of these types can usually be made and depends on a clear understanding of the basic principles of inflammation produced by the various bacteria, coupled with a knowledge of the anatomical relations peculiar to the hand, and a study of the course any given infection will normally pursue. This in brief is the basis upon which the book is written and the author presents the results of a large number of personal experiments to demonstrate his views. A great deal of this matter is new, but it confirms the claims of other investigators. The illustrations, whether original or borrowed, are carefully chosen and aid greatly in the proper understanding of the text. The book is a very interesting one and gives evidence of thorough and painstaking study, such as is not often met with in American surgical text-books. It will bear careful examination, and the author is to be complimented on the clear and satisfactory manner in which he has presented the subject.

LEITFADEN DER ELEKTRODIAGNOSTIK UND ELEKTROTHERAPIE FÜR PRAKTIKER UND STUDIERENDE. Von Dr. TOBY COHN, Nervenarzt in Berlin. Vierte, vollständig umgearbeitete und vermehrte Auflage. Price 6.60 marks. Berlin: Verlag von S. Karger, 1912.

Dr. TOBY COHN is well known to many American physicians as a teacher of electrodiagnosis and electrotherapy especially in their applications to nervous diseases. His handbook on the subject has enjoyed much popularity, the continuance of which is well deserved by it in its new edition. It is singularly simply and clearly written and is well illustrated; especially praiseworthy in the latter respect are several charts covered with transparencies giving the anatomy of the various motor points of the muscles. The new edition of the book has been made complete by the inclusion of a chapter on d'Arsonval and Tesla currents, on sinusoidal current, etc. It is heartily recommended to readers in search of a guide in the German language of electricity as applied to medicine.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held April 4, 1912.

THE VICE-PRESIDENT, DR. GLENTWORTH R. BUTLER, IN THE CHAIR.

THIS meeting was held under the auspices of the Section on Neurology and Psychiatry, and the subject for the evening was "Psychanalysis."

The Fundamentals of the Freudian Psychology.—Dr. WILLIAM A. WHITE, Superintendent of the Government Hospital for the Insane, Washington, D. C., said that in the great storm of criticism which had been aroused by the Freudian hypothesis it had seemed that there had been very little tendency to endeavor to separate the fundamental from the incidental, and that much of the criticism which had been addressed against the incidental had by implication been supposed to apply to the fundamental. It seemed to him fallacious to look upon the principles of so-called Freudianism as if they had their origin and growth and development in Freud himself. To his mind the most valuable asset of the Freudian psychology to the present-day problems of the mind was the mechanistic and rationalistic viewpoint which they gave to these problems. The psychoses and the neuroses no one longer considered to be something mysterious that came from the nowhere and settled down like an incubus on the patient. It was universally recognized that these varieties of disorders grew out of the material of which the patient's mind was composed, and that for their understanding and for the application of remedial agents the particular psychosis or neurosis must be fathomed. Freud had given them a method of psychanalysis by which they were able to delve into the intricacies of the patient's mental tangles and come to a reasonable knowledge of how their disorder had been built up. The great fundamental thing that Freud had done was to give them a rationalistic viewpoint for the psychoses and neuroses and a method which enabled them to better understand their patients. Freud had described certain processes of repression and of sublimation, and such mechanisms as those of condensation and decomposition, over-determination, and displacement. They were the mechanisms of every-day life. It was the sexual material of the Freudian psychology which had brought down all the volume of acrimonious denunciation. Freud's explanation of the development of the sex instinct was the best piece of literature on that subject extant. It was a wonderful analysis and interpretation of the facts of sexual life. The Freudians believed in the very great importance of the sexual as a factor in the psychoses and neuroses and they explained this great importance by the equal importance which the sexual played in the mental life of every individual. They believed that there was no other one factor in mental life that was so dominating, no other one factor that had associated with it such tremendous emotional values, that it predominated even over the instinct of self-preservation. It was because, therefore, of the tremendous importance of the sex factor in life that it was found at the basis of the neuroses and psychoses. Dr. White called attention to this analogy. If they were not sexual beings, if reproduction were not the fundamental goal of the individual life, and if something else were that goal, if something else played as important a part in the life of the individual as the Freudians believed that the sexual now played, then would not the processes of mechanisms of the Freudian psychology still be true, and would not the only differences in the picture of the psychoses and neuroses be differences in content? He thought this distinction between process and content was of the very greatest importance in attempting to evaluate the contributions Freud had made to modern psychology. The main discussion arose about the relation of the sexual in its various ramifications and it behooved the scientific man to bring out his material which he desired to contribute in a judicial attitude of mind and with a full realization of the fact that the truth could not be evil.

Sex Issues from the Freudian Standpoint.—Dr. JAMES J. PUTNAM of Harvard University said that sex issues of one or another sort lay at the very heart of the emotional life; this was a fact that every child knew. One need not, and could not, go so far as to maintain that the complex mental state that one called love, which Dante averred to be, when normally developed, at the root of all that was good and, when abnormally developed, of all that was bad, was wholly describable in sex terms. But one could with confidence maintain that it was impossible to give form and color to the philosophical conception of the office of love; that was, one could not show how and why this sentiment was at the root of happiness and misery, of courage, cunning, crime, war and conquest, poetry and romance, of the home and the community, of civilization itself, without using sex terms on a large scale. The question at stake was not as to whether the consideration of sex issues was important as a preparation for a study of the psychoneuroses, but solely as to how these issues could most profitably be studied, whether the particular way in which Professor Freud and his colleagues had approached this problem was a good way. A rigidly scientific attitude was an absolutely essential prerequisite for anything like a fair discussion of sex problems. One must be able to look squarely and without loathing at the facts, or one must say farewell to honest judgment. The details of that portion of one's life which had to do directly or indirectly with the function of reproduction were usually guarded, either as something too sacred or too unpleasant to be talked about. Persons whose interests were most at stake, namely, the neuropathic patients, must inevitably pass through a period of self-humiliation if they consented to lift the veil from their own memories or to study the psychological mysteries of their own childhood. The arrogant attitude of social prejudice should not be tolerated by scientific men. Either everything that related to the function of reproducion was wrong, and the reproductive act was in itself disgraceful, and the sexual relation of marriage a sensual self-indulgence to be tolerated only as an unavoidable necessity, or else, on the other hand, everything that related to this great function was worthy of the broadest, the frankest, and the closest study. Self-reproduction was indeed a law of life. Childhood was a fatherhood with reference to manhood, and the large minded, energetic, breathing man should not fail to recognize, in the day of his full development, that his qualities owed their origin, in part, to the working out of the sex instinct which, to be conceived truly, should be conceived broadly. It was obvious that in discussing human nature in this way they had to deal with many traits that seemed wholly, or mainly, without relation to the sex function. The men and women who were nervous were usually, at the time of their obvious breakdown, leading complex and highly respectable social lives. Why then classify their traits as sexual? The point was this: In infancy and early childhood there was, during a period before clear thought began and verbal language was habitually used, a time when, in a scientific sense, every child was an egoist and a sensualist, occupying himself in dealing with a body of sensations, some of which he found strangely pleasurable and longed to reproduce. It was fair to say that the unfavorable judgments of the majority of Freud's critics had been based on the unpleasant impression made by descriptions of the sexual experiences of men's childhood, which seemed unnecessarily lurid and to be exploited in unnecessary number. The best definition of the psychoneurotic of almost every type was that he was virtually a child, that was, he was an individual playing a child's game with the weapons of a man. Freud had never asserted that abnormalities of sex were the sole basis, the final, underlying cause, of the psychoneuroses. Freud's chosen problem was solely to consider in what aspect or department of the life of experience, beginning with birth, the actions of the real underlying causes, whatever those might be, found themselves most strongly expressed, most strongly accentuated, best illustrated and brought most effectively into coordination with the rest of the drama of experimental life. Why was it that the sex life and sex instincts, the philosophical, the biological, the social, the historical, the medical, seemed to be of such enormous significance? It was perhaps because self-reproduction was the great law of life. This law was of such vast significance that it at once included and went beyond the principle of desire, or of pleasure and pain, as the basis of conduct. Desire undoubtedly underlay not only envy and jealousy, but also fear and depression.

Hysterical Dreamy States, Their Psychological Mechanism.—Dr. A. A. BRILL read this paper. He said that the hysterical dreamy states that he was about to discuss were not the protracted crepuscular episodes followed by partial or complete amnesia which were described by Ganser and others and which were often taken as psychic equivalents of motor epilepsy, but they represented those peculiar conditions so often observed in psychoneurotics which were first described by Lowenfeld and later by Abraham. They showed the following fairly well defined stages: First, there was a stage of fantastic exaltation the content of which dealt with the individual's hopes

and aspirations. This was followed by a stage of dream-like withdrawal from reality. This second stage was followed by a very rapid third stage which was distinguished by a suspension of consciousness, an absent-mindedness, during which there were no thoughts, so to speak, and the whole episode was followed by depression followed by anxiety with its concomitant manifestations. Almost all the cases observed by the writer showed these three stages, but he wished to add that the first stage was usually preceded by a period of craving. He cited the case of a patient at the Vanderbilt Clinic who was a weaver by trade and who complained that for months he was hardly able to attend to his work, which required concentration of attention, as a great deal of counting had to be done. His "foolish thoughts," as he called them, absorbed his mind to such an extent that he forgot his work and stopped weaving until aroused. As an example he gave the experience of the previous day, when he unconsciously began to think what he would do if he had two thousand dollars. He would start a shop and earn a lot of money by oppressing his employees. With this money he would open a big factory and employ a lot of greenhorns whom he would force to work long hours for little pay. He further enlarged his business and had hundreds of people working for him; he became greater and greater. Suddenly he found himself crying because he had lost all his money in Wall Street. Again he married a very nice girl who loved him but was afraid of him. He was very tyrannical and brutal. She cried and told him not to kill her, but he paid no attention to her and became more and more excited. He scarcely knew what he did, when suddenly he woke up wringing his hands and crying because she was dead. All of this patient's day dreams were of this same nature; they dealt with wealth and murder. Recalling Freud's saying that the contented individual did not indulge in fantasies, he assumed that these dreamy states represented some of the patient's wishes. It could not be said that this dream was really a realization of his wishes, as the money thus rapidly gained was as rapidly lost, leaving the patient unhappier than he was. It might also be asked why these dreamy states came in attacks and why they were accompanied by complete oblivion to external impressions, and why the patient perceived them as unreal and strange. When they came to the second dream they could no longer think of any wish realization, for the patient was single and was very much in love with his fiancée, whom he wished to marry. From a study of dreams they learned that every dream contained the hidden fulfilment of a repressed wish which usually referred to the two great impulses, hunger and love. Freud had shown that certain episodic manifestations of hysteria were simply substitutive gratifications for abandoned masturbation, and Abraham maintained that the same was true for the hysterical dreamy state. While he had not been able to make a complete analysis of this patient, still the facts that he had obtained were sufficient to confirm the assumption that his dreamy states were substitution for his masturbation. He had been given to sexual indulgence and excessive masturbation until he fell in love, when he determined to abandon these practices. The sadistic day dreams came on after a few weeks of hard struggle. The writer thought they were justified in saying that there was a direct relationship between the suppressed sexual activities and his fantastic day dreams, and he drew an analogy between the three stages of the dreams and the act of masturbation. The author also cited another case in which he thought it was evident that the day dreams were a substitute for abandoned masturbation. He said that in the study of the psychosexual constitution of the individual we found that it was made up of many component parts and partial impulses which ran through a definite evolution. These impulses were active in infancy, but normally they were gradually repressed, leaving only slight traces of their former existence. He had thoroughly discussed this question in "Freud's Theory of Compulsion Neurosis" (*American Medicine*, December, 1911), and wished here to refer only to exhibitionism and cruelty. It was well known that children, unlike adults, liked to show themselves naked; they liked to exhibit. Shame was a matter of training. Cruelty in their sense of the term was common to childhood. That exhibitionism and cruelty were closely related to sex was scarcely necessary to mention. Freud had shown that when these impulses were repressed they formed certain reactions like modesty and sympathy, but as no impulse was entirely suspended one could always find some trace of it in the individual's character. If for some reason these impulses could not be suppressed, or when later in life there was a failure of repression, the individual remained a sexual exhibitionist or a sadist, or he suffered from a neurosis in which these impulses came to the surface in some negative form. The author concluded that this type of day dream was simply a substitution for abandoned masturbation, and an unrequited libido seeking an outlet invested those thoughts which were in some way connected with the individual's hopes and strivings. These dreams looked quite innocent at first sight, but on closer investigation it became very evident that they represented the repressed wishes of the person's psychosexual life, and thus constituted a concealed form of masturbation.

The Application of Psychanalysis to Insanity.—Dr. C. MACFIE CAMPBELL of Bloomingdale Hospital read this paper. He said that the application of psychanalysis to insanity meant the study of the disordered conduct of each patient not only in relation to his clearly conscious ideas and purposeful acts of volition, but in the light of the subtle underlying forces which were apt to influence mood and thought and activity without the individual being clearly conscious of the process. This method had thrown a flood of light on individual symptoms, and had made intelligible episodes and processes which previously meant little or nothing and which had only a certain descriptive interest. Delusions and hallucinations could no longer be considered as merely a ghostly ballet flitting across the stage of the disordered mind without any relation to the moving forces of the individual's personality. In the psychanalytic study of a case of insanity they endeavored to work out the complex determination of the individual forces, to estimate the natural immunity of the individual, *i. e.* his constitutional traits and reactions. They studied the factors which increased or diminished the resistance of the individual, *i.e.*, the influence of environment and of education in its widest sense, including all cultural influences, and finally they endeavored to understand the circumstances in relation to which the psychosis developed at the special time. The aim was to study the psychosis as the definite resultant of forces which could be appreciated, if not definitely measured, and thus to see in the mental disorder a further example of pathological biological principles. The writer related the history of several cases to illustrate these general principles. In conclusion he stated that no psychanalytic doctrines could be presented in tabloid form, that they could only hope to reach common ground in the course of long and frank discussion on the basis of a rich case material with detailed observation. He had not attempted to show that any mental disorders were fully disposed of, even after psychanalytic study. In the complex reaction of organism to environment there were many levels at which the phenomena could be studied; human conduct had to be considered as a sort of hierarchy of functions and even the most ethereal life was a plant the roots of which were deeply sunk in the material world. While in parasyphilitic dementia and some other conditions, the process could be sufficiently worked out for practical purposes at the elementary level of toxins and tissue reaction; in many disorders such categories were quite inadequate and they had to take into consideration the higher categories involved in the term conduct. Psychanalysis was no key to the psychosis, but it was a ferment whose influence could not be overestimated. It met with much opposition for much the same reason that Carlyle opposed the doctrine of evolution, namely, because he felt that it stripped life of its value. Men had learned to reconcile the doctrine of evolution with those conceptions which gave value to life, and the psychanalytic studies had reached down deeply to the roots of human life, but the practical gardener need not lose his appreciation of the beautiful. They could get over this attitude and in all sincerity and humility be willing to accept whatever facts their observation brought before them.

What Is Psychanalysis?—Dr. E. W. SCRIPTURE presented this paper. He first related an experiment that Dr. Jung made in which he fixed the guilt in the case of a young man suspected of stealing money by subjecting him to the following test: A set of words was prepared, including a number referring to the suspicious circumstances. These were mixed with about twice the number of indifferent words, the total being one hundred. The young man was instructed that when a word was called out he was to respond as quickly as possible with the first thing he thought of. The time was measured with a stop watch. After first going through the list once the words were again called off and the patient was to repeat the same word as before; if he could not recollect he was to give the first thought that came to him. The average time of response was two seconds. They noticed that the word "give" brought forth the word "steal."

This was unusual and suspicious; moreover, the time was lengthened. After some indifferent results the word "burglar" brought forth the word "thief," natural in an ordinary time, but there was evidently much disturbance aroused by the thought so that the patient could not associate at all with the common word "cook." Later the word "thief" brought forth the word "burglar" after the immensely long time of 4.6 seconds. The disturbance was so great that the patient forgot what he associated. The result of the one hundred associations was so convincing that Dr. Jung at once accused the patient of being a thief and finally the patient broke into tears and confessed. Experience had shown that whenever a word touched upon some topic in regard to which the patient was sensitive the records showed one or more or all of five different characteristics, namely: The time of response was lengthened; the first response was forgotten in the memory test; the association was likely to be superficial or trivial; there might be no association at all; or the disturbance was likely to last over the next one or more experiments. In the preceding case the disturbing events were known to and realized by the person himself, but the method was just as readily applied to cases where the person did not realize his condition. A more remarkable characteristic of the association test was that the disturbance might occur when the test word touched upon topics that had troubled the individual seriously in the past, but that had been so suppressed as to have been forgotten. The results thus enabled one to draw definite conclusions as to what they were and to get at the actual cause of the hysterical condition. Dr. Scripture also related experiments which had led to the conclusion that an idea which had not entered into the subject's full consciousness could be associated to an idea in consciousness, and could serve to reproduce it on a future occasion. He also showed that the intermediate idea in many cases did not remain completely unconscious, but appeared in a following association. In infancy they acted according to their impulses, but they were trained to suppress them more and more. During sleep, regulations and suppressions were relaxed to some degree and the suppressed impulses had a better opportunity to present themselves as dreams. Dreams were representations of suppressed impulses. The dreams of children and many dreams of adults were frankly sexual, but their suppression was usually so vigorous that one's natural desires were not permitted to express themselves even in dreams; there was, however, a way out. If the suppressed desires could so disguise themselves that they did not shock us, they could often succeed in presenting themselves to us. This was the origin of symbolism in dreams. The habit of symbolism being once established in dreams it was applied constantly, and often quite unnecessarily. The impulses which sought to express themselves through this symbol were always of two kinds, namely, wishes or fears. Dreams represented the working out of unfinished problems. Psychanalysis was a group of methods used for analyzing the human mind, particularly those portions of it which were not directly conscious. It was quite analogous to the work of dissecting and to the microscopic study of the body. It was careful, cautious, and exact, and was a worthy complement to the scientifically accurate anatomical and physiological neurology of the present day.

Dr. M. Allen Starr said that the conception of the process was the fundamental point. He had occasion some years ago to be thrown in contact with Freud in his laboratory. He warned against the physicians of America accepting entirely a theory which probably depended for its existence largely on the environment of the man who had originated it. Vienna was not a moral city and the people he was thrown with were frivolous and obscene. They were concerned largely with conditions which pertained to sexual affairs, yet Freud was living in a congenial atmosphere. One should always look at the environment of the individual and his character and before considering Freud's hypothesis as being a true hypothesis in connection with psychanalysis one should question whether Freud had not misrepresented conditions, and turned into a frivolous vein the really new science of psychanalysis by which neurologists were enabled to study mental processes as exactly and mathematically as they had previously been able to study the human body by the use of the microscope and the scalpel. There were many other influences which gave rise to complex psychoses besides the sex instinct. Personally Dr. Starr had no regard for Freud or for his theory. He did not believe that so much credit should be given him for what he had done. While he was in Vienna the sexual life and conditions pertaining to it were of prominent interest. In America, on the other hand, there were many other things which gave rise to complications, motives and facts; there was more interest here in financial and social affairs than in sexual affairs. "An ounce of Muldoon was worth a ton of Freud."

Dr. August Hoch believed that what Freud brought out would stand the test of time. Freud showed the importance of a consideration of the emotions and their mechanisms and he brought out the great importance of education and what belonged to it. Psychologists had found many things of value in psychanalysis, yet there were many things that could not be, or had not been explained. The physiological side of the question, about which they knew very little, should be taken up. Psychology had been greatly benefited by psychanalysis and this was a subject that should be taken up seriously.

Dr. Smith Ely Jelliffe asked what Freud had given us—merely an hypothesis, something to dig with, a tool to help us to find out something? There was a psychodeterminism. In going on with our subject there were two things to be borne in mind—race-preservation and self-protection, and these were the two instincts which made up the stuff that built practically everything men did.

Dr. James J. Walsh said that the subject under discussion should be looked at from an historical standpoint and he referred to what had occurred in the past—hypnotism, mesmerism, electricity with the Leyden jar for the cure particularly of headaches, etc. Was psychanalysis to be placed in the same category as these?

Dr. William A. White said that psychanalysis should not be taken up by asking patients about sex matters, for this was not the leading thing; it was an explanation and not an interpretation by the patients. As to whether psychanalysis would really help the insane, he could not answer this question because he did not know what was meant by the insane.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held March 28, 1912.

Dr. F. A. Dorman in the Chair.

Ovarian Dermoid Lying in the Right False Pelvis with Intrauterine Pregnancy.—Dr. A. Ernest Gallant reported this case. The patient, a nullipara, 37 years of age, had been referred to him on December 4, 1911. Her last menstruation had occurred on September 4. She gave a history of "trouble on the right side" eleven years ago and of peritonitis seven years ago. Examination revealed a large kidney-shaped mass in the right iliac fossa. It had been palpable for the past two weeks and the patient thought it varied in size. Owing to the fact that the right kidney was prolapsed and palpable above the other mass it was thought that the tumor must be either a misplaced pyosalpinx or an ovarian cystoma. In order to cause as little disturbance as possible to the fetus an early operation was advised. At operation a cystic mass was found bound down by very tough bands extending in every direction and difficult to displace. During the operation the cyst ruptured and about three ounces of a fatty substance escaped. The sac was filled with hair and sebaceous matter. The tumor measured three by three inches and was kidney shaped. The patient made a good recovery and the pregnancy went to term without incident.

Dermoid Ovarian Cyst.—Dr. A. Ernest Gallant reported this case. The patient was a nullipara, 23 years of age, who had suffered for over a year with right-sided pelvic pain. Examination showed the cervix anteflexed and the fundus twisted to the left and fixed by a tumor the size of an orange which filled the right cul-de-sac. The cervix was dilated and a rubber drain sutured into it. The peritoneal cavity was entered through the left rectus sheath and the omentum was found adherent to the parietal peritoneum. The bladder, uterus, and whole pelvis was held by bands many of which had to be cut or forcibly torn in order to free the prolapsed adherent left ovary. The right ovary and tube were elevated, the latter ruptured and considerable cheesy matter escaped. These were removed and the broad ligament was sutured *en masse*. The appendix was also taken away. After a stormy convalescence the patient recovered.

Ruptured Ectopic Pregnancy with Mushroom Blood-clot Attached to the Fundus Uteri by a Small Pedicle.—Dr. A. Ernest Gallant reported this case which he had seen for the first time on February 7, 1912. The patient was 31 years of age and had been married 12 years. She had borne one child and menstruation had been normal until January when it was less than usual. She had had some vaginal discharge for three months when on February

3 she was seized with cramps, air hunger, and collapse, falling to the floor and remaining unconscious for some time. The cramps continued until February 7 with diminishing evidences of shock. Examination showed the abdomen distended and tense; it contained fluid with a central tympanitic area. A firm nodular mass was felt midway between the umbilicus and the pubes and extending across the hypogastrium. This mass was about the consistency of fibroids. The right side of the pelvis was filled by a boggy mass and the uterus could not be defined. The large tumor was freely movable and ballottement was easily solicited on the left side. A diagnosis of ruptured ectopic or rupture of the stomach with fibroid uterus was made. On opening the abdomen on the following day about three pints of bloody fluid escaped. There were no clots and no adhesions in any part of the abdomen except at the left extremity of the tumor where the omentum was adherent to a very slender pedicle four inches long. The large mass was firmly attached to the fundus uteri by a very strong tough base about three quarters of an inch in diameter and in freeing it a small portion of the uterine tissue was cut away. This area was very vascular and was closed by continuous catgut sutures. There was a mass of tissue in the left cul-de-sac not unlike exudate which with the ovary was lifted out. The right tube was tortuous and contained a small amount of clear fluid; the left tube seemed normal. The patient made a good recovery and returned to her home twelve days after the operation. The specimen presented was made up of numerous blood sacs some of which had ruptured during removal and the bulk of the mass of blood fibrin had clotted in a most extraordinary way. The base showed the small portion of the uterine tissue cut away and a sort of cavity in which the fundus was imbedded before removal. On the left extremity was a sac which resembled a fetal shell, though no sign of a fetus was discovered.

Dr. F. A. Dorman said he had seen a number of ovarian dermoids which complicated pregnancy and, on several occasions, operation was not necessitated because of a loosening up on the pedicle which permitted the child to be born without interference. In one particular case he was positive that he had to deal with a double ovarian dermoid; he felt confident of this because of the characteristic conditions noted, i. e., the ridges of cartilaginous tissue. He could recall three cases at least where he was convinced by both observation and touch that he was dealing with a double ovarian dermoid. He dreaded the effect of the rupture of contents of the dermoids because they were so prone to produce a peritonitis. He was convinced that this material would lend itself to the favoring of the growth of germs and greatly enhance suppuration in the peritoneal cavity.

Dr. S. W. Bandler said that it was generally considered that the contents of a dermoid cyst were very infectious and that it was rather a disagreeable complication to have the contents of such a cyst poured into the peritoneal cavity. It was hard to understand how the contents could contain bacteria, but it seemed probable that the cheesy matter produced additional annoyance by chemical irritation and it was a foreign substance difficult of absorption. Dr. Bandler reported the case of a girl 10 years of age upon whom he had recently operated where the abdominal tumor was the largest he had ever seen in a young person. The cyst extended on the right side almost to the liver and on the left side almost to the umbilicus. It proved to be a multilocular cystadenoma. Many of the sacs were opened before the tumor could be removed. After a number of sacs were removed, deep in the center of the tumor was found a sac containing cheesy matter, hair, and bones. Had a careful examination not been made the dermoid character of the tumor would have escaped notice.

Case of Toxemia of Pregnancy, with Acute Yellow Atrophy of the Liver.—Dr. H. G. Stearns reported this case in which the predominating characteristics were vomiting and icterus and postmortem focal degenerative areas in the liver. The patient was 24 years of age and had had one previous pregnancy five years ago, about which nothing definite could be learned. Her last menstruation had occurred in October, 1911, and vomiting associated with pain in the epigastrium began about December 10. When first seen on January 10, 1912, she was slightly emaciated and distinctly jaundiced. The temperature was normal, respirations 28 and pulse 136, small, but perfectly regular. She was placed on nutrient enemata and the necessary amount of fluid furnished by a Murphy drip. At the end of a week the pulse had improved in quality and dropped to 120. Feeding by the mouth was started carefully with peptonized milk and albumen water. The quantity given by the mouth was from seven to fourteen ounces in twenty-four hours. On January 20 the urine suddenly fell to ten ounces in twenty-four hours; there were no albumin and no casts. This was brought back to thirty ounces promptly by increasing the fluids per rectum. Vomiting now became uncontrollable and, although the pulse was ranging about 100, it was decided after consultation to produce an abortion. It was believed that the strength of the patient was sufficient for the usual methods without subjecting the patient to an anesthetic and a rapid emptying of the uterus. The usual means failed, however, to elicit the faintest sign of uterine contraction, and early on the morning of February 2 she died rather unexpectedly. The interest centered particularly about the pathological condition in the liver. Microscopical examination showed an advanced stage of focal degenerative areas which were strictly limited to the central lobules in the immediate vicinity of the central vein. There was no increase of connective tissue outside the areas of necrosis. The capillaries were moderately distended and there was quite an advanced disintegration of the endothelial lining. Many of the endothelial cells were free in the capillary spaces, some being actively phagocytic, containing bodies of disintegrated cells, some red, some white, and some granular detritus. The areas of focal necrosis were of irregular size, some microscopical ones taking up only part of the field under the oil immersion lens; others were so large that they took up half or three-quarters of a lobule. In these necrotic areas the continuity of the liver cells in their normal relations was entirely lost and replaced by a granular detritus composed of dead vacuolated liver cells, the majority of which contained sharp golden brown spicula. Many liver cells were devoid of nuclei and showed advanced stages of acute degeneration. The cells in the peripheral parts of these focal areas of necrosis showed advanced swelling, with eccentric nuclear arrangement. Many of these cells contained a brownish-black pigment not unlike bile. The liver tissue in the peripheral parts of the lobules seemed to be fairly normal. The central vein in many of the areas of focal necrosis seemed to be entirely obliterated, not only by a granular swelling, but by advancing pressure in the surrounding necrotic zones. The sections from this liver showed but one phase of the acute degenerations of the liver which had been described as occurring in the various toxemias of pregnancy, in deaths at different times during the stages of the disease. It therefore belonged to and was a very representative type of an acute atrophic degeneration of the liver not unlike those that had been described as acute yellow atrophy of the liver from various causes, both exogenous and endogenous.

A Case of Toxemia of Early Pregnancy, with Unusual Hemorrhagic Manifestations.—Dr. Harry Mayham Keator reported this case. The patient was 27 years of age and gave a family history that was negative so far as tuberculosis, cancer, hemophilia, or anemic tendencies were concerned. As a child she had been poorly nourished and not very strong. At the age of thirteen she was healthy and had no illness during school life. Just before her first menstruation she had had nose-bleed. She was married at the age of 27 and two months later had a prolonged period accompanied by dizziness and shortness of breath. The following month the period was accompanied by much pain. A month later she skipped a period and began to suffer from nausea and vomiting. The writer had first seen her about two and one-half months after this lost period. At this time her vomiting had become very severe and responded to no form of treatment or suggestion. She was anemic and jaundiced and had occasional nose-bleeds and blood-tinged sputum. Her heart was active with a weak, hemic murmur. Her lungs were normal but both liver and spleen were palpable. Vaginal examination showed a soft cervix and a uterus enlarged to the size of a three months' pregnancy. The uterus seemed to be easily lifted and the patient was placed in the knee-chest position for a few minutes daily in the hope that the change in the position of the uterus might influence the vomiting. Rectal feeding was begun but during the succeeding five days the patient became much worse. There was no cessation of the vomiting and the nose bled frequently. The urine showed a trace of albumin and occasional hyaline casts and red blood cells. She had no temperature or vaginal discharge. Purpuric spots began to appear on her arms and legs and as her condition continued to grow worse they emptied the uterus of a three months' fetus which was apparently not viable. The following day the patient felt better but the bleeding from the nose, bloody sputum, and bloody urine persisted. On the second day an attempt to remove the vaginal packing started hemorrhage and the uterus was immediately repacked. A second attempt to remove the vaginal packing was attended with the same tendency to hemorrhage.

calcium lactate in thirty grain doses, ergot, strychnine, and whiskey were tried with no effect. The nose-bleed continued and the patient became delirious. After a specimen of her blood stood ten minutes in a test tube it showed no tendency to clot. Transfusion seemed to offer the only hope of introducing the substance into her blood that would cause clotting. Her husband, a college athlete, was the donor. The blood flowed for a half hour probably flowing twenty minutes in all during which time several interesting phenomena occurred. The donor's pulse which was 72 at the start went up to 82. The patient's pulse remained at 140. Her face and lips became flushed at first and her pulse stronger. The condition of the patient then suggested that no blood was flowing but it could be felt and removal of the canula demonstrated that the blood was flowing. The pulse became weaker and the patient looked badly. After the vein was tied off the patient went into semicoma and collapse, became pulseless and blue, and had a chill. She responded to strychnine hypodermically and whiskey per rectum. An hour later she complained of uterine pain, peristalsis became marked, and the bowels moved freely. The bladder resumed its tone and the general condition improved. There was no more nose-bleed and no more bloody sputum and the following day the vaginal packing was removed without causing bleeding. The patient's convalescence was gradual. She was kept under considerable stimulation. The chief point of interest in this case was the appearance of moderate jaundice and the tendency toward hemorrhage with the very long clotting time of the blood. With the introduction of the non-hemolytic human blood by transfusion the necessary quality was regained. Dr. Keator said that any prognosis for future pregnancies would be appreciated.

Dr. F. A. Dorman said that Dr. Stearns' case was rather a peculiar one because there was but little atrophy of the liver and the course of the disease was so chronic. He was led to hope that something might be accomplished by treatment but it was a false hope. This was a case, in his opinion, of typical acute yellow atrophy. No petechial spots appeared. Before death the patient was conscious. He thought that the report of Dr. Keator's case was of exceeding interest.

Dr. Asa B. Davis said the reading of the paper brought to his mind two interesting cases. The first patient came to the Lying-in Hospital in the fifth month of her pregnancy. She had had persistent vomiting and was very much emaciated and had a sallow greenish complexion. She was put on treatment, rest in bed, rectal feeding, hot baths, nitroglycerine, saline enemata, etc. She improved and left the hospital at the end of two weeks, after having been instructed to report in person at intervals and to let them know at once if she were not doing well. After nearly a month had passed she applied for readmission. Her condition at this time was much worse than when she was first admitted. The vomiting of large quantities of dark fluid was persistent. Treatment was begun as before to which she did not respond but vomited bright red blood and labor was induced three days after admission. Hematemesis was in check for a time but then became more frequent and in larger quantities than before. Having in mind Dr. J. E. Welch's work with human blood serum, 30 c.c. was given this patient subcutaneously immediately after a large hemorrhage from the stomach. There were no further signs of hemorrhage after the first injection although two others were given about ten hours apart. A premature child was stillborn. The patient left the hospital ten days later in good condition. The second case was seen in the early months of pregnancy and they were led to think she would get well, but she suddenly grew worse and emptying the uterus was necessitated. This did not stop the vomiting and she grew worse and worse until she was moribund. Serum was then given and a gradual improvement followed. There was no hemorrhage whatever in this case. Her husband and a number of friends donated about eight quarts of blood the serum of which was used during a period of about one week. Recovery followed in this case which had seemed absolutely hopeless.

Dr. Samuel W. Bandler reported a case that had been under his observation about four years ago. It was a well-marked case of pernicious vomiting. The patient seemed to be doing well under treatment but developed a decided jaundice and he immediately performed a vaginal cesarean section and emptied the uterus. The patient made a good recovery. In cases of nausea and pernicious vomiting of pregnancy the introduction of saline to the amount of one quart or more daily per rectum, in small amounts repeated several times a day, was the ideal form of treatment. It was remarkable how patients would improve and not lose much in weight if they were absorbing a quart or two of saline daily, even if the amount of nourishment taken was very small. Dr. Bandler thought it was rather a grave responsibility to decide when the gravid uterus should be emptied; many cases that were not doing well would eventually, with the exercise of patience, be able to take nourishment and go on to full term with very little annoyance. It was rather a hazardous thing to allow pregnancy to continue once jaundice developed in connection with pernicious vomiting. In regard to Dr. Keator's paper, he said that a great injustice had been done to the female sex by attributing so many conditions to nervousness, neurasthenia, hysteria, or to reflexes sent out from the genital tract, when, as a matter of fact, a large proportion of these cases were suffering from nothing but hyperthyroidism. Too little attention had been paid to minor degrees of hyperthyroidism. They were apt to leave out of consideration the large number of patients who suffered from gastric and nervous symptoms, with varying degrees of tachycardia and tremor, in whom there was no exophthalmia, and in many of whom there was slight if any enlargement of the thyroid gland. Dr. Bandler took the view that the secretion of the ovaries bore a decided and antagonistic relationship to the secretion of the thyroid; an over-secretion of the ovaries might over-stimulate the thyroid. On the other hand, if the ovaries failed to secrete normally and the thyroid worked well there was the relative hyperthyroidism. The relationship between the ovaries and the thyroid had been observed at puberty, during menstruation, during pregnancy, and certainly at, and after the climacterium. He asked Dr. Beebe to mention his explanation of the swelling of the thyroid during menstruation and during pregnancy, and to state why thyroid diseases were so much more prevalent among women than among men.

Dr. S. P. Beebe said there was one point of interest about the thyroid gland and that was that there was a limit to its functional capacity. During pregnancy there was but a small increase in the size of the thyroid gland and sometimes it failed to return to its normal size after pregnancy. During pregnancy there was an increased demand for oxygen and increased functional activity of other organs; this called for an increase of thyroid function. They all knew that it was possible to produce experimentally in animals at birth thyroid glands in a pathological condition. It was difficult to explain these results. A considerable percentage of the cases of Grave's disease dated their development to some definite pregnancy when the thyroid gland increased in size. At the termination of the pregnancy these symptoms became very marked and acute development followed. In cases of Grave's disease if pregnancy occurred the patients were better during the pregnancy than before; the thyroid secretion was increased and they seemed to improve. On the other hand, the process might go so far that the patient with fairly well-marked symptoms of Grave's disease showed toxic phases which demanded the administration of thyroid during pregnancy. Patients who were myxodematous were not likely to go through pregnancy; they were liable to suffer from the toxemias of pregnancy. Furthermore, the children were not likely to be strong and healthy. He cited the case of a woman who had symptoms of deficient thyroid secretion when not pregnant who became pregnant and her child died shortly after birth. There was a persistence of the thyroglossal duct. The child died as the result of infection. Two years later this patient again became pregnant and gave birth to an apparently healthy child who later developed symptoms of cretinism. She was under treatment but the symptoms continued in spite of the efforts to combat the condition. When she became pregnant for the third time she took small quantities of thyroid extract and iodine and her third child was born apparently healthy in all respects.

Dr. Bandler discussed the relation of the toxemias of pregnancy to the thyroid gland and stated that in these toxemias almost immediate relief was obtained by the administration of thyroid and he reported one instance where a girl of nineteen was brought to the hospital in convulsions at term. Her uterus was emptied but the convulsions continued. She was given thyroid gland hypodermically and immediately, within one hour, her blood pressure was lowered, her temperature reduced from 105 to 102 F., and no more convulsions occurred until two hours later. Thyroid was given again and she made a satisfactory recovery.

Dr. Beebe said he had had four other cases which behaved in the same way. The human thyroid should be administered hypodermically. There was no question but that better results were obtained by giving the thyroid from one of the same species. It was better to give a preparation not made by grinding the gland, he said, because this contained substances which were not wanted and some that were positively harmful.

SECTION ON PEDIATRICS.

Stated Meeting, Held April 11, 1912.

DR. WILLIAM SHANNON IN THE CHAIR.

A Brief Statement Concerning the Agents Causing Measles and Scarlet Fever.—Dr. WILLIAM H. PARK said that in measles the microscopic examination of the blood, tissues, and fluids of the body had revealed no microorganism which could be considered of etiological importance. Franz Mayr, in 1848, and others at about the same time, inoculated healthy children as in vaccination with a drop of blood taken by puncturing the skin of a child during the outbreak of the rash and found that measles followed. In vaccinated children who had recovered from measles no infection took place. There was no local reaction. He also produced the disease by taking nasal mucus from a case of measles and placing it upon the nasal mucous membrane of two healthy children, one showed catarrhal symptoms on the eighth and the other on the ninth day, and both showed a typical exanthema on the thirteenth day. The skin desquamation was certainly much less infectious than the blood or the secretions of the nose and throat. Numerous investigators had tried to infect monkeys with measles, but had met with only occasional success, until the recent work of Anderson and Goldberger, which was afterward confirmed by Hoktoen. They found the virus much less infectious for monkeys than for man. The blood carried the virus for a period from at least as early as the development of the rash to at least forty-eight hours afterwards. The same was true for the secretion of the nasopharynx. After that period it was not infectious for monkeys. This was in conformity with the belief of many that measles was not communicable after the temperature had fallen to normal. The virus was filterable through a Berkefeld filter, resisted desiccation for twenty-four hours, and was destroyed by heat when exposed to 55° C. for fifteen minutes. Immunity was acquired by monkeys that had passed through the disease. The complicating bronchitis, bronchopneumonia, and coryza were caused by the bacteria engrafted on the earlier slight inflammation due to the virus of measles. In regard to the infectious agent in scarlet fever the virus was as yet undetermined. It was capable of transmitting the disease in apes and possibly in the lower monkeys. Landsteiner and Levaditi had recently produced in a young orang-outang characteristic scarlet fever by the combined inoculation of the tonsils and subcutaneous tissues. They had failed to produce scarlatina in a large number of trials in lower monkeys. This was similar to their own negative experience, when a year ago they injected subcutaneously six monkeys with ten cubic centimeters of blood, each receiving blood from a different case of scarlet fever. Bernhardt and Cantacuzene thought they had succeeded in producing the disease in the lower monkeys; the former believed that he produced the disease with heart's blood, crushed tissue of lymph gland, blood, and throat exudate. In studying the virus most stress had been laid on a streptococcus or diplococcus. Mallory had suggested a protozoan. The streptococcus was probably the only organism that should be seriously considered. It was undoubtedly present in the throat in great numbers in every case of scarlet fever. It was also present to some extent in the blood of all severe cases and in that of many of the less severe type. Milk from infected cows abounded in streptococci and had caused a disease hard to differentiate from scarlet fever. Several Russian investigators believed that they had produced immunity by streptococcus vaccines. On the other hand, there was the fact that the condition of the mucous membranes in scarlet fever was extremely favorable for the development of the streptococcus. In their experience they had found that the streptococci found in scarlet fever had no distinctive characteristics separating them from those found in other infections. Koler had been unable to find streptococcus antibodies in more than 11 per cent. of scarlatinal convalescents. Landsteiner and Levaditi were able to reinfect with streptococci the tonsils in apes immune to scarlet fever. This would be difficult to understand if the streptococcus caused the disease. Most of the recent investigators who had approached the problem from the experimental side believed that the streptococcus was a secondary invader and that the scarlet fever virus, like that of measles and typhoid fever, was an unknown agent. Mallory's bodies had too little evidence in their favor to be considered as a causative agent. The inclusions which Dr. Nicoll would demonstrate were probably of interest from the diagnostic standpoint rather than the etiological.

Inclusion Bodies in the Blood of Scarlet Fever as a Means of Differential Diagnosis.—Dr. MATTHIAS NICOLL, Jr., and Dr. ANNA M. WILLIAMS presented this communication, which Dr. Nicoll read. He said that Professor Dohle of the Institute of Pathology of Kieff had reported that in thirty cases of scarlet fever blood examined by him he had found almost without exception certain inclusion bodies in the polynuclear leucocytes. These bodies had not previously been described. By various methods of staining they could be differentiated from the nuclear substance, even when they lay near it. They could not be found after the sixth day of the disease. A large number of control cases were examined and inclusion bodies were found in but three. One of these was a case of pneumonia and the author thought the specimen might have been mislabeled, and the others were cases of carcinoma in one of which the bodies were not typical, and in the other the bodies could not be distinguished from those of scarlet fever. Dr. Martin Kretchmar of the University of Strassburg reported that he had been able to confirm Dr. Dohle's work. With the purpose of testing these findings the writers of this paper had begun work. They had studied blood smears from 51 cases of scarlet fever, together with 25 control cases, with the result that 45 cases of scarlet fever showed inclusion bodies such as Dohle described, and six failed to do so. Of the negative cases one had been ill for eight days or more, two for ten days or more, one for twelve days, one for fourteen days, and one for thirty days. The great majority of positive cases had been sick for less than a week, and most of them for less than four days. In making the examinations two or three smears were taken from each case; one was stained with Manson's stain and another with Giemsa's stain over night. The inclusions were found chiefly in the polynuclear leucocytes and varied in size and shape from small coccus forms to large irregular masses one-fifth the size of a red blood corpuscle. Bacillary forms were also seen. With Manson's stain the nuclei took on a deep blue color, the cytoplasm a very faint blue, and the inclusions a tint between the two. With the Giesma stain, the inclusions took on a clear delicate blue identical with that of plastin. The nuclei colored magenta. With Manson's stain the inclusions stood out more clearly. In a fresh case of scarlet fever the bodies were found in nearly every polynuclear leucocyte. They had been unable as yet to determine how long the bodies persisted. Generally they were found during the first week at least. Of the control cases only three showed inclusions. These were a pneumonia case in a luetic patient, a case of erysipelas in an infant, and a complicated measles case in which the diagnosis was doubtful as to whether there was a complicating scarlatina or not. In order to eliminate the personal element from the investigation, the nature of the cases from which the blood was taken was not disclosed to the examiner until the findings had been jotted down. With the exceptions noted, not the slightest difficulty was experienced in picking out the cases of scarlet fever. At the present time, they thought they were justified in concluding that a blood examination in the first week of the disease would serve to differentiate scarlet fever from measles, German measles, and probably from toxic eruptions. They were not ready as yet to express any opinion as to the nature of these bodies.

Some Features of Scarlet Fever and Its Complications.—Dr. HENRY W. BERG read this paper. (See page 881.)

The Treatment of Scarlet Fever—Prophylactic, Dietetic, Medicinal, and Serum Therapy.—Dr. LOUIS FISCHER read this paper. He urged the necessity of individualizing in each and every case. He said that the principal aim of treatment should be the prevention of complications, if this was possible. Rest in bed for five or six weeks was imperative whether the case was mild or not. This supported the heart and in a large measure prevented cardiac complications and nephritis. He thought that allowing the child out of bed during the first week or ten days was responsible for many fatal complications, especially of the lungs and ears. Elimination of toxins was of the greatest importance. The toxins of scarlet fever did not favor peristalsis and therefore it was advisable to administer daily a teaspoonful of cascara elixir alone or assisted by a soap-water enema. As the toxins of scarlet fever disturbed the secretion of the kidneys, it was advisable at the very beginning of treatment to give several times daily ten to fifteen grain doses of citrate or bitartrate of potassium in addition to a little lemonade to stimulate diuresis. In septic cases active catharsis should be maintained and calomel or podophyllin should be given each day. High colonic flushings with

one drachm of inspissated oxgall added to one pint of tepid water would produce thorough intestinal cleansing. As the toxins inhibited the internal secretions, the administration of adrenalin as well as of thyroid was beneficial. In the treatment of the fever one should seek the cause; but antipyretics should not be given as they depressed the heart, masked the symptoms, and disturbed the clinical picture. If pyrexia caused delirium, hot mustard baths would allay irritability, and, if convulsions appeared, lumbar puncture should be employed to remove the intracranial pressure. The temperature should be reduced by a laxative such as citrate of magnesia, which, in addition, was a good diuretic and quenched thirst. In case of hyperpyrexia due to severe infection, rapid reduction of temperature was effected by washing the colon with one quart of tepid saline solution. The use of five per cent. formalin spray in the nasopharynx would destroy bacteria in that locality which were liable to persist and might cause reinfection. This treatment should be continued several times daily throughout the disease. The instillation of a few drops of five per cent. solution of formalin into the nostrils twice a day was useful as a prophylactic in the disease. They had found at the Willard Parker Hospital that the administration of 1,000 units of diphtheria antitoxin to every patient coming into the hospital with scarlet fever had reduced the complication of diphtheria by at least 25 per cent. If diphtheria developed an additional 5,000 units of antitoxin were given, and this was repeated if necessary. If, in a severe case of scarlet fever, the odor of necrosis was present, 5,000 units of antitoxin were given whether the Klebs-Loeffler bacilli were present or not. As loose necrotic patches and postnasal discharges were a source of danger to the Eustachian tube, it was important to wash the nasopharynx with normal saline solution morning and evening or oftener. Following such washing Dobell's solution or 20 per cent. argyrol solution would disinfect the nasal passages and in some cases prevent aural complications.

Daily examination of the middle ear should be made as otitis could thus be detected early and treated before it had extended to the mastoid cells. Excepting in rare instances, the writer was not in accord with the too prevalent idea of operating on the mastoid for ordinary mastoid tenderness. A free incision into the drum was usually sufficient to relieve the pressure of acute otitis media. The external application of a hot water bottle or a hot poultice would frequently aid in absorbing mastoiditis. The ice coil and ice bag had given no satisfaction in the writer's experience. When cervical adenitis existed careful inspection of the nasopharynx and middle ear should be made and, if these could be excluded from complication, a warm flaxseed poultice and the daily inunction of compound iodine ointment rubbed into the tissue had proved effective. This treatment applied only to hard, nonsuppurative glands. Catarrhal discharges due to the streptococcus and gonococcus demanded strict hygienic measures. In cases of multiple furunculosis due to the staphylococcus almost specific results followed the injection of an autogenous vaccine containing from 50 to 100 million bacteria. As they understood neither the etiology nor the bacteriology of the disease there was no specific serum in use today. Although Moser's antistreptococcic serum showed specific results within from twenty-four to forty-eight hours, this had not been the case with the antistreptococcic serum or with the streptolytic serum in this country. In erysipelas complicating scarlet fever the local treatment with Burrow's solution or the use of 20 per cent. aqueous ichthyol solution was good in some cases. He had also had excellent results from the application of pure alcohol, the saturated gauze being covered with oiled silk. The supersaturated solution of magnesium sulphate had been used successfully at the Willard Parker Hospital. When pertussis complicated scarlet fever large doses of codeine should be given, one-eighth to one-quarter of a grain every three hours for a child from one to two years of age. If codeine failed, sodium bromide combined with chloral hydrate might be tried. No complication of scarlet fever was more dreaded than measles because of the danger of bronchopneumonia, croup, otitis, and empyema. Exposure to cold draughts in bronchopneumonia ended fatally. Warmth and moderate temperature were well borne. Daily supervision of the urine would be a guide to the early diagnosis of acute renal congestion. Suppression of the urine demanded the application of dry cups twice daily followed by a bath at 104° F. for about two minutes, after which the patient should be wrapped in a warm bath towel covered by warm blankets. A cup of warm tea or hot lemonade would stimulate both diuresis and diaphoresis. This active treatment should be repeated every twelve hours until acute suppression subsided. Agurin, diuretin, and theocine, two to five grains for a child from three to five years of age, three times daily, might be given. The salt-free diet, so plausible in theory, had not proven useful in practice. Broncho- or lobarpneumonia complicating scarlet fever were best treated by placing the patient in a large room with plenty of fresh air, but avoiding draughts. These patients did badly when put outdoors, and roof treatment was dangerous. If empyema complicated scarlet fever paracentesis should be resorted to to relieve the purulent exudate, but the shock of operation should be avoided if possible. The heart should be carefully watched during the entire course of the disease. Myocardial insufficiency could be avoided by judicious feeding and continuous stimulation. Strychnine should be given early in the disease before the heart showed signs of weakness. Caffein sodium benzoate one-half grain was an excellent diffusible stimulant. Digitalis was dangerous. Digitoxin, also known as digalen, in five to ten drop doses, three or four times daily, would support a weak heart. The indiscriminate use of whisky as a routine measure should be condemned, as large doses irritated the kidneys. Better results could be obtained by using an injection of 10 or 20 drops of 1-1000 adrenalin solution, repeated every hour until the proper effect was noted. The temperature would be found of no help in estimating a cardiac complication. When symptoms of collapse were noted the injection of 5 to 10 drops of camphorated oil (20 per cent.) would prove beneficial and should be repeated until the effect on the heart was noted. As to diet, the fat and casein content of the food should be reduced to less than the normal patient required. The writer gave milk diluted with an equal quantity of water, sweetened whey, or fat-free milk fermented with the Bulgarian bacillus. In cases in which milk was not well borne vegetable protein in the form of split pea soup could be given, likewise fruit juices could be given with advantage. After convalescence was well established whole milk and carbohydrates in the form of steamed farina, tapioca, cornstarch puddings made with milk and sugar, but no eggs, could be given. Meat was too stimulating and should be entirely excluded from the dietary of the scarlet fever patient.

Dr. JOHN A. KOLMER, Professor of Pathology, Philadelphia Polyclinic, said that he could not add to what had been said regarding inclusion bodies except to state that all recognized the importance of such findings if they would hold good in differentiating true scarlet fever from the scarlatiniform serum rashes. These were the rashes that had given them a great deal of trouble in Philadelphia during the last year. There should be some way by which they could make a diagnosis from a clinical standpoint. His personal views in regard to the relation of the streptococcus to scarlet fever corresponded with those expressed by Dr. Park, that the streptococci were secondary invaders. There was one fact that should be recognized, and that was that the streptococcus virus produced in the blood some condition which very much favored the growth of the streptococci in the blood and organs of scarlet fever patients. The question of streptococcic immunization in the prevention of scarlet fever was worthy of special mention. If it was true that such an immunization would prevent scarlet fever then it might be contended that streptococci were the cause of the disease. Reading the literature sent out by the Russian investigators one was impressed with the value of the method, but from an experimental standpoint it was not of value. The vaccine was given three times, at intervals of one week. Experimentally a vaccine prepared and administered as they advised did not materially raise the streptococcic opsonic index of the blood. The speaker had immunized about 350 persons in Philadelphia one year ago by the Russian method; 14 of these developed rashes suggestive of scarlet fever. He thought the Russian reports should be viewed with healthy skepticism. In treating scarlet fever they had tried the use of the antistreptococcus serum. A horse was immunized with streptococci taken from scarlet fever patients. They did not know how the serum acted, but it was probably not bacteriolytic. It was most important to standardize the serum. Some cases were certainly benefited by the antistreptococcic serum while there were others that were not; neither was it possible to say which cases would and which would not be helped by the serum. If one had the serum on hand it should be given, especially to the septic cases of scarlet fever. The presence of the streptococci could not be determined in the blood by blood culture. Dripping saline into the rectum was a very valuable treatment for the severe septic cases of scarlet fever. This was also true in the treatment of

diphtheria, but, of course, it should be combined with the use of antitoxin. Dr. Kolmer said he had been interested in the rhinitis which developed in scarlet fever patients; when one sent a patient home with a running nose there was danger of a return case. They had treated 200 cases of septic rhinitis by means of bacterins; this was not designed to combat the scarlet fever virus, but was aimed against the superadded infection. There were many cases showing the presence in the nasal secretions of staphylococci, and in these cases stock bacterins would give very satisfactory results.

Dr. Henry Dwight Chapin said he wished to speak on two points: first, one feature in the diagnosis, and, second, a complication often overlooked in scarlet fever. It was not always easy to differentiate between a tonsillitis of scarlet fever and an ordinary tonsillitis. However, in real scarlet fever there were certain points that aided in making this differentiation. First, the condition of the tongue, which in the first day of the disease would be found covered with a white fur and the papillæ could be seen coming through; on the second and third day it would clear up on the tip and edges and then there would be found the typical beef tongue. Secondly, there was the punctate form of eruption which was marked over the soft palate, and this they did not get even in the most severe cases of tonsillitis. In regard to the overlooked complication, this was myocarditis, which was more common than was supposed, probably because it was not more often recognized. Even in a mild form of the disease the pulse would run up after two or three weeks, and instead of being 70 or 80 it would be 90, 100, or 120, and it would remain there. When this occurred the heart should be carefully watched and one should think of myocardial involvement. One should examine the heart very carefully and keep a record of the pulse.

Dr. Arthur Richard Braunlich did not believe there was anything very characteristic about the desquamation of scarlet fever; he had seen patients with measles desquamate as did those with scarlet fever. The majority of the cases of scarlet fever did not have a typical temperature curve; the slightest enlargement of a gland was sufficient to change the temperature curve. Very often the tongue was the most typical thing met with in scarlet fever; the typical strawberry tongue which appeared on the fourth or fifty day was present in a large percentage of the cases. In about 23 per cent. of the cases the diagnosis depended upon the punctate eruption, the temperature, and the pulse rate. As to treatment, plenty of water should be given to get the diuretic effect; if enough was given to a child twelve or fifteen years of age he could be made to pass 150 ounces of urine a day. He believed that giving plenty of water in the beginning of the disease would prevent many of the complications.

Dr. Lewis A. Sexton believed that one of the most convincing points in the differential diagnosis of scarlet fever was the vasomotor paralysis caused by pressure. This paralysis lasted for two or three seconds, when the skin again assumed its original scarlet color, to again blanch after a lapse of from five to eight seconds, after which it remained blanched for several seconds and, in some cases, where the erythema was intense it could be noted for several minutes. This condition was never found in the serum therapy rashes or scarlatiniform erythemas other than scarlet fever. A common and painful complication of scarlet fever was arthritis. In the Willard Parker Hospital this occurred in 7 per cent. of the cases. In two cases of suppurative shoulders the gonococcus was found in each. In the other cases of the series of 147 cases of arthritis the streptococcus was found. He had noticed that in the early stages of the disease the pulse rate was out of proportion with the temperature, and that a rapid pulse was among the first manifestations of the disease. The rapid pulse often persisted for several days after the temperature had reached normal. He thought that if each patient could have more individual attention with the nose and throat kept clean and swabbed out two or three times daily, with a 25 per cent. argyrol solution complications would be reduced to a marked degree. He believed the danger of infecting the ear by giving nasal irrigations had been overestimated. In the diphtheria service, where 1,558 cases were treated in 1910 and 327 cases had nasal irrigations, not a single mastoid developed. This might be due to the fact that the facilities for this form of treatment were the very best and the treatments were carried out by experts. With regard to mastoids, he believed that with free incision of the tympanum as soon as any bulging appeared and the application of the ice coil, many of these mastoids that would otherwise have gone to operation could be aborted. After the irrigations of the ear they employed equal parts of a 1-5000 solution of bichloride and 50 per cent. alcohol, putting ten drops warmed into each ear. The results from the treatment of gonococcus infection with vaccines, although there had been temporary improvement in several cases, had been ephemeral. They had had comparatively few cases of nephritis following scarlet fever. In 1910 they treated 2,302 cases and had only 55 cases of marked nephritis; but 17 per cent. of these cases showed albuminuria. In 1911 they treated 1,984 cases and had 34 cases of marked nephritis with 18 per cent. showing albuminuria. They accounted for the small number of cases of nephritis by the strict régime in diet, this being limited to milk or fluids for the first eighteen to twenty-one days, during which time the patients were kept in bed. In the treatment of nephritis they relied on eliminatives, hot packs, and hot baths. Maximum doses of nitroglycerin were given one-half hour before each pack as a vasomotor dilator to increase the diaphoresis.

Dr. Philip D. Kerrison said that he had been asked to limit his remarks to the indications for mastoid operation in cases complicating infectious diseases. In the majority of cases the operation was undertaken not so much because of the urgency of the immediate symptoms as for the purpose of preventing certain dangers, viz., those inherent in a rapidly spreading suppurative mastoiditis which might endanger the patient's life, and the truly remarkable rapidity with which the drum membrane in these cases might be destroyed. As to the indications for operating there were many conditions which made this the best course, namely, presence or absence of adenoids, the constitutional condition of the patient, the environment; so that it did not seem wise to lay down dogmatic rules for surgical intervention. This much was known, however: the so-called mastoid antrum was as large in a child as in an adult, while the mastoid cortex was comparatively very thin. Any severe suppuration of the mastoid was likely, therefore, to be followed early by mastoid edema or subperiosteal abscess. Either of these conditions usually indicated the presence of pus within the mastoid cells. Postauricular redness or swelling in these cases might be regarded as positive indications for opening the mastoid. Again, where there was a red and infiltrated drum membrane through which a copious discharge persistently flowed they were obliged to operate on the mastoid for the purpose of preventing destruction of the ear. The list of indications might be extended beginning with mastoid tenderness, sensitiveness to pressure, etc. The subject was one in which dogmatism should be avoided.

Dr. Thomas Allison Smith said he had been asked to discuss empyema following scarlet fever. During the past two years something like 6,300 cases of scarlet fever had been admitted to the Willard Parker Hospital, and among these there developed 17 cases of empyema, less than three per thousand cases. At no time during the past two years did the statistics give this complication as occurring in as many as 1 per cent. Empyema was a late complication of scarlet fever. It usually appeared in the fifth, sixth, or seventh week, and it might complicate a pneumonia or occur independently. The records showed that these cases of empyema were apt to be a part of a general septicemia. The mortality was high, not so much through the empyema *per se* as because this complication occurred in very young and very sick children. In adults and in older children satisfactory drainage of the empyema could be best accomplished by the excision of a section of one or more of the ribs. In the very young and very sick children, among whom the condition was met with in the Willard Parker Hospital, this procedure was not advisable. It seemed to him that an operation without the employment of an anesthetic was far more preferable than one which entailed great shock. Drainage was satisfactory in these children without removing sections from one or more ribs.

Dr. Joseph E. Winters said it was impossible to discuss intelligently the treatment of scarlet fever without bringing it down to the treatment of the individual case. One of the greatest authorities said that epidemics differed as much as a flea bite and the plague. One of the things for consideration in grave cases was the temperature; in the virulent cases there was high temperature, rapid pulse, delirium, vomiting, and diarrhea, and when all were present they were uncontrollable. Sometimes the high temperature was best treated by warm sponging; when this failed one should not hesitate to use cold packs. Dr. Winters reported the case of a nurse who had a temperature of 106° to 107° F. and the cold pack was used with almost magical effect. In another case the same treatment had no effect. In another case where there was wild delirium he had given one-third of a grain of morphine and one-eighth of a grain of strychnine hypodermically. This patient had a bad pulse. Within twenty-four hours the

delirium had passed away and the patient made a good recovery. Sometimes large doses of alcohol were valuable, but these should never be given except late in the disease. In the treatment of adenitis, if seen at the very inception, ice should be applied, but should not be continued for more than twenty-four hours; if after that time the adenitis continued to increase hot flaxseed poultices should be employed. If the tongue was kept clean from the very beginning of the disease one would almost never see a case of adenitis. If a child was kept in bed with proper attention to the skin, proper diet, and proper location of the bed nephritis would not develop. The best treatment for nephritis was purgation and diaphoresis, but digitalis should not be employed. Digitalis increased the distention of the afferent vessels and aggravated the pathological condition. He preferred aconite, as in other congestions.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

SURGICAL OPERATIONS. By Prof. FRIEDRICH PELS-LEUSDEN. Translated by FAXTON E. GARDNER, M.D. 726 pages; with 668 illustrations; cloth; price $7.00. Rebman Company, New York, Publishers.

TEXTBOOK OF OPHTHALMOLOGY. By Dr. PAUL ROEMER. Translated by Dr. MATTHIAS LANCKTON FOSTER. 275 pages; with 186 illustrations in the text and 13 colored plates. Vol. I; cloth; price $2.50. Rebman Company, New York, Publishers.

DIE DIAGNOSTISCHE UND PROGNOSTISCHE BEDEUTUNG DER HARNSEDIMENTE. Vol. II, No. 4. By Dr. C. POSNER. 48 pages; paper; price 1.40 M. Carl Marhold, Halle, Publisher.

FORTY-FIRST ANNUAL REPORT OF THE MANAGERS OF THE MIDDLETOWN STATE HOMEOPATHIC HOSPITAL, MIDDLETOWN, N. Y., TO THE STATE COMMISSION IN LUNACY FOR THE YEAR ENDING SEPTEMBER 30, 1911. 78 pages; paper.

FOOD FOR THE INVALID AND THE CONVALESCENT. By WINIFRED STUART GIBBS. 81 pages; cloth; price 75c. net. The Macmillan Company, New York, Publishers.

Medical Items.

Syphilitic Neuritis.—P. J. Menard states that syphilitic polyneuritis involves both the sensory and motor nerves and is characterized by a combination of motor, sensory, and trophic symptoms. It is more frequent in men than in women, is rare in children, and generally occurs between the twentieth and thirtieth years of life. It occurs generally in syphilis of a benign character, and may begin suddenly by a paralysis of the limbs, of the eye muscles, or of the face. The symptoms may also come on rather slowly, being preceded by peculiar sensations of formication, burning, tickling, and pain. In rare cases these are accompanied by fever, delirium, and weakness. Strabismus and diplopia are common symptoms. The paralysis is flaccid, the reflexes are diminished or absent, and the reaction of degeneration is present. The symptoms last for some time and disappear very slowly.—*Gazette des Hôpitaux.*

The Vaginal Cesarean Section: Technique, Results and Indications.—C. Jeannin ranks the vaginal cesarean section of Dührssen with the classical abdominal cesarean section, but with different indications. The vaginal operation cannot be made use of when the pelvis is contracted or obstructed by a tumor. It is valuable in cases of failure of the cervical tissues to dilate. It may be used in the interest of the mother in eclampsia, in the separation of the normally implanted placenta, in a rigid cervix, in cardiac troubles, and in amniotic infection. In the interest of the child it may be resorted to in prolapse of the cord, and when the mother is dead or dying. In general, it is indicated whenever rapid delivery is necessary and the cervix cannot be dilated rapidly. It is contraindicated in atresia of the vagina, very large fetus, abdominal implantation of the placenta, and previous infection. It is easy of performance and safe when the necessary rules are obeyed. It consists of opening the anterior and posterior cul-de-sacs and separating the peritoneum from the uterus up to the junction of the cervix and the fundus; the anterior and posterior lips are incised largely enough to allow of the delivery of the child by forceps or version. —*Le Progrès Médical.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended May 3, 1912:

NOTES ON THE NEUROLOGY OF VOLUNTARY MOVEMENT.

BY GEORGE VAN NESS DEARBORN, M.D., Ph.D.

CAMBRIDGE, MASS.

(From the Laboratory of Physiology of the Tufts College Medical and Dental Schools, Boston, Massachusetts.)

SYNOPSIS.

ONE of the most obvious needs in the physiology of the present time, after its years of greatly productive accumulation, is integration, synthesis, correlation. In no bodily system is this need more conspicuous than in the universal neural fabric, and if we can get to understand voluntary action we have then already learned all the rest, for it is the acme of human activity from every point of view.

I.

Lacking the two-phased power of imitation and of inhibition, plants can hardly be said to make voluntary movements. Nevertheless, in as much as plants are partly individuated, both structurally and functionally, something inheres in their vital reactions that is indistinguishable logically if not biologically from voluntary activity—most obviously if one confuse organism and environment and think of their basal unification. However interesting, the voluntary powers of plants, if we grant them at all, come not within the scope of this present argument.

On safer, or at least less polemic, grounds, we can pass to those organisms classed as animal, and we find at once in that form morphologically the simplest, Ameba, all the criteria of volition reduced to its simplest terms. If, from another point of view, we observe here, too, the essence of externally determined reflex action, this apparent opposition only makes more striking the philosophic truth (all peace to the shades of the departed Transcendentalists!) that all voluntary action is reflex and all reflexion in a total viewing voluntary, just as truly as "Aristotle Platonizes."

More immediate to our present purpose, the fact is that behavior as the sum total of an animal's manifestations of irritability is a matter continually of *wholes* and not of partial reactions. It is an ordered unification determined by deep-lying biological purpose and not by local stimuli. In the normal animal this were certainly demonstrable were demonstration expedient. Physiology has (nearly) passed the evolutionary period in which what really are complex resultants of numberless varied forces are taken for simple events. We physiologists (none too rapidly, to be sure) are giving up that sometime eagerness for detailed description that studied the isolated nerve-muscle preparation and the isolated frog's heart. We are outgrowing (slowly enough!) that kind of physiological histology, so to say, because it really is not worth while to mislead the student too often wrongly, teaching him that what is only a part of a whole is something in and for itself.

From the technical side we have the most complete sanction for thus viewing the behavior as something different from the organism of animals. The most elaborate study of elementary behavior ever made, perhaps, that of Jennings, forced its author to conclude against the local (tactic) theory of protozoan and animalcular behavior. In his own words, "The responses to stimuli are usually reactions of the organisms as wholes, brought about by some physiological change produced by the stimulus; they cannot, on account of the way in which they take place, be interpreted as due to the direct effect of stimuli on the motor organs acting more or less independently. The organism reacts as a unit, not as the sum of a number of independently reacting organisms." ("Behavior of the Lower Organisms," page 107.) Mediating the stimulus and the actual behavior reaction, be it what it may, Jennings describes "physiological states" even in animalcules: "(1) The stimulus changes the physiological state of the organism as a whole; (2) this change in physiological state induces a certain type of reaction." In the protozoan this physiological state is simple and conspicuously chemical, while in man it involves such complexes as memory and the emotions (Jennings). It is the object of this essay to specify somewhat in detail in relation to nervous pathways some of the complexes involved in the corresponding behavior of man—voluntary movement.

But one can turn readily to the animalcule itself and see all the inherent nature of voluntariness revealed in a minute's seeing. The paramecium (ciliated protozoan of any of many forms) goes about his biological business in the cubic centimeter of water and vegetal débris upon the microscope slide just as our lawyer and physician friends,

our traveling salesmen, and our scavengers go about theirs in the city streets. Busy with initiation, actuation, and inhibition, each of these, infusor as much as doctor, exemplifies anew at once the complexity and the universality of voluntary movement in adult animal organisms. This is a proposition that is outside the need of demonstration, an axiom that stays unrefuted because the only quasi-refutation so far suggested is clearly a matter of viewpoint, of interpretation, and never at all a matter of reality. On the essential facts of the matter biologists and zoologists substantially agree, or might, did they make the opportunity to try.

Now Paramecium of course lacks all vestige of nervous cell and fiber. This animal's structure and behavior is suggested here solely to remind the reader that voluntary movement is primary and not secondary; second, inherent in the body-protoplasm and not in nerve especially; third, universal in the action of animal bodies.

This last proposition, it is clear, needs explanation, and this we may offer thus: Evading the problem (because also one purely of opinion) as illustrated in Ameba, the first traces of nervous system in the animal "series," show clearly enough that all parts of the animal employ for their coordination all parts of the nervous system. In the medusoids and in the starfish, for example, there is nothing that can be classed as brain—unless indeed, it all be so classed. It is only when we come to such animals as Talitrus (the sand-hopper), Strongylus, and the familiar earthworm (Lumbricus) that we see a gathering mass of nerve tissue that by analogy with higher animals we may call a definite brain. The behavior of such animals is neither less voluntary nor more than that of the medusa or the starfish, and if these have cerebrums while those have none, biologically speaking, it is accidental, dependent on the needs of complexer sensory functions in the forward moving part of the organism. In other words (and this is the point), the animal's voluntariness inheres in its body and its behavior, and not in its "brain." Of this we may be logically sure enough on the principle of uninterrupted structural and functional continuity between animals that have "brains" and those that have none. With an assurance that seems to admit no doubt we may (may we not?) extend the argument from continuity and analogy as far "upward" as we please in the animal "scale." Finally, as the logical and structural limit, we reach ourselves, and find corroboration of our belief in a certainty of voluntary freedom that no sane man today (save as his point of view be changed!) denies. Then anthropomorphically reversing this trite argument we arrive where we began, at the voluntariness of Ameba and Paramecium. Physiologically at least the argument seems sound, and it surely is irrefutable save as one's point of view (which is unessential) be different or opposed. As introductory to a discussion of voluntary neurology the conclusion of this argument may read: *Structure and introspection both go to demonstrate that voluntary action is as complex and as universal in organisms as the organism itself and its behavior.* Reflex action, as such, may be of local determination, but voluntary movement is inherently more or less universal in its determination, and represents thus the animal's essential will as free. This seems to be a reasonable conclusion derivable from even a cursory glance at the facts and theories of the animals in which little differentiation has gone on.

A further necessary introductory remark bases itself on an homologous comparison of the physiological aspects of voluntary function with the "mental" phases of the individual's activities. Here we come upon something very general and obvious and hard to understand, namely, the continual and persistent ignoring by physiologists of that foundation fact of psychology that we may designate as fusion ("association" or integration), whose importance for neurology, despite its Herbatian exaggeration for psychology, has never been adequately acted upon.

In describing the mental process as a whole, for example, it is, of course, customary to describe it from three points of view, respectively feeling, willing, and knowing. The very first thing to be said in describing feeling, willing, and knowing, is that they are not separate parts of "mind"; you cannot say that any one portion of the stream of consciousness is knowing, or feeling, or willing. They exist only as aspects or ways of seeing, and tend merely to support each a different view of consciousness for purposes of description—analysis artificial for descriptive purposes.

Our discussion here is of the willing aspect of consciousness, the volition-phase of the mental process, and this we will consider, as briefly as is meet, from a physiological point of view. For most practical purposes we can use the word action as a synonym of willing. The idea of will, except in one particular (namely, free choice), means a little more than that of crude action, however, and more nearly the idea of doing, and it is this idea that is especially fitting for the purposes of physiology. The will is only a name, then, for the action of a body and mind under the control of a personality.

There is, then, no period of consciousness that is entirely willing, but mind is always partly feeling and partly knowing as well. In other words, the process is always made up of these three aspects and it is an artificial interpretation of the mind if we abstract any one of them, even for the purposes of description. This statement has been emphasized by repetition because it is the stigmatum, open and conspicuous almost as the day, by which most discussions of the neurology of voluntary movement prove their incompetency. In lieu of a real and complete knowledge of the brain and its myriad paths, guiding the world by their intricate connections, why do not physiologists and neurologists see that descriptive psychology on the simplest introspective basis gives the neurologist a framework and a plan the most certain of all things short of Des Cartes's famed "cogito ergo sum," and a scheme vastly more substantial and sure than the physiology of the neurons and their relationships promises to be in many busy years to come? In fine, we know for a fact certainly and without cavil, that by the well-nigh universal process of neural fusion, will is never just pure will, and no voluntary movement, therefore, actuated by any set of neuronal actions so ridiculously simple as the older physiologists would lead us to believe. In short, in the phrase of the day, the Rolandic cortex and its efferent channels have been badly "overworked."

The physiological basis of the human will lies in the neuromuscular mechanism: the muscles, epithelium, receptors, and nervous circuits in the nervous system. Thus and herein we have the main physiological basis of the will, namely, in the actions, mental and bodily, going on in the organism. Long ago, by Foster in England, the muscles were

called the "master tissues" of the body because it is by means of them alone that the individual can *do* things. Imagine, if you could, isolated nerve cells in the cortex of the brain grinding out ideas; we could well see that those ideas would be of no use to man unless they led to some sort of action, and we can have action resulting only through the intricate neuromuscular mechanism of the body. In this respect this apparatus, as the physiological basis of the will, forms the foundation, too, for everything in life worth having to the individual.

We certainly cannot know too much about so surpassingly important a mechanism. It represents the inherent humanity or personality of the individual man or woman as does nothing whatever else. A prominent reason why we do not already know really much about it is that we have underestimated its complexity and so thought it known, when in reality few realized even how formidable its problem is. Another corollary of the contented condition of mind of many physiologists is that most of them have attacked the bull wrong end first, the *terminus ad quem* rather than the *terminus a quo*—contrary to ordinary procedure in most affairs in which the simple is usually studied before the most complex. In short, and more explicitly, in the work on the theory of voluntary movement infantile behavior has been, unfortunately for the theory, almost wholly ignored, and that without apparent reason.

If neurologists have, as has been suggested, adequate sanction in the wholly certain events of consciousness for conjecture as to the concomitant "neurograms," surely they can use to the advantage of adult neurology the accumulating observations of child study, of motosensory development while relationships are still relatively simple—for is not the child, and neurologically in particular, father to the man? It seems *à priori* likely that analysis of human behavior during the first year of extrauterine life might supply us with data that would make easier of unravelment the knot of adult voluntary control; *à posteriori* the presumption seems to be corroborated. At any rate, if nothing else develops from child study in the direction of understanding voluntary movement, one thing, and that an important thing, plainly evinces itself, namely, that current doctrine of deliberate control is too complacently self-satisfied and so fails in a large measure to appreciate at once the difficulty and the extent of its obligations to the advancement of knowledge. How infinitely far away from the simple quasi-neurology of most published treatises of to-day is the intricacy of human motives! And yet how essential is it to consider inherent in every voluntary movement as its heart and core and every essence by definition of the will itself, an "imminent idea," an essential *motive*. In proportion as a movement lacks motive is it reflex and mechanical; and in proportion as it results from motive are current notions of voluntary movement absurdly inadequate. However short and shuffling, a single step towards the goal is better than much leaping in the air.

II.

At birth the outfit of the human animal is an impulsive one, because built principally out of protoplasm which has inherent in it the impulse to activity. This impulse determines action of some kind. In the second place, the efficient organism of the child at birth is inherently "reflex," the neuromuscular part of it being made up of a series of circuits and "reflexes" that includes, in the third place, a whole series of purely reflex inhibitions. The young infant has a well-defined set of these reflex inhibitions, as may immediately be seen from the phenomena of reflex attention manifested by adapted inhibitions to sensory stimuli of adequate kind. In the fourth place, the young infant at birth has a well-determined set of reflex innate desires dominated by dull pleasure and pain. In these four ways, at least, we can characterize the psychomotor outfit of the infant when he "comes into the world." We will find instances illustrating all these characteristics in the books on child study, and a moment's experimentation demonstrates them readily on the latest dear comer into our household. Such an impulsive and inhibitory reflex mechanism dominated by dull pleasure and pain contains, but latent and potential, the material out of which develops the motivated freedom which constitutes *humanity* free to do or not to do, and therein the only truly moral thing on earth, as Immanuel Kant has long since proclaimed.

About the actual stages of development of the different parts of the brain and cord in the child at birth (we are concerned in this essay only secondarily with the autonomic system) there is still much unfortunate ignorance, so difficult is the practical problem of neurohistology. Already then, however, the cerebellum is more or less complete in general, we may suppose, because it is an afferent and efferent mechanical center carrying on mechanical coordinations. Again, the reflex apparatus of the cord, etc., is at birth fairly well finished. The mechanism of reflex inhibitions is more or less completed (we know but little as to its location unless it be in the cortex) and, sometimes, it seems as if reflex recognitions were more or less possible very early in the first year. In this suspected recognition we have a strongly psychical element, and a highly developed and complex thing—reflex recognition of the nursing bottle for instance, of its mother's face, and of other things very important to the child, such especially as the power of recognizing the difference between a smile and a frown. It would be difficult to suggest the brain paths for such functions as reflex inhibition and recognition that did not involve widely separated portions of the cortex of the hemispheres, if not of the internal nuclei. However doubtful the neurology, the facts of occurrence at an early date allow, none the less, of no doubt at all. What seems especially needed is definite knowledge as to the relations of the cortex, the thalamus, and the medullary bulb at and soon after birth. When we have that we shall truly understand, it seems likely, such basally important human functions as recognition and inhibition—and not before.

A child three or four months old of course cannot make even the most simple voluntary movement. Show such an infant a big red rubber ball, and however much he wishes it, he cannot stretch out his hand to get it. He can and does, however, make general arm and leg movements, and this fact shows that there is ready communication of indefinite motor excitement through the central nervous system. It is not until the sixth or seventh month of life at least that the child begins to show capability of stretching out his hand deliberately towards an object. He cannot do it before, obviously because his "motor" neurons, the "centers," have not developed or have not interconnected, or both. The known physiological facts are corroborated by observations on infant behavior that lead us to believe

that the neuronal lack in question is largely the connection, extensive and complex, between the rind of the hemispheres and the reflex vegetative mechanism of the sympathetic, the cord and bulb, and cerebellum.

The first step in the process of the personal evolution of voluntary movement, then, is probably an actual development in the extent and in the complexification especially of the cerebral neurons; the underlying development of voluntary movement is an anatomical one: an integration of the personal neurons above with the already elaborate system of vegetative, racial, neurons below. For the purpose of making things short and technical we may call this basal process "chemotactic neuronal integration." Now, in fact, we do not know much about chemotaxis, the movement of certain cells towards or from other cells under chemical attraction. The subject has been discussed chiefly in regard to the movement of plants and of protozoa. It is, at any rate, a growth or movement of protoplasm brought about by forces we call chemical. One finds an elaborate discussion of the subject in the writings of Max Verworn, for example. Ramón y Cajal, conceded to be one of the experts of the world upon this subject, and his opinions important because he has studied things in the light of the latest methods (including osmosis, etc.), supposes that the interknitting of the neurons occurs under some form of chemical reaction. The whole tendency of physiological causation being in this same direction, and no other theory even as satisfactory, we may tentatively accept the hypothesis as the cause or method of the early correlation of the neurons underlying the evolution of the individual as a free agent. As we have already seen, the cerebellum at birth, as the mechanical means of coordination, is much more complete than the cortex of the larger brain, so that we have to think of the growth at the basis of motor development as taking place more in the large brain than in the cerebellum during the early months of extranterine development, as well as later, and indeed throughout the life of the individual. The whole tendency at present, as Hemmeter has recently pointed out, is to unify themotaxis in the nervous system with harmonic and perhaps with kolionic action at the "synapses."

Much growth at the basis of deliberate motor development takes place also, there can be little doubt, in the large internal nuclei of the hemispheres. The gross association paths, between the large grey regions in the brain probably are more or less complete at about seven years of age, but the finer neuronal development takes place in the brain undoubtedly even up to sixty years of life, or further yet. In so far as the mere weight of the brain is concerned (white matter mostly) we must recall that it is almost attained by nine or eight years of age, but the much more important development for the individual goes on long after that period. This later development is probably not represented in weight, but rather in the ever new connections of the neurons already constructed in the brain, and in the finer development and integration of those neurons. Especially do we have excellent reasons to suppose that circuits grow and integrate in the spinal cord and gradually push further and further upward and later become connected with the cortex of the brain; henceforth the process throughout is one perhaps largely of elaboration of the cortex of the brain and of the nuclei. The impulsive and reflexive circuits grow and radiate upward more and more, so that finally, by the seventh or the eighth month, it becomes possible for the infant to direct personally *new* and deliberate movements, the motives and the relations of things having now gradually clarified themselves in the unrolling dawn of the mind, considered as a means to life efficiency through memory and intricate association of the old and the new.

Another factor in the process of the development of voluntary movements in the young infant is that of a gradual conscious clarification of the "motor ideas." Here come in again the impulse to activity as well as reflex action. In fact, from the earliest stages of intrauterine life, say at four or five months, every time the infant moves at all there are sensory impulses or, to speak more accurately, afferent impulses, sent to its brain, and the brain, as we know, is the chief organ of consciousness. Gradually, in the course of weeks and of months of kicking about and of general reflex activity, these sensory impulses which are continually being sent to the brain become clearer and plainer to "the organ of consciousness," if not to the actual focussed consciousness These sensory and afferent impulses certainly become gradually clearer to his brain. It is, therefore, from a perfectly correct psychological and physiological point of view that we affirm that the sensations produced by the movement of the young infant (movements incessantly and reflexly made) gradually become connected with and associated in the conscious motor centers of the brain itself. Probably the sensations that are most conspicuous in this are those of the joints; they are all kinesthetic sensations, however, touch being only an aspect of the kinesthetic sense. These kinesthetic impressions, sensations, influences, or call them what one will, are the "motor ideas" emphasized by the late lamented James. They seem to constitute, one for each common and definite movement reflexly made, the chief psychomotor basis for the conscious development of the motives that underlie voluntary behavior considered as the sum of the deliberate movements of an individual.

This clarification of motor ideas, then, is an important factor in the development of voluntary movement. The only reason why a child of eight or nine months can deliberately extend its hand to grasp an attractive object held out to him is that he has already made a thousand more or less similar movements, the motor sensations of which have become clearer and ever better connected in the conscious motor centers of the brain; he has been, as it were, *studying these movements out* for weeks and months, and finally, we must be sure, in a conscious way.

The impulsive activity of the young infant is practice, as, later on in its life, play is practice, for the still later conduct of his bodily affairs. All the impulsive activities produce sensations, almost percepts, which fuse together in the brain, and the brain is built in such a way that the child can combine all these sensory, afferent impulses coming from its impulsive activities into concepts of movement, motor ideas. On the basis of these, after months of trial he learns to make new voluntary movements. These new deliberate actions, weak and tentative and simple, usually start with the lips, because they are the most sensitive organs of expression; next the arms come under control, and gradually the forearm and the hands. While the very essence of this new power of making a novel voluntary movement is psychologically the gradual

clarification of the motor ideas, according to first principles, these are as much physiological as psycological, for the essense of this power lies as much in the integration of the motor neurons functionally as it does in the consciousness of the kinesthetic sensations which becomes plainer and plainer and more explicit as the development proceeds.

An important aspect of this gradual clarification of motor, kinesthetic, ideas in early voluntary development is the practice and gradual deliberateness of the reflex inhibitions already mentioned above. These are properly considered to be practice restraints for the development of attention as the direction of conscious animal activity.*

Ribot long since pointed out that attention is inherently inhibitory. The only reason that we are able to direct our consciousness to any one object is of course that we can inhibit all the other things around us from disturbing that one line of attention. In the reflex inhibitions which we see so well defined and so complete at birth, we might think of the infant as having all sorts of neural practice for the development of reflex and voluntary inhibitions and thus for the coming of voluntary attention. Conspicuous sounds will stop the general movements of the infant and, in short, many sorts of evidence are at hand indicating that the reflex inhibitions are very complete in the young child. Doubtless these indeed are acting much more often in the baby than we are aware of even in our most careful observation of them. Inhibition is a repression, a negation, a restraint, and for that very reason actual definite inhibitions are not easy to detect among the activities of the young infant.

A third factor in the development of deliberate movement as a faculty in the infant, for lack of a better term we may term the desire in each case to make the particular movement. This factor, always present in the young child and much more conspicuously than in the adult, is obviously a feeling, and an inherent part of the neural complex of the infant's behavior. It is a part of the innate interest and desire to have and to do things. This desire, usually explicit enough, is especially so in so far as interest is concerned, for the things that the young child likes, it will try to get and thus desire serves as an inseparable part of the apparatus by which the infant induces himself, often with much effort at first, to make a voluntary movement. On the other hand, we often find in adults the condition known as abulia, a lack or defect of will-power of a certain kind, and of course melancholia, where there is no desire for anything and where the afflicted person seldom makes a voluntary movement that can be avoided. The incapacity of the child too young as yet to make movements deliberately obviously partakes in both of these conditions, although probably from a different cause, and more like the former than the latter. The practical point here for clinical neurology consists in the certainty that an act of will is anatomically involved with brain-paths and brain-neurons that represent the purely affective aspects of mind, for desire is neither volition nor ideation, but an elemental emotion necessary to normality of life.

A fourth factor to consider in the process of the development of voluntary movement is a practical, working knowledge of spatiality, of that which we call "space." The practical development of the concept of space in the infant's mind helps to develop its powers of voluntary movement. A child, for instance, would not reach out for the moon if it consciously realized that the moon were hundreds of thousands of miles away from its grasp. The child does things which the rational being fully informed would not attempt to do. This complex acquired sense of space is apparently one of the essential factors which help to develop the power of making voluntary movements, just as this phase of our elemental understanding of things depends for its existence in the mind on the tridimensional voluntary movements of the body. Some of the details of this interdependence will be developed later on in discussing the determinants of the adult's deliberate movements. Here it is enough to suggest how interrelated they are and that in the child probably the consciousness of space, either to actuate or to inhibit, is attentive consciousness not yet buried by habituation in the mass of oft-repeated commonplaces, controlling but unfelt, as it is found in the adult.

The last factor of the development of voluntary movement that we need here specify is that which we may designate, but too elaborately, as self-confidence, always more or less important. At first in the infant this awareness is apparently an actual definition of a clear and a concise knowledge of the power to make one particular movement.

The books detailing observations of child development* give instances that show beyond doubt that, except in movements properly classed as semi-voluntary or hereditary, this kind of cue is often necessary for the first performance of a new voluntary movement. With all the mechanism constructed and put together needful for a certain movement, still the movement may remain unperformed for lack of knowledge, certain and definite, that that particular movement is performable. It is held to be true that knowledge of the power to do certain things, however the knowledge be acquired (whether by the suggestions of some other person or by the individual's own observation or by the chance of its own movements) serves as an important factor in the inexperienced volition. This is in the direction of the development of self-confidence. We all know that if we encourage a child and tell him that he can do certain things that he is usually capable of doing those things and often of doing them well. The reason why one-half the people in the world are not great, one sometimes thinks, is because they have no reasons to suppose that they can do great things. This awareness of power to do a certain thing or to make a mere movement, in the case of the young child, is the basis of its self-confidence and persistence in its later life. Of course children vary greatly in this respect, as in others. Some children go thirteen or fourteen months or more without walking because no one has ever shown them that they can walk. A certain child may have been really learning for a long time, in that its walking apparatus was continually developing, and when the walking-awareness, so to say, came really into the mind as a definite and concrete suggestion of competency, walking was at once an accomplished process, learned without practice. This is not a really good example because walking is only a semi-voluntary movement.

It remains only to be suggested that this element determining voluntary action may be actuating or

*For a discussion of attention in this general direction see a monograph by the present writer published by the American Physical Education Association, 1911.

*See, for example, the present author's "Moto-Sensory Development," 1910, page 141.

it may be inhibitory, but that always it is a purely ideational or cognitive process involving extensive cortical areas.

Such are some of the psychoneurological conditions that attract most conspicuously the attention of the physiologist observing infantile behavior. Without a doubt, these and other determinants are lively conscious experiences (the redundancy here is for emphasis) in the active states of the young baby. There is no one not too old or too amnesic to hark far enough back, groping in the dim dawn of his memory, but what will recall that even at that late day of three or four years of age voluntary efforts were still matters of serious conscious import, although already the most frequently repeated movements had become by habituation easy and their underlying conditions, sometimes painfully conscious before, subconscious and dim to almost any extent. This is the process that goes on inevitably year by year and it marks at all stages of personal evolution the basal opposition between the reflex and the voluntary, between the mechanical and the free, between the vegetative (or racial) and the personal or human. Thus, for example, the consciousness of spatial depth in the early months impressed in the motives to voluntary action, in the naive adult is never thought of as a conditioning element of our personal willing at all (as is discussed more fully below).

It is the perhaps leading thesis of this research that voluntary movement is much more than the mechanical contraction of a functional group of cross-striated muscles originated by some twentieth-century homunculus at some definite spot in the cerebral cortex—how much more and in fact what more the foregoing relates. Deliberate or voluntary movements are the very essence of individuation, of personality. To define the parts of the nervous system that contribute to the innervation of these movements, however trite or simple, is of necessity to understand first the multivarious factors of human motives, and, second, the neural concomitant of each of these. Whoever observes any behavior that contains (as what does not?) movements expressive of human life, will see that the determining elements of motor adjustment are as numberless as the shades of thought and feeling, mediate and immediate, in the human personality. That some of these factors are what we are obliged to call "subconscious" invalidates no whit their determining influence over voluntary actions, and to fail to include in any discussion of the concerned nerve parts these various influences and their "centers" is to fail entirely to appreciate the problem's unparalleled complexity.

III.

Let us pass now to the adult conditions of voluntary movement and their neural tracts. It is likely that we may better classify the suggested elements found by their physiology (neurology) than psychologically, and it is the bodily basis of voluntary movement that we especially seek in this essay. We just now have left the conditions as they seem to be at the end of the first year after birth; let us take the factors up again more as we may suppose them to be in an average clever individual at the most efficient, that is, the middle, age. Many thousand things have happened in the voluntary motor mechanism of the average man in these forty years, but for our present purpose two of the classes of events are of particular importance. These are, on the one hand, a gradual systematization of the cortex of the hemispheres and, on the other, by the universal law of habit the anesthesis into subconsciousness of many elements of deliberate action which during infancy were probably highly conscious. We are only now beginning to realize how elaborate is the plan of the nervous system in its control over the mechanical units of action: unification, integration, functional classification and subordination carried out with an elaborateness not approached elsewhere in the world and indeed far beyond our present detailed understanding. Having said this, the present writer may seem (but is not!) inconsistent if he supposes the possibility at least that with all this seeming complexity it may turn out the simplest of arrangements after all, this being of course a hint that all our present notions about the action of the neurons may be wholly wrong! As for the relative anesthesis in adult life of nerve-processes which in infancy are of necessity in full attentive consciousness, this is neither more nor less than the process universally going on in all animals; and yet it will account apparently for much of the obvious delay in the detailing of the neurology of voluntary motion. Recent writers, as we shall see, for years have been discussing the epiphenomenal accompaniments ("imagery") of voluntary movement, whereas the true determinants representing the really controlling nervous impulses in each case are years and years before "buried" in the "subconscious," because not longer useful in focussed consciousness, being habitual and no longer new.

Let us discuss the proposed neurology of adult deliberate action under three more or less arbitrary heads which we may designate, respectively, nervous circuits, spatiality, and the grey fabric of the hemispheres.

The *nervous circuits* which underlie voluntary movement are really of course the functional framework, so to say, of all neuro-muscular-glandular activity. The idea is the modern successor of the reflex arc, the succession being made necessary by our increased knowledge of the nature and uses of kinesthesia. Here again our classification is arbitrary to some extent, but none the less useful, perhaps, for descriptive purposes, and withal tentative.

The simplest "circuit" that we have to consider is that which we may call intramuscular. The knee jerk, for example, is far too quick to be a spinal reflex, so that we have to suppose it a direct reaction from the thick subpatellar tendon of the muscle-mass concerned, a direct stimulation of the elastic muscle-fibers. It is obviously only for the sake of logical completeness that we start with this, for a literal circuit here is hard to define, and moreover useless for our present purpose.

The next type of circuit is similar to the vegetative circuits of the sympathetic system, such for example as are concerned in the movements of the intestines, by the plexuses of Meissner and of Auerbach. A third type is of a partly reflex and partly sympathetic nature, and represents those reactions that are primarily reflex and yet in part under the control of the sympathetic system. A good example of such a circuit would be found in an attack of painful cramp from distention of the gut. This would constitute for the purposes of our discussion an example of a circuit intermediate between one purely vegetative (under the entire control of the sympathetic system) and an out-and-out reflex. A fourth kind is the typical reflex, termed "epicritic." Other circuits go up to the bulb and may be termed

medullary circuits, and comprise those that have to do with respiration and heart-action and many of the other vital functions which are apparently controlled by the medulla. The next variety of circuit we may term the nuclear circuit, such as those that go up into the big neuronal masses in the interior of the brain and whose activities in part at least are of the type of emotional reactions.

Lastly, the most complex type is that properly known as the cortical circuit, and this especially is accompanied by consciousness and, more important still, is under voluntary and initiative control. It is an important circumstance that each one of the circuits mentioned includes more or less of the apparatus of all of those below it. Thus you have a series ever enlarging upward. Anything that might happen in the lowest circuit would more or less affect the higher, and anything coming from the highest would have all the other circuits more or less under voluntary control, unless prejudicial to efficiency. The highest and longest and most complex circuit, the top one only, then, properly speaking is *voluntary* in nature.

These circuits of nervous influence, as various as their unique routes through the central nervous system, are not represented, of course, by separate neurons. Again, some of them are of actuating and some inhibitory nerve impulses, some produce action while others inhibit it, in some cases not only stopping the contraction of the muscles but actually and actively relaxing them. Sherrington especially reports an experiment upon the reflexes in dogs in which active relaxation of the muscles occurred. We need to know more of this! Inhibitions in the adult have long since reduced themselves largely to the reflex type. Moreover, the inhibitory impulses by their nature are negative and have been lost sight of, so that oftentimes we do not realize that they are present at all in the adult individual. For example, the very essence of the action of alcohol upon the finer cortical centers in the brain is an inhibition (depression?) and yet, as we all too well know, the moderately intoxicated person shows signs of anything rather than that of inhibition or negation. It needs emphasis here that in general the part played by inhibition in voluntary movement, as also in attention* is preeminent. Inhibition, however, is too little known still to allow of its discussion at this time in this complex connection. The work of Nikolaïdes and Dontas (confirmed by Wooley and Fröhlich) demonstrating actual inhibitory fibers in the muscle nerves, is a recent important step along this path.

There is a classification of the nervous circuits we have mentioned other than that of actuating and inhibitory, and it is one that is of more immediate use in the theory of voluntary action, namely, their division into circuits on the one hand between the skeletal muscles and the cord and into those, on the other hand, between the grey cord and the grey fabric of the hemisphere above.

As to these former nervous impulses: Few facts more helpful to our knowledge of personal control have appeared in late years than that the muscles of the body, anatomically but not physiologically individual, are mainly coördinated in the posterior grey horns, these being subordinated in some certain directions (equilibrium, resistance-purchase, etc.) to supervision from the cerebellum. As a corollary of this, important very to our present intent, it is clear that the separate muscles have no direct representation at all in the cerebrum proper.

The truly personal control, then, of the cross-striated musculature comes through influences of the second variety just suggested namely, those between the spinal horns and the grey fabric of the hemispheres, cortical and nuclear. This control, moreover, is certainly "symbolic"; that is, a properly adapted single influence probably controls a whole movement, although in the spinal grey this may involve the coördination of very many muscles in a functional group. Moreover, this control as it comes into these muscle group centers of the cord, is a *resultant* of numerous complex factors which it is the business of the hemispheres to produce by the stress and the strain, by the thrust and the pull of the individual psychophysical conditions at the moment or constitutionally, or both. It is the resultant, apparently, that controls the grey cord's group action.

One of the most essential of the factors in the neurility of voluntary control we now all recognize as kinesthesia. We do not, of course, need to enlarge upon its nature here, for Goldscheider, von Frey, James, Bastian, and many others have made its organs and its preeminently important functions in the conduct of life common knowledge manifest to all, details, however, being added continually. These kinesthetic impressions or impulses come from the moving parts into the grey matter of the hemispheres. Take the elbow or the wrist joint, the fingers, or the shoulder joint, and consider all the scores of muscles, tendons, and bones involved, as well as the skin over these moving parts, and include also the sense of touch, and we can see what an enormous complex of kinesthetic sensations and impressions must crowd continually into the central nervous system from every part of the ever-moving body.

The familiar work of Mott and Sherrington on the afferent spinal roots in dogs was quite conclusive as to the status of these movement "sensations" or influences. It will be recalled that the efferent nerves in these experiments were left complete, the outgoing motor neurons, but the dogs none the less were quite incapable of making any efficient voluntary movements, properly speaking; Munk then took up this work of Mott and Sherrington and demonstrated that the dogs after a time could make voluntary movements, but that they had to learn to do so by the vicarious use of their eyes, these organs taking up symbolically the functions usually ascribed to kinesthesia. Experiments upon certain paralytics who lack the power to make a voluntary movement show this same fact of vicarious symbolism to be true. It is sufficient to say, in short, that the kinesthetic impulses from the moving parts of the body start, or at least direct and control the voluntary movements of the individual considered as mechanical events. Unconscious kinesthetic influences appear to direct the gross movements with the help of vision, while the conscious muscle-joint impressions control the fine adjustments by an inhibitory mechanism until they, too, have become subconscious by habituation. (Uncompleted research by the writer.) Whether we believe with Bastian or with his opponent Ferrier as to the topographical nature of the great cortex, we cannot fail to see that the circuits between the muscles and grey cord and brain and back again are at once *the framework and the substance* of the neural process in voluntary movement, the former half of the circuit

*See the monograph above cited, published by the American Physical Education Association.

in each case being kinesthesia, be the details what they may.

Our next problem concerns the coordination of these circuits of nerve influence and their control as agents of initiative and truly personal voluntary movement. This we discuss briefly in the first place under the second suggested head, *spatiality*.

The origin of the idea of space in the mind of the individual, like "space" itself, has as yet not been studied out in any detail, so that we have none too good an idea of what is neurally concerned in this matter. For a part of the origin of our idea of space we certainly have to go back in our imagination to early infancy, as indeed we have already suggested. The eyes alone probably do not give the infant a sense of depth when it is born, a fact hard, indeed, for the adult to realize, because space, time, and causality form the three basal categories of the whole adult understanding, from an empirical viewpoint. As is well recognized, there are two opposed theories in regard to the development of the idea of space in the individual. The first of these, known as the nativistic theory, supposes that the space idea is born in the child, and the second, the genetic theory, believes that the idea is developed only when (voluntary?) movements begin, and that the retinæ of the infant at first give him a knowledge of space in only two dimensions; on this supposition, all objects appear only as particolored areas, without depth.

Now, a skilful enough artist might readily succeed in painting upon a canvas curtain so exactly and so perfectly that even adults would confuse his production with tridimensional space itself; this to be sure, would be a difficult thing to do, but from at least a theoretical standpoint it would be perfectly possible. Suppose, for example, an artist were to paint a piece of canvas the height of a room and that he succeeded in such perfection of color and form that anyone would confuse the picture with the room itself; from this picture we would perhaps be able to realize what impression the newborn child has of space: no idea of depth is present, but all objects appear to him as if variously colored areas spread out in the two dimensions at right angles to his line of sight.

We must stop to recall a little how such a bidimensional notion gradually develops into a true idea of depth. The first factor of this spatial process, basal for the neurology of voluntary movement, is the kinesthetic sensations of vision. The six extrinsic muscles of each eyeball all work at once by actively relaxing or by contracting. These muscles have the most sensitive of all kinesthetic sensations, more sensitive than any other in the body unless it be in the skin, the proportion of nerve supply to an eye muscle being four or five times that of the gluteus maximus, for example; thus their kinesthetic control is very sensitive. We do not have clear vision, of course, unless the lines of sight of both eyes come exactly upon the foveæ centrales; as a result, in almost every movement of life, at almost every moment, movements of the extrinsic muscles of the eyes themselves, together with the movements of the head and of the neck, must contrive to keep the line of sight of each eye exactly upon the fovea of each retina. If one were standing still and a moving object was perceived partly back of him he would turn his eyeballs in order to see; failing by this means, he might turn his head around, and he might even have to turn his whole body in order to see more clearly. These movements of the head and of the neck, or even of the whole body besides, together with the movements of the extrinsic eye muscles, are purely reflex adjusting movements adapted continually to clear vision. The stronger the stimulation in the biological scale of values the more necessary is it to turn the head around and the farther down the body are the muscles innervated in the process of adjustment. All this, of course, is familiar physiology, but without a doubt the kinesthetic impressions arising in all such adjusting movements as these concerned with vision are a prominent factor in the development of our idea of space during the first two years of life.

In addition to the gross movement of the eyes there are the well-known fine adjusting movements. The spokes of the wheel of an automobile going at the rate of about twelve miles an hour furnish a fine opportunity for observation of these inconspicuous adjustments of the eyes, for in the frequent momentary apparent stopping of the wheels we can see when the minute jerks of the eyeball occur. These are wholly unconscious under ordinary conditions, but they serve importantly to finish out the gross adaptive movements of the eyes. They doubtless are a factor in the spatial kinesthesia, although wholly unconscious to the adult.

In an homologous way we might consider the kinesthetic sensations from the ears, similar to but less important than the kinesthetic sensations of vision. We turn our ears toward a sound, and thus hearing also helps somewhat to give us an idea of space. The movements of the human pinna are ordinarily so slight that we disregard them, and in any process of adjustment we use the muscles of the neck and the trunk chiefly in order to turn our organism "toward the sound."

This kinesthesia complex obviously is a factor, however small, in our idea of space in which to move.

Another element of this space evolution is possibly represented in the retinæ themselves. It is difficult, if not impossible, however, to understand how these visual impressions alone could give us a sense of depth. Location by means of the retina itself (a form of local sign) is very inexact and, upon the whole, retinal sensations are of little account considered as separate from the kinesthetic sensations of vision (which they never are) in the theory of voluntary movement. It seems that we use the retinal sensations proper in the guidance of a motion only when the line of sight comes upon the fovea centralis, and then it is the usual kinesthetic sensations that guide the voluntary movement. In moving the hand we certainly use the eyes chiefly to determine where we shall begin and where stop the movement. The eye locates the start of an average voluntary movement in the light, but the retinal sensations are too inexact for fine adjustments of the eyes or of the limbs. None the less, we mention them as a probable factor in space conception.

The semicircular canals also have a part in this process of elaboration of our space conception, a very important part, probably, in particular in its relation to the innervations of voluntary movements. Here more anatomically and definitely than elsewhere are the three dimensions of space represented. In connection with the cerebellum (the great center of mechanical coordination of all afferent influences, at least) we have probably to consider the canals, therefore, as the space receptors

proper, with meaning, however, only in reference to and in neural coordination with general muscular activity.

A fourth factor in the spatial mechanism of our minds is comprised in the kinesthetic sensations combined from bodily movements always in space. Such movements as kicking and impulsive reaching out for objects and many other reflex movements send into the young infant's brain a great multitude of kinesthetic impressions, and these effects from movements made in the three directions gradually combine themselves with those from the movements of the eyes and from the canals to furnish a real idea of depth. Thus gradually the concept of space or of perspective is developed, but it must be noted that it is developed wholly from actual muscular movement, whether it be the eyes, the canals, or the joints (usually all together) that are concerned. The movements of the adult, made in the three planes and represented by different sets of sensations, are carried out continuously on this notion of depth, and the adult neuromuscular mechanism appears to work always upon this basis only.

The *eyes gradually become "symbolic"* for all these sets of spatial kinesthetic impressions more and more as the youth grows up. They act in the capacity of supervisors of the movements of the individual certainly, but only in order to set going, so to say, these groups or complexes of kinesthetic impressions flooding into the brain's grey matter. Just as a word or a mere emotional sound, even, can represent an immense amount of meaning, so the eyes as supervisors over these motor impressions are symbolic of a large number of neurograms in the brain, control the complexes of kinesthetic impressions, and so help produce voluntary movements. This dominance of vision normally over kinesthesia is seen in the subconsciousness of the latter sensations when the eyes are open, although the resident movement sensations (largely in the joints) are conspicuous enough in the blind or when the eyes are shut. The purely symbolic character of vision, on the other hand, its relative unimportance in motor control, is evidenced by the great efficiency of many persons when vision is not at all concerned.

If these facts are difficult to understand we must recall that the whole method of the nervous system is that one nerve center shall be in control of other nerve centers in the body. Despite this ordinary apparent (symbolic) dominance of vision over kinesthetic control we may be sure that neurally—that is, *really*—the visual control is of minor importance save in the locating (starting) and stopping of the movement in many cases. It is easy to see, on the other hand, how this close relationship between vision and kinesthesia could reinforce the contributions of the latter to our understanding of spatiality.

The last factor in space conception we need discuss (and that mostly for the sake of completeness) is the local sign element of kinesthesia and of touch (kinesthesia). As everyone knows (and no one understands) each spot of the skin and to a less extent of the muscles, joints, and viscera, also, has some means of suggesting its location in space relative to others. Whatever be its precise neurology, whether the uniqueness of each sensation be central or peripheral, we know no better than did Lotze, who featured this aspect of sensation. Of course, the natural presumption would be that the relativity of the local signs is due to some kind of central comparison, or contrast. Be this as it may, there is little doubt that we include this comparison, in consciousness, as a factor in the elaboration of space conception by the individual. In the actual guidance of voluntary movements the local signs probably take a larger share than has been accorded them—namely, in certain movements where guidance is by the method of trial and error. (This is a question worthy of research by those who would lay the foundations of a true theory of motor efficiency.)

In the blind the foundation space consciousness is certainly much more definite and distinct than in normal individuals, as is also their resident kinesthesia (called by them touch). The relative inaccuracy of voluntary movement in the blind is not hard to understand when we consider the paucity at once inevitable and great, of their eupraxic centers, products largely of experience that they cannot have had.

Such, perhaps, are the chief elements neuromuscularly considered of the conceptualization and practice of spatiality in man. Perhaps we may be allowed to quote from a recent article (by the present writer) on apraxia:

Into the further details of the neurograms of these various factors of original space conception we need not even attempt to go, nor is it necessary to do so in order to be assured that their afferent impulses come from every portion of the body and directly or "symbolically" involve every portion of the brain. One need only consider how widespread is the visual "tract" through the hemisphere "fore and aft"; how expanded and how involved are the auditory centers if we include the essential vestibular functions; how spread out and interknit are the taste "centers," those of smell, of touch (shown by Van Biervliet recently to be a phase of kinesthesia), and of orientation, equilibrium, and local signs. Such in the sketchiest of outline only is something of the brain neurology, it may be, of the afferent intelligence that fuses into the fast-growing infant mind as a basal working knowledge of the space in which alone he can move and so have his being.

The cerebellum and all its connections comprise the neurology of much of this spatiality. To leave the cerebellum out of any discussion of the neurology of voluntary movement is to dehamletize, so to say, the text, for without this all-related center voluntary movement has no principle of action, no rule of conduct. It needs only a drunken man reeling home, or other afferent ataxia, to demonstrate the proposition. We can almost, then, speak of the cerebellum as the space center at the physiological foundation of all voluntary movement.

In proportion as the individual intimately knows this space as represented to him thus by the nervous system is he capable and skilful and efficient, master of himself and of his plastic environment. In short, in the neural (and muscular) mechanism that develops originally a personality's notion of space we appear to have the chief foundation of the neuromuscular mechanism of voluntary movement in its most obvious details and framework both at once.

We have now (inadequately) considered the first two of the three heads under which we proposed to discuss the nerve-basis of voluntary movement in the human adult: the first of these was the nervous circuits and the second spatiality. The third heading now is *the grey fabric of the hemispheres*. This

includes all the neurons that have their cells in the hemispheres; of these brain areas obviously the greater part is the cortex, but the optic thalamus and the ill-understood structures at or near the base of the brain must also be included in this grey matter.

The efferent or "motor" nerve-impulses (see Sherrington) are of course also a great factor in voluntary movements. We will find in all discussions of these from the psychological side (the subject furnishes an important topic for all psychologists) that many emphasize "imagery," the sensations concerned in voluntary movements, which constitute what James called motor ideas of these movements. The work of Kirkpatrick, Woodworth, Bair, Rowe, et al., discusses this matter at length, but for the most part they keep outside those determinants of voluntary movement which we properly can call motives or motor ideas. To some extent at least they have discussed what we may term the epiphenomena of deliberate action. A concrete illustration of this appears as a by-product in a recent research that was carried on by the author along a similar line. Each subject was asked what was going on in his mind during the time he was making a certain hand-movement from one point to another. Some of the subjects said they had visual images, others that they had (resident) sensations in their joints and muscles, while others heard things, or "felt the movement," or heard the click of the recording-pen; others did not specify, but said that their attention was directed towards the effort necessary to do the experiment as required and that their consciousness was directed "to the effort itself." All of these various things (of which any subject could have had any number), whether remote or immediate to the muscles, etc., seem of very little account in the actual guidance of the real movement. The latter was the same in the case of every subject and was made under the same conditions, and each subject invariably reported something different, and in some cases all the sensations reported were different. We may reasonably conclude therefore that these various side-experiences could not have guided the movement itself, for in all the subjects this was essentially identical. Thus, it is to be observed that the accompanying "imagery" is not an important factor in the guidance of a voluntary movement. In the first place the laws of habit, and, in the second place, those of attention in part determine what is in the focus of the mind when we voluntarily make a movement. Most persons are visualizers; others are motiles, or audiles. So far as the movement itself is concerned then, especially if it be rhythmic, it is more or less by "chance" what particular things we shall experience while making it. On the other hand, the essential guidance of voluntary movements, in regard to both efferent and to afferent impulses, comes probably in part out of the mass of associations fusing in the cortex of the brain and in the thalamus and brain-stem (Head and Holmes). Many of these influences, it must be again remembered, in the adult, have in the course of years gradually sunk into the subconsciousness. What these cortical resultants of fusions are as opposed to those producing "imagery" that we have called epiphenomena, we must now hasten to explain, and as briefly as we can.

The grey fabric of the hemispheres is essentially an enormously complicated reticulum almost infinitely bound together in function, coordinated in many intricate ways whose complexity we can not clearly imagine—nor begin to. We know that the complexity must exist and we presume that its chief function is to receive sensory kinesthetic impulses and so to arrange them that they result in body-movement of one kind or another, under conscious inhibitory and other control. The cortex of the brain, only about one millimeter thick, owing to the sulci and fissures that dip down into the hemispheres, has an area of very considerable extent, and the neurons of the internal nuclei add to it materially. The ultimate search of neurologists of course is the detailed modus operandi of this reticulum, but these details yet are probably years and years ahead of us. Certain general and absolutely safe guides show us the trend, the direction of the advance, in fine lay for us unmistakably a course in which we can be quite secure. These guides are more certain than neurohistology and the physiology and the anatomy of the brain; we know of them and of their trustworthiness each of us from personal experience which can be verified by any man at any waking moment. Already we have seen what the kinetic basis and what the framework, so to say, of the voluntary "neurograms" probably are; our present task is to point out certain probable factors of the grey fabric's *resultant* which in every case, by its action on the cerebellum and the cord, determine the details of a voluntary movement.

The first of these cortical determinants we may set forth briefly under the name *ideas of usefulness*. Like the other elements of the neural motives of voluntary movement, these ideas may be to any degree subconscious, but that they are continually effective in the brain, how can we doubt?

The early elaboration of human behavior into very numerous psychomotor complexes on a basis of economy and habit devolves especially, we may reasonably presume, on two important portions of the brain (connected intimately, however, with all the rest)—the frontal lobes (*via* the central) and the cerebellum. If we know anything at all of the frontal cortex it is that one at least of its duties is this elaboration of motor ideas, how to use objects, for example, how to rotate the arm or roll a shot between the fingers, turn a doorknob, place the hands on the head, touch the end of the nose with the index finger, athetose, so to say, the fingers; how, in short, to do the uncounted thousands of voluntary things of which "education" worthy of the name before the eighth or ninth year largely consists.

Nerve centers have in early years elaborated many such psychomotor complexes, have interrelated them, and have put them in bewildering intimacy with all the other centers in the brain and below it. Broca's convolution furnishes what is probably by far the most complex example of an enpraxic center, and its function is just the elaboration, interrelation, and extrarelation of a certain set of objects, namely, words. These spoken, written, printed, graven, depicted, sculptured, or materialized by the sign manual, constitute the physical basis, so to say, of the one uniquely human process of language information and language expression. Need one try to imagine the details of Max Mueller's speech center in terms of neuroxones, dendrites, nerve cells, or of ions and osmosis and reversing colloids? Yet this must be done some time by some one or else all our fashionable attempts at localization must be given up.

In a way quite homologous to this, every common object other than words and *every useful voluntary movement* must have representation in the frontal cortex, we may, we must, assume. If, then, a man does not know how to use a sextant or an eidograph or a planimeter or a pencil or a pair of shears, it is so only because his frontal cortex has never acquired or, from disease, has lost that particular psychomotor complex. No more can be taken out than has been put in. As has been often well pointed out, the newborn child is almost wholly apraxic, although even then something in his mechanism of efficiency represents the use of his mother's breast just as it represents and provides the means of finding it in space. The cleverest adult obviously is he who has in his frontal cortex the greatest number and the greatest perfection of detail and relationship of these motor ideas (neurograms) of movements of utility. Voluntary movements of the other of the two suggested classes, those not involving the use of particular material objects, employ a center commensurate in elaboration and universality of use with the "object" that they do employ, namely, space. This determinant of deliberate bodily motion we have already discussed.

Another element in the usefulness of the grey fabric of the hemispheres let us designate as *the memory images of movements*, the "motor ideas" proper of the lamented James. These, as it were, stand between the functions of the cerebellum (as mechanical coördinator of incoming impressions) and those complexes just suggested as having site in the frontal (and parietal) cortex. They are most closely dependent on the kinesthetic influences coming from the moving parts, yet intimately concerned with all other regions of the central nervous system up and down. This grey region perhaps may be set down as the Rolandic area in all its extent, lateral and mesial, anterior and posterior. Even then, be it observed, only a small fraction of the total mechanism required to explain voluntary movement can be ascribed to the Rolandic areas. A memory image, the motor idea, of a movement is very much too narrow a condition or relation, far too simple and incompetent to serve as the determinant of any portion, however small, of the free and always new behavior of a human personality. As we have tried to explain, just in proportion as it is not free and new, just in proportion as it is habitual, reflex, and familiar, have the motor centers lower down the central nervous system taken it up and controlled the movement. In the first year or two of life obviously these Rolandic neurons are of preeminent importance, but with the increasing complexity of the individual's behavior parallel to his evolving personality, this region of the grey fabric, we may suppose, becomes relatively more and more subordinate, although remaining always, it is likely, the chief storehouse of motor vestigia on which voluntary action must continually draw for patterns and plans of behavior, however simple. Here is worthy function enough for the venerated anterior and posterior central convolutions of the cortex cerebri, without need of supposing it capable of coordinations far beyond its capabilities or connections!

A third factor of voluntary action seated especially in the grey fabric of the hemispheres, we may term *awareness of ability* or self-confidence in the power to make any particular movement. Of course the ordinary universal voluntary movements of our life have been made some of them several times, some of them hundreds of times, but some of them, too, millions of times, so that for very many such movements the awareness of ability is long since trite and by habituation, as usual, become subconscious. It certainly still retains, however, at least partially determining action in the making of these and other deliberate movements.

In the adult the matter of self-confidence is based on the early infantile process seen in the development of voluntary movement. In the young infant there is continually an addition to the movement already made; the child puts its arms out and is aware meanwhile that it can do that, then puts its arms out a little further, and so on, and thus keeps adding to what it knows already that it can do in the way of making voluntary movements. We can often see, if we watch an infant, that in the case of certain complicated movements, such as twisting the doorknob, for example, if the child is shown that he can do the thing and is made to believe so by any means, he will usually be able to perform it at once, provided, of course, the actual neuromuscular mechanism of that action be then developed and ready for use.

In the infant especially, but also in the adult, this knowledge of the power to do a thing is often developed by imitation. The child sees some one do something and the observation becomes a suggestion to him that he, too, can do it. He then does it because his mechanism is so built that he can and, in fact, almost must under the impulse to activity, as has been discussed already. This knowledge of the power to make a certain movement in the case of the adult appears more broadly and yet only partly as self-confidence. A person's supposition that he cannot do a certain thing prevents his doing that thing or at least his doing it well. The writer recently had an experience in this direction on taking lessons in blacksmithing. It was quite impossible to believe that a student entirely unfamiliar with all such work could do the things that the skilled master executed with the utmost facility and skill. The minute, however, that an average person tries and thus sees how much he can really do, starts in to make a tool, for example, out of a piece of steel, his effort becomes conscious and voluntary and self-stimulating, knowledge of his power to do a thing comes in play and his motor ideas with often surprising ease gradually work themselves out in action much as desired. This mere matter of trying to do a thing is useful, neurally speaking, largely because the motor ideas in the brain actualize only in that way. The great dynamic importance of this aspect of self-confidence we cannot here stay to consider. Its relations of course are of unexcelled importance in human efficiency, for millions of men and women are virtually slaves who might well be masters did they know how potentially efficient is the average mechanism of human voluntary movement.

The cerebral site of this factor in deliberate action it is impossible at present to describe, or even to suggest. It is evidently an extensive one, partaking, as it does, in the two preceding determinants of voluntary movement. That it is something by itself apart, in some, at least functional, neural way, the neurology of abulia strongly suggests for in this condition it especially is in defect. Perhaps here we enter the new field of the relation of the hormones to cerebral motor activity, especially to feelings of pleasant self-confidence, it may be.

Herewith is connected probably many important matters pertaining to neurasthenia and its "burden" of worry and malaise, and to euphoria and the sthenia of happiness.

Another determinant of voluntary action coming out of the fabric of the hemispheres we may characterize as *the interests and the emotional tones* which underlie such action.

The term interests we should here use in a broad sense and include therefore those that are vegetative and under sympathetic control (food, sex, etc.); those we speak of as individual dispositions; and finally those narrower interests, more purely cortical perhaps, that directly relate the person to his voluntary activity—a man's trade-interests for example, or his habits of sport, shooting, riding, or tramping. Were it possible or necessary to attempt here to work out the neurology of an individual's interests so understood, we should see how large a part of the nervous system is involved in it. We should see especially that these nerve-conditions, these neural habits, these interests in short, *actually determine the mechanical nature (speed, accuracy, extent, force) of the separate voluntary movements*, and therefore underlie and help determine them.

In a quite homologous way, psychomotor conditions that are strictly of an affective sort certainly help determine every voluntary movement as it is made. In the first place every conscious, that is for the most part, voluntary, movement has in its psychomotor nature at least a slight tone of pleasantness, or, if the fatigue-rest balance be negative, a slight tone of unpleasantness. The feeling-tone of pleasantness or of unpleasantness which accompanies the voluntary movement is a part of these associations in the cortex of the brain out of which comes the essential guidance ("resultant") for the action. The psychology of skill (see Book's work on typewriting, *e.g.*) emphasizes that unless a person enjoys his work he does not do it well, and the converse tends to be equally true. On the other hand, a motor mechanism that is in perfect vigor with an anabolic balance in store gives out from the brain-centers an emotional tone of joy, whether slight or intense, for intense it may, though rarely, be. This mass of associations in the brain-cortex is always ready to take conscious control at the slightest need, for the individual only has to "make up his mind to do a thing" and the mass of grey associations is physiologically keen to make the movement required and to direct and control it.

But besides the tone of pleasantness (or of unpleasantness) underlying all bodily action, all that is voluntary at least, more directly still do emotional tones of many shades help determine the deliberate movements. The absolutely cold mechanical movement of the cross-striated musculature is theoretically possible, but in practice it hardly exists, or if it does, the movement *pro tanto* is mechanical and impersonal, which is only another name (is it not?) for reflex. Man, lazily unaware of his own best interests, works only when impelled to do so by *desire*, and desire certainly is an underlying affective tone.

The brain parts of these interests and emotional tones determining (in part) voluntary movements are as yet by no means sure, of course. But if we study dispositions, moods, and temperaments, we shall see that their neurology is hardly narrower than the grey matter of the whole nervous system. On the other hand, the center of the emotions is certainly in part the optic thalamus and most likely involves, too, the corpora striata—these, of course, overseeing the coordination of the whole musculature for this purpose by way of the kinesthetic cortex of the hemispheres and of the cerebellum.

The recent important exposition by Head of London of the thalamus as the great sensation center adds still greater interest to that portion of the hemisphere. On the other hand, no one can foresee the extent to which the hormones, especially epinephrin, will invade the physiology of emotion.

The fifth (and last) element of the grey fabric of the brain concerned in determining voluntary movements we need only mention here as *inhibition*. Obviously inhibition is at the basis of voluntary movement in a way, as it is also at the basis of attention, but how we cannot describe in this article. Many neurologists, of course, say that the great cortex is inherently an inhibitory organ, restraining and thus regulating and controlling all bodily activity of a voluntary kind, just as the gates in an irrigation dam may be said to control the growth of the vegetation under the dam's jurisdiction. There is certainly a very widespread belief among neurologists that the whole cortex is concerned in inhibition, while most of the recent discussions emphasize the above suggested relation of inhibition to voluntary action, the dam of water corresponding to the impulse to activity as represented in the hind brain, the cord, and the autonomic system of impersonal motor tendencies.

Such are some, perhaps the chief, of the motives concerned in every voluntary movement which must be no longer ignored in discussion of the neurology.

It is interesting to observe that from the subjective side of voluntary movement the intention is often the most conspicuous part of the action, sometimes, indeed, the whole of it. One frequently has a strong awareness of what one intends to do (to say, for example), but sometimes does not actually know whether the intention was materialized, expressed, or not. Sometimes, in other words, the motor idea is so strong that it quite drowns out the memory of the performance if there were one. These facts and others similar strongly imply how fully the consciousness of voluntary movement is confined to the grey fusion process: the resultant being once made up (by the resolution of the personal will forces in the brain) the actual movement-neurograms, or influences, are performed more or less mechanically and subconsciously by the motor apparatus lower down the spinal axis, and the movement may occur or it may not without essential difference in the awareness of the individual.

A subtitle of this essay might be "A Tentative Neurological Analysis of the Motives of Human Bodily Action."

IV.

The foregoing obviously is essentially an elaboration and an analysis of the conditions of voluntary action with as much of the neurology of the same as is warranted in the present early stage of cerebral physiology.

The main thesis of this essay may be succinctly stated in three sentences, thus: *As a necessary preliminary to the exact neurology of the will, every deliberate movement, however simple, must be accorded a personal motive, often intricate, whose factors, in part merely neural, must be sought for. Each of these factors, psychological or physiological, implicit in a voluntary movement, has as its concomitant a functional set of nervous impulses.*

Because of the variety and complexity of the factors determining it, every deliberate movement must be considered the resultant of influences coming from practically every part of the brain or even of the entire grey fabric of the nervous system.

To understand a problem is assuredly a necessary antecedent to its solution, yet the problem of the neurology of voluntary movement has regularly been simplified out of all resemblance to the reality, with a consequent failure in the advancement of this practically important phase of neurophysiology.

VACCINATION OF THE TUBERCULOUS;

A STUDY OF THE DUAL EXISTENCE OF CONTAGIOUS DISEASES.

By JAMES J. WALSH, M.D.,

SCRANTON, PA.

LATE RESIDENT PHYSICIAN AND BACTERIOLOGIST, WHITE HAVEN SANATORIUM.

THE infrequent concurrence of tuberculosis with other contagious diseases has for many years been an observation which, especially to those doing tuberculosis work, admits of little dispute. Of course, in this regard tuberculosis is not different from the other contagious diseases which, while in active progress, do not seem to tolerate the presence of any other contagious disease. As early as 1885 Dr. Lawrence F. Flick, in his masterful monograph, "The Contagiousness of Phthisis," writes: "I have been unable to find a single authenticated case in which any other contagious disease was concomitant with consumption." At that time Dr. Welch, of the Philadelphia Municipal Hospital, wrote Dr. Flick, saying: "Although I have seen upward of 5,000 cases of smallpox, I do not recollect that I ever came across one in which there was also well-marked phthisis. Possibly some of these patients may have been suffering from phthisis in its incipient stage; on this point, however, I cannot speak positively, since I have no recorded observations in that direction." Dr. Flick writes further: "An astonishing fact in connection with this matter is that during the reign of the severe epidemics of typhoid fever and smallpox, in 1864-65 and 1871-72, deaths from consumption decreased, to become augmented as soon as the epidemics ceased. This might argue that some consumptives died of typhoid fever and smallpox during those years, were it not that the mortality from consumption throughout the whole city for those same years was much above the average."

Investigations beginning with Luigi Sacco of Milan and continuing down through Zöhrer, L. Pfeiffer, and others lead us to believe that the simultaneous progression of variola and vaccinia is exceptional and not the rule, even where the time of infection and period of incubation of each disease would favor their simultaneous progression. Immunity as conferred by vaccinia is not complete until after the sixth day; so that, given the condition that the infection with smallpox was at such a time before vaccination as to entail a neck and neck race between the first manifestations of these diseases, the coincident variola and vaccinia would be antagonistic to each other and the infection which took hold of the individual first would dominate the subsequent chain of symptoms.

The incubation period of erysipelas is from one to two days as compared with vaccinia, three days. When erysipelas is inoculated at the time of vaccination and develops vaccinia does not occur and immunity is not produced. There is well-founded evidence that vaccination in syphilities is distinguished in no way from that in non-syphilitics, but, as with tuberculosis, we know of no data which compare the percentage of "takes" in syphilities with those in non-syphilitics.

The frequency of the pneumococcus as an organism of secondary infection in phthisis, and the comparative infrequency of croupous pneumonia in existence with tuberculosis, would seem to support the observation of insusceptibility of the tuberculous to other infectious diseases.

Personally, in taking histories I have always looked with suspicion on the declaration of patients that they have suffered such infectious diseases as typhoid fever, acute rheumatism, pneumonia, etc., during the time which examination shows to have been after the onset of active tuberculosis. The acute infection is not infrequently found to have been nothing else than an acute exacerbation of tuberculosis.

Varicella vesicles and vaccination pustules are found together, but von Jürgensen says that "experiment shows that in simultaneous inoculation with varicella and vaccine the latter develops, while the former shows no results."

The writer's knowledge of statistics on the relation of vaccination and smallpox to tuberculosis is extremely limited. The work which is here set forth was suggested by the statement, which coincided with Dr. Flick's observations, that tuberculous individuals were comparatively insusceptible to both variola and vaccinia. Any literature on the subject must be extremely limited and the author unfortunately has not been in a position to obtain whatever does exist. Some 25 years ago a study of the results of vaccination in a limited number of tuberculosis patients was undertaken by Dr. W. M. Angney, of the Consumptive's Home in Philadelphia. The report of this investigation was that two cases took mildly, but in neither case was the vaccination typical.

From the results we have obtained in vaccinating patients at White Haven Sanatorium I am drawing no conclusions, at least until I have the statistics of others; all that is set forth here is what appeared to us as the most significant points in observations of over 100 and close study of eighty-six cases. While successive attempts were not practiced in the presence of negative reactions, I feel confident, after close observations of the work of the vaccinators and the subsequent character of the lesions, that faulty technique could rarely be suspected as the cause of a "no take." If we erred in our conclusions as to whether a vaccination was positive or negative, it was in favor of it being the former. Those cases which were questionably positive, we admit, frequently lacked the Jennerian plateau, and we may have been, like most practitioners, only too willing to consider them as at least vaccinoid forms of revaccination.

Our study comprises vaccination of patients in all stages of active pulmonary tuberculosis, with and without its common complications, and also cases with diseases arrested. In classifying the cases I have retained the "One, Two, Three" degree of involvement, which at White Haven may be loosely interpreted to mean slightly advanced, advanced, and far advanced lesions respectively. No patient was inoculated who had been vaccinated successfully within the last seven years. We endeavored to count nothing as being a positive vac-

cination which did not show the typical local manifestations, viz., vesicle, pustule, and areola. In those who reacted positively nothing out of the ordinary course of vaccinia was noted. While the patients were all adults, who are supposed to react more acutely to vaccination than children, only three patients could be considered to have been characteristically sick after the insertion of the lymph. Some of the patients were studied for unfavorable symptoms arising in the pulmonary lesion; none could be detected.

In studying the degrees of reaction to the lymph we charted them as (*a*) negative entirely, (*b*) positive local manifestations of vaccination, and (*c*) positive local, with constitutional symptoms.

It was difficult, of course, to determine in some instances whether the constitutional symptoms were due to vaccination or were simply such as are apt to occur at any time in the course of tuberculosis. Especially difficult was it to say that a rise in temperature already febrile was due to the positive vaccination which showed on the arm. In most cases the temperature after vaccination was studied with that charted for three weeks previous to inoculation.

In the 86 patients studied, 25 were number 1; 43, number 2; and 3, number 3 cases; 15 had diseases arrested. As we progressed with our study we were not as anxious to associate our results with the degree of involvement as with the active duration of the disease and the present degree of activity. Therefore, taking into consideration all symptoms of tuberculosis, we have divided the patients into four different classes: (*a*) those showing diseases arrested; (*b*) those showing slight activity; (*c*) moderate activity; and (*d*) pronounced activity of the pulmonary lesions.

Of the 86 cases, 57 or 66.28 per cent. did not take vaccination, while 29 or 33.72 per cent. were charted as responding positively. Twenty of the 29 cases that took vaccination were expectorating tubercle bacilli at the time of inoculation. Seven of all the cases had never been vaccinated. In two of this lot attempts at vaccination had never been practiced; these two were vaccinated successfully by us. On the remaining five vaccination had been tried unsuccessfully 11 times; three of these were vaccinated successfully by us.

Classifying the patients on the degree of activity of the pulmonary lesion we had 15 with disease arrested; 44 with slight activity; 15 with moderate activity, and 12 with pronounced activity. Of the 15 with the disease arrested, 14 or 93.3 per cent. responded negatively to vaccination; 1 or 6.6 per cent. positively. With slight activity, 27 or 61.3 per cent. were negative; 17 or 38.7 per cent. positive. With moderate activity, 10 or 66.6 per cent. were negative 5 or 33.4 per cent. positive. With pronounced activity, 6 or 50 per cent. were negative; and 6 or 50 per cent positive.

Summing this up, the highest percentage of "takes" (50) was in those with pronounced activity, but an equal percentage in this class showed "no take." The highest percentage of "no take" (93.3) was in those with the disease arrested.

A study of the 12 patients showing pronounced activity of the pulmonary tuberculosis, taking into consideration their history and the manner in which they have ever responded to treatment, leads one to believe that at least nine of them were of that class which seems to possess little power to establish resistance and immunity to tuberculosis.

Of the 29 patients who took vaccination, close observation showed that 17 manifested local symptoms of vaccinia only, while 12 had constitutional symptoms in addition to the typical arm lesion. The 3 patients, two women and a man, who suffered the worst reactions were, of course, in the constitutional class, but not one of them was in bed over three days. These three patients were ones in which the pulmonary condition manifested only slight activity and two had only slight apical involvement.

The lowest percentage of positive results was in those with disease arrested or, in other words, those who probably possessed the highest resistance and the most quiescent lesions. Most of this class were nurses.

The highest percentage of positive results seemed to be in those who on account of the slight degree of their tuberculosis were required to develop little resistance, and in that class which, with a moderate or great amount of tuberculosis, was manifesting a minimum of resistance.

It may be, as H. R. M. Landis suggests, that the person well built up and manifesting good resistance to any disease is also naturally less predisposed to all other infections and in this case resists the infection of vaccinia. Whatever this and all the foregoing statements are worth, 18 of the patients, mostly nurses, gave the following history of vaccination since the onset of their tuberculosis. All attempts to vaccinate them before have proved futile. Of the 18 who reacted negatively before, 17 were negative now; 1 was positive, and this in a man showing good resistance with a moderate degree of involvement and on 8 hours' exercise. A further analysis of the history of the 17 cases which have failed to respond positively to vaccination since the onset of tuberculosis shows that 15 were vaccinated once, two twice (6 trials in one of these), one four times, and one five times.

Nothing definite could be gleaned from the leucocyte count which was made on 11 patients at about the eleventh day of vaccination. Of the 11 leucocyte counts, three showed an average of 5,000; three showed an average of 9,000; four, an average of 10,500 and in one the count was 14,800.

Personally, I cannot consider that our series of cases argues much for or against the supposition that the tuberculous are not predisposed to other contagious diseases. Careful analysis leads me to believe that the statistics favor the statement, although this may not be apparent without study. Superficially they seem to show that if there is any value to the statement that the tuberculous are not predisposed to variola or vaccinia it is necessary for such individuals to manifest a certain degree of resistance to tuberculosis, that is, the higher the degree of resistance to the tuberculous lesions, the less likely is the individual to take vaccination successfully.

407 Wyoming Avenue.

The Viscosity of Blood in Disease.—A. Plessi and D. Vandini state that the viscosity of the blood depends on several factors; among these are the morphology of its cells, the plasma, the quantity of hemoglobin, the amount of globulin in the serum, etc. The authors experimented with patients affected with various diseases and with normal individuals as well. They found that hirudin is the best agent for lessening viscosity. In anemias the viscosity of the whole blood is decreased. In pulmonary inflammation the viscosity is less than normal. In intestinal infections and in abdominal carcinoma it is diminished. In pulmonary tuberculosis it is increased in the early stages, and when cachexia has developed is normal.—*Rivista Critica di Clinica Medica*

THE PASSING OF BISMUTH PASTE

By WALLACE BLANCHARD, M.D.

CHICAGO, ILL.

ORTHOPEDIC SURGEON TO THE HOME FOR DESTITUTE CRIPPLED CHILDREN AND TO THE UNIVERSITY HOSPITAL, CHICAGO.

HAVING treated 100 cases of sinuses from tuberculous bone disease very successfully with bismuth paste, and having treated 152 cases even more successfully with a non-toxic substitue, I feel in a position to offer a vigorous protest against the further use of bismuth paste.

In the MEDICAL RECORD of January 20, 1912, Leonard W. Ely of Denver, Col., adds another to the ever-increasing number of deaths resulting from the use of bismuth paste. The case reported was of Pott's disease with a pronounced kyphosis and a freely discharging lumbar sinus. After a few injections of the bismuth paste the sinus closed, but the patient soon developed a black tongue, ulcers of the mouth, bloody stools and sleeplessness, death shortly following. Deaths with the same train of symptoms have been reported from nearly every section where bismuth paste has been extensively used. A dozen cases of severe poisoning and two deaths have occurred in Chicago.

I was the first to report any considerable number of cases treated with bismuth paste (Journal of the American Orthopedic Association, August, 1908). The treatment showed wonderful results. Old sinuses from tuberculous joint disease were cured in from two to six weeks, but after seeing several cases of severe poisoning and hearing of a number of deaths, I began experimenting with a view to the elimination of the bismuth. The conclusion was soon reached that Beck's theories of the bismuth being a cure because it became radiumized in the body and that it also served as a sort of trellis on which healthy granulations could grow, were altogether fanciful. There is no doubt that the curative action of the paste is purely mechanical. A danger in the use of bismuth paste that so far has attracted but little attention is the likelihood of the heavy bismuth settling down in pus sacs and sinuses and becoming permanently residual. I have several cases both cured and uncured in which the *x*-ray shows accumulated masses of bismuth that have every indication of remaining permanently. In one case, a boy of twelve years, the *x*-ray shows a mass of bismuth nearly as large as my hand that has been residual for nearly three years and will probably remain so as long as he lives.

The ideal paste for flooding tuberculous sinuses and filling pus cavities must be non-toxic and absorbable. It must sufficiently solidify at body temperature to crowd out the pus, compress the unhealthy granulations, and exclude the air. The following formula for a sinus-flooding paste meets every requirement and is entirely innocuous. Formula No. 1: White wax, 1 part; vaseline, 8 parts; mix while boiling.

Iodine may be added in badly infected cases. Iodine scales can be reduced to a powder by the addition of 20 per cent. of potassium iodide. One, two, or more grains may be put in a small cup. The usual glass syringe should be filled with the hot paste. Half the contents of the syringe must now be injected into the cup and the nozzle of the syringe used to mix the idodine powder into the hot paste. When this mixture is drawn into the syringe the fresh iodine is rather unevenly distributed in the hot paste and it is ready for use. Immediately after injecting the sinus a thick pad of gauze saturated with alcohol should be bound over the opening. The evaporation of the alcohol cools and hardens the paste and prevents its escape. In some cases it is well as a preliminary step to get a skiagram showing all the sinus ramifications and pus pockets. For this purpose I am injecting sinuses with the following mixture. Formula No. 2: Ferri subcarbonate, 1 part; white vaseline, 2 parts; mix and boil.

The iron makes as good a skiagram for diagnostic purposes as the bismuth, without its dangers.

The results in over 150 cases of old turberculous sinuses flooded with the wax vaseline-iodine paste showed about 35 per cent. cured by from one to eight treatments. Thirty per cent. more were cured in a year and about 35 per cent. remained unimproved. This last 35 per cent. had retained sequestra or were amyloid and hopeless. The ultimate results of cases cured show just about the same with the wax-vaseline-iodine paste as with bismuth paste. But in the uncured and the relapsing cases the advantages of the wax-vaseline-iodine treatment were very great. There were no deaths. There were no cases of poisoning with a painful train of symptoms. There were no cases in which the sinuses and pus sacs were clogged by the heavy bismuth settling down and becoming permanently residual.

In occasional favorable cases the abscess stage of tuberculous hip or other joint disease may be cut short by opening the cold abscess with a small puncture, draining it by mild manual pressure and filling it to its full capacity with a thick paste so as to completely exclude the air and keep the sac sterile till it becomes obliterated. For this purpose the following is an excellent paste. Formula No. 3: White wax, 3 parts; soft paraffin, 2 parts; white vaseline, 24 parts; mix while boiling. This abortive treatment can succeed only when the abscess shows upon the surface, the area of tuberculous destruction is small and the quantity of pus is limited.

Experience has taught several "don'ts" in the use of any flooding paste for the cure of tuberculous sinuses. Do not inject a sinus case in which the *x*-ray shows a sequestrum. The sinus in this instance is a natural drainage tube. It may be healed, but if so the patient will develop a rise of temperature and pains until the pus finds a new exit. By this process the patient is made very much worse. First remove the sequestrum surgically and then the sinus may be cured to advantage by paste flooding. Do not inject a primary newly opened sinus. The walls are not definitely formed and the injected paste will wander unrestrained, making new sinuses and pockets, causing rise in temperature and disastrous results. Do not obstruct necessary drainage. Wait for several months until the sinus track is well formed and the discharge has thinned down to a semi-transparent and only slightly purulent condition. I have seen two cases of fatal meningitis follow after the interception of necessary drainage by the inopportune use of bismuth paste. It is in the old long-suffering bedridden cases in which the bone disease has run its course and the old chronic sinuses persist that paste flooding gives truly wonderful results.

Fully 70 per cent. of the old neglected or unfortunately treated cases of Pott's disease and tuberculous hip disease with from two to a dozen sinuses and a constant semiserous, slightly pus-colored discharge were cured in from a week to three months.

One should not be in a hurry to use the flooding paste and should remember that the curing of a sinus does not mean the curing of the tuberculous bone disease. If the formation of pus continues the abortive treatment will be a failure and must not be repeated. The bismuth paste treatment has proved a wonderful boon to a class of cases that were practically incurable up to the date of Beck's discovery. The elimination of the bismuth improves the treatment by removing the grave danger of clogging the pus sacs and sinuses with residual bismuth and the constant danger of poisoning with, perhaps, fatal results.

I. PNEUMONIA SIMULATING LOCALIZED PERITONITIS.

II. TYPHOID FEVER OBSERVED DURING THE INCUBATION PERIOD.

By H. E. L. ZIEGEL, B. S., M. D.,

NEW YORK,

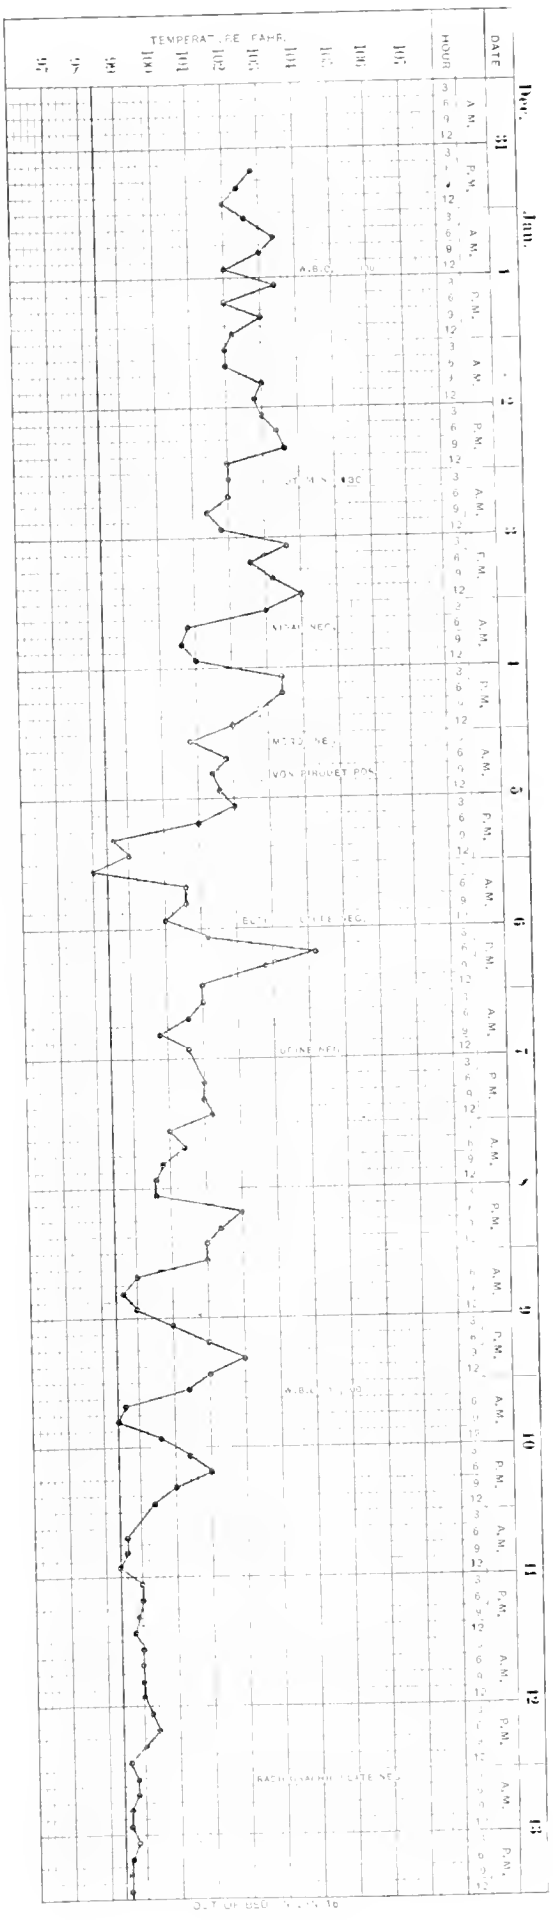
ADJUNCT ATTENDING PHYSICIAN TO THE BETH ISRAEL HOSPITAL.

I.

Partly because of the proximity and intimate nervous relations of the diaphragmatic pleura and peritoneum, inflammations of the viscera contiguous to the diaphragm are sometimes difficult of recognition and differentiation. Thus pneumonia with abdominal signs is apt to be mistaken for abdominal surgical conditions.

The case to be described is that of a male 22 years of age who six days before admission to the surgical service of Dr. A. E. Isaacs at Beth Israel Hospital had been taken ill with malaise, chilliness and general pains. On admission the patient complained chiefly of sharp sticking pain in the right hypochondrium, which pain had appeared the day before admission and had steadily increased in severity; the rectal temperature was 103°, the respirations were 34; at the base of the right lung posteriorly breathing was diminished and fine râles were heard; the gall-bladder region was rigid and tender. At this time there was no cough; there was no vomiting, no jaundice. During three days' observation in the surgical ward the temperature ranged between 102° and 103°, the pulse averaged 100 in frequency, there was moderate dyspnea, and the pain, tenderness and rigidity in the right hypochondrium continued. A radiographic plate of the chest showed no abnormality in the position of the diaphragm. Cough and mucopurulent expectoration now developed as new symptoms.

In the meantime the surgeons had concluded that the case was not without medical aspects and when asked to see the patient I found: Temperature of 104°, respirations from 30 to 38, moderate dyspnea and slight cyanosis, cough and mucopurulent expectoration; over the right lung posteriorly dulness began at the level of the scapular spine extending downwards to merge into flatness at the angle of the scapula, the flatness extending to the base; over the dull area the respiratory murmur was not changed in quality but was diminished in intensity with occasional moist râles, and over the flat area breathing and fremitus were absent, voice was diminished. In the right hypochondrium rigidity was marked and tenderness exquisite. No Head zone



Two cases reported to the Section on Medicine, N. Y. Academy of Medicine, March 19, 1912.

was present. A deep inspiration caused abdominal pain and cough.

The history and signs were interpreted as those of a deep-seated consolidation in the right lung involving the diaphragmatic pleura. The patient was transferred to the medical side. For the next five days the pain, fever, cough and prostration with the above-mentioned physical signs continued, except that the tenderness and rigidity in the gall bladder region disappeared in three days. The temperature, as shown by the chart, ranged between 102° and 104°; the leucocyte counts averaged 18,000; the urine was negative. Recovery was without incident, though the temperature did not become and remain normal till the eighteenth day of the illness.

This case belongs to that group of atypical pneumonitides which we have been in the habit of calling "influenza pneumonias." For the reason that pneumonia with abdominal signs is far from rare, it is well to remind ourselves of its existence so that in instances like the one reported surgical intervention may be avoided.

II.

Because fortuitous circumstances afforded an opportunity of observing the patient during the incubation period, this case of typhoid fever is reported. A young lady 25 years of age was being observed for and was recovering from chlorotic anemia; the hemoglobin had in the course of two months increased from 58 per cent. to 75 per cent.; the red blood cells always numbered more than 4,500,000; and the white blood cells from 9,000 to 11,000. When the patient complained of inconstant frontal headache, vertigo, tinnitus aurium, orbital pain, and of feeling very tired, she was sent to an ophthalmologist who reported that there was no refractive error sufficient to account for the symptoms or to require correction. Headache and fatigue had been present previously and failure to find any other cause for the additional symptoms resulted in their being attributed for the time being to the anemia. At this time there was neither anorexia, abdominal pain, constipation, diarrhea, nor sleeplessness. Noteworthy is the fact that though there was no epistaxis, yet menstruation—previously absolutely regular, four-weekly, and of three days' duration—now came on while the above-mentioned premonitory symptoms were being complained of, the period being four days ahead of time, very profuse, and of six days' duration.

On the day before the invasion with a chill, herpes appeared on the chin, and there were chilly sensations and a rectal temperature of 99.6°. On the following evening the temperature rose to 101° after a severe chill; the patient was put to bed and this was called the first day of the disease. On the second day the morning temperature was 100.8°, the evening temperature 102.8°; the white blood cells now numbered 4,800—this leucopenia being regarded as significant for the reason that on several previous occasions when a complete blood count was made the leucocytes always numbered more than 9,000. Uranalysis on the second day showed a negative diazo reaction, but the Russo test was positive. The diagnosis of typhoid fever, now tentatively made, was confirmed two days later by a positive Widal reaction.

The illness ran a moderately severe course with no complications except an acute degeneration of the kidneys due to toxemia and a hypostasis of the right lung, both of which cleared up at the time of defervescence. The temperature curve, as shown by the chart, is of classical text-book type, showing the step-like rises during the first week; during the second week it was continuously high; during the third week there were successively greater morning remissions with successively lesser afternoon rises.

The following are the main points of interest in this case:

1. Menstruation, which had previously occurred every 28 days, came on during the incubation period four days earlier than usual, and was profuse and prolonged.

2. A leucocyte count of 4,800 on the day following the invasion was significant for the reason that in the course of the patient's previous observation for chlorotic anemia the leucocytes had on two occasions numbered more than 9,000.

3. The positive Russo test obtained on the second day of the disease confirms the view that occasionally this reaction is of practical value as an aid to early diagnosis in typhoid fever.

8 West Eighty-sixth Street

A CONTRIBUTION TO THE TREATMENT OF TUBERCULOSIS.

By C. G. AMENDE, M.D.

NEW YORK.

Because of advancing years and recent deaths of old friends the writer desires to publish some observations upon the above subject earlier than perhaps they should be. The small number of the special cases for this report prevents the establishment of any general principle. But they are believed to merit some attention.

The idea underlying these observations, begun over twenty years ago, was that by internal antisepsis similar results might follow as by external. When this principle was extended to all infections cases actually superior results were obtained, especially in diphtheria, typhoid fever, puerperal fever, etc. The principal chemicals employed were quinine, iodoform, and creosote. Aided by a local application one death only from diphtheria occurred in about nineteen years, many of my cases, though, being out of town. That the earlier theory of a direct destruction of the special germs was incorrect, and that the actual process was by antibodies, toxins, etc., is immaterial as to result.

In tuberculosis the combination finally settled upon was for adults a pill three times a day containing one grain of quinine and one-fifth grain of iodoform, aided in severer cases by five-drop doses in capsule of creosote. When the pills are gelatin coated, being tasteless, they are taken without a murmur for any length of time. As they thus could be obtained in large quantities only they had to be dispensed directly, which, however, had the advantage that the patients were kept under control. Children, of course, receive a small dose in proportion.

One severe case treated with these drugs became a lamentable failure. After some treatment here, for which the boy came over from New Jersey, he was sent to friends in the Platte River valley, but getting weaker and weaker he returned home and died soon after.

Of the three other severe cases, which should go far to establish the remedial value of this treatment, the first one is Mr. A. D., who had, at the age of thirty-five years, and at that time (June, 1900) not under my care, a severe pulmonary hemorrhage

which necessitated abstinence from work for six weeks. In September the same year he had another hemorrhage which laid him up for three weeks, and in January, 1901, he had another very severe hemorrhage which left him in a critical condition. In response to an inquiry by relatives living in my house I ventured that the best thing for him to do would be to go to a dry climate. After the third hemorrhage he now came to me and was placed upon the quinine pills and creosote. I advised his going to southwestern Texas and he went on a farm near San Angelo. The letter advising his safe arrival there lifted a stone from me because of much opposition from relatives. He stayed there, at an altitude of near 1,800 feet—an altitude of 4,000 or 5,000 feet as at Denver would surely have brought on another, and then fatal, hemorrhage—till May, 1902. After the lapse of eight months he reported that with the best will he could send me no more sputa, because expectoration had ceased completely. Hereupon the creosote was withdrawn, but the pills were continued after his return home for six months longer. He then first settled near the shore of Peconic Bay because of the salt water air there, and some years ago he followed the factory wherein he worked up into Sullivan County. He has repeatedly said that since that time in Texas he had not expectorated any more.

The condition of the atmosphere as regards tuberculous patients may be divided into three principal groups, the dry air west and southwest, ocean air, and inland air. The latter two can be designated as moist airs. The air blowing in from the ocean contains, according to the strength of winds, more or less salt; the inland air can be called salt-free air. That inhalation of air containing these minutely divided particles of salt benefits sick lungs more than salt-free air is obvious. Nearby inland air may be separated into higher-up and lower. Contrary to general opinion, the air of higher regions, over 1,200 feet above sea level, contains more moisture, has more fog and clouds than regions below that. It is proven by the difficulties pianomakers experience with finer work which must be dry. They have more trouble up in Sullivan County than in Riverhead, L. I.

Another to me interesting case is that of Mrs. H., then of Jersey City. In contrast to Mr. A. D. she had a well developed chest, but was tuberculous and in the family way. With removal of some obstructions in the respiratory passages she was placed upon the pills, but these only. They then went to Massachusetts with earnest admonitions against further pregnancies, useless of course. When they returned again in February, 1906, the child, born in 1899, had gone through two operations for tuberculous ostitis of the left radius, with a resection about four inches long, but which had again begun to suppurate. Administration of the above mentioned pill in proper proportion had but little effect. But after three *x*-ray treatments the wound closed and remained well till their departure west in April, 1908. On leaving the mother took along a quite large supply of the pills because "they always did her so much good."

The third case, Mrs. M. R., age 53, is confirmatory of the preceding, although yet under treatment. Since a pleuropneumonia, about 19 years ago, she has suffered almost continuously from pulmonary, laryngeal, and for quite some time asthmatic troubles. She was placed, after a pulmonary hemorrhage in 1910, upon the pills and creosote. She went to live on the heights of Yonkers where she became very seriously ill, leading the family physician there to wonder how she could live with such a lung. Returned to New York and improving, it became important to find for her a place with suitable atmospheric conditions and not too far away. From personal experience and, too, observations I decided that she try the eastern part of Sheepshead Bay, L. I. The Bay, swept and cleansed by rather strong tides is there protected by a narrow strip of land from the sharpness of the air currents close to the outer shore, but ocean winds blowing in from east, south, and west produce there a quite salutary condition for lung diseases. When settled, prejudiced friends upbraided her against the well considered situation, whereupon she made two round trips from the bay, then a week in upper Brooklyn, and another on the Heights of Yonkers with the result that she found the bay to agree best with her. Tinged sputa occurred off and on especially after a longer interruption of this medication by arsenical treatment. With beginning of the winter she went to Lakewood, where she continued to improve so, she asserted at a recent visit, that she had not expectorated for two months, walked daily 5 miles, and had gained in weight. Actually her face is like a picture of health. This, then, signifies an essential check in the progress of the disease.

Concerning the osteomyelitis case, further suggestions were derived from the following. Last November a lady, Miss B., came to the office with suppuration from the posterior ethmoidal cells, thick yellow pus descending from behind the middle turbinated bone. Finding it to consist of staphylococci, administration of a stock vaccine produced in a few weeks disappearance of the pus, which has not reappeared up to the time of this writing. Instead an abscess developed three weeks later on the under side of the orbital arch near the nose, and at about the level of the ethmoidal fissure, suggesting a connection with the former abscess. Probing proved unsuccessful principally because of the presence there of an osteoma which made the eyeball protrude. This second abscess proved most recalcitrant to the treatment, so that necrosis of some of the bones there must have set in. Finally it too subsided, and at present no pus has appeared since a week.

Where, now, in spite of the protection by the outer hard layer of bone undoubted tuberculous invasion of the canals disappeared, under *x*-ray treatment added to the medicinal; and where in the previous case staphylococcal necrosis was arrested through its bacterin, at least so far, might not extension of these processes to other tuberculous foci in the osseous system facilitate, and perhaps much simplify their treatment as well.

319 West Forty-fifth Street.

A NEW CRUTCH FOR EXPOSING THE PERINEUM.

By CHARLES AUBREY BUCKLIN, M.A., M.D.,

NEW YORK.

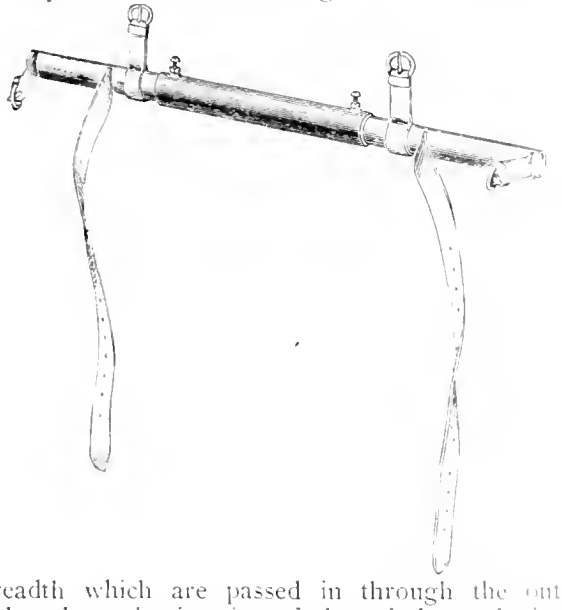
This crutch is effective in placing patients in position for operations on the rectum, anus, uterus, vagina, bladder, and urethra.

The metallic crutch shown in the illustration weighs two pounds and can be made lighter if desired. It can be carried in a bag ten inches long, and is capable of extending the distance between the knees from thirteen to twenty-one inches when required. This instrument is made of ready-made

materials, thus minimizing the cost of construction. It consists of a middle and two end pieces of light brass tubing each ten inches in length. The outside diameter of each end piece is one and one-half inches.

The form of these end pieces admits of dispensing with pads, it being recognized that less injury is done to tissues by pressure from round smooth metal surfaces than any other form of bearing. These metallic surfaces can be maintained in aseptic condition more perfectly than any cushioned surfaces.

At one-fourth of an inch from the outer extremity of each end piece is a transverse strap hole one and one-sixteenth inches in length and one-eighth of an inch in breadth. Spaced three inches from the internal edges of the external strap holes on the end pieces there are the adjacent edges of inner strap holes of the same size. The strap holes are in alignment, as shown, and receive straps twenty-seven inches in length and one inch in



breadth which are passed in through the outer holes along the interior of the tubular end pieces and out through the inner holes. The buckles of the straps are covered with leather and are left hanging from the outer strap holes. The strap ends thus hang outside of the knees entirely clear of the space occupied by the operator in his manipulations.

The end pieces being circularly adjustable, the operator can place the straps in any desired position; it is recommended that they be placed about the legs just below the knees. The buckles for receiving the ends of the neck traction strap are covered with leather and are spaced about 3 inches from the tubing, being attached to short straps which encircle the end pieces of tubing, and which, when the instrument is in use, rest against the two shoulders formed by the ends of the middle piece of tubing.

The neck traction strap is 56 inches in length and 1 inch in breadth. With this breadth of neck strap a pad is unnecessary. The short buckle-carrying straps are adjustable so that the line of traction of the neck strap is self-adjusting to the proper position. (See the illustration.) The middle piece of tubing has an internal diameter of 1¼ inches and accommodates the inner extremities of the end pieces of tubing. Within 1 inch from each end of the middle piece of tubing is an internally screw-threaded socket to receive a set-screw which is locked by a lock-nut. These six parts are ready-made pieces of brass. It is recommended to place these adjustable set-screws with their axes parallel with the line of traction of the neck strap in which position they are entirely away from annoying contacts. The set-screws have notched heads and are easily adjusted by the application of a small silver coin which serves as a screw-driver. Should it be desired to warm the crutch, the middle piece is removed and placed in boiling water for 3 minutes, which will warm the entire crutch sufficiently to remove the chilly sensations occasioned by unprotected skin coming in touch with cold metal.

With a portable crutch an operator is prepared to perform any perineal operation at a private house without any assistance to take charge of the patient's limbs, and in a more satisfactory manner than is possible with the use of a bandage.

23 Mansion House Road, Glasgow, Scotland.

Clinical Value of the von Pirquet Reaction in Children.—E. Merioz and B. Khalatoff tested 337 children in the Children's Hospital, Geneva, by means of the von Pirquet reaction. They got 175 positive results, that is 51.9 per cent. of the total. Of 189 clinically tuberculous children 143 reacted positively; of 78 non-tuberculous children clinically, there were 29 positive reactions. The authors believe that the conjunctival reaction is not safe in children and that the cuti-reaction is both safe and valuable as an aid to diagnosis. In an infant a positive reaction is rare, and gives information of great value. The nearer the child is to the adult age the greater likelihood is there of a positive reaction. In pneumonia with tuberculosis and in tuberculous meningitis the reaction may be negative just before death. In all negative cases a second test should be made.—*Revue Médicale de la Suisse Romande.*

Non-Tuberculous Hemoptysis.—Gabel and Gigoux have observed many cases of small repeated hemorrhages which are not necessarily caused by pulmonary tuberculosis. These hemorrhages do not consist of pure blood, but consist rather of blood-streaked mucus which appears after some slight effort such as clearing the throat. In these cases not only should the lungs be carefully examined but also the pharynx, larynx, trachea, and base of the tongue. In most instances the bleeding is found to come from small varices at the base of the tongue. Galvanocauterization of these spots will effect a cure. The varices are especially apt to be found between the ages of 40 and 50 years in women, in whom there are also found varicose veins of the leg or hemorrhoids. Small hemorrhages also result from congestion or inflammation of the pharynx, larynx, or trachea, occurring in Bright's disease, cirrhosis of the liver, and non-tuberculous pulmonary disease.—*Lyon Médical.*

Treatment of Backward Children by Associated Glandular Extracts.—R. Dupuy believes that he has reached valuable results in securing the development of backward children by the use of a combination of the extracts of thyroid, suprarenals, hypophysis, and genital organs, in cases in which thyroid medication alone was disappointing. This treatment causes an increase in height and weight, sensorial and psychic development; an increase in arterial tension, urinary elimination, and metabolism, and a disappearance of morbid phenomena such as enuresis and ocular troubles. This condition results from the presence of syphilis, tuberculosis, alcoholism, or malaria in the antecedents, the acute and chronic infections of pregnancy, premature delivery, overwork and privations of the mother, bad feeding and infantile maladies.—*Journal de Médecine de Paris.*

PROGRESSIVE LENTICULAR DEGENERATION.

PRACTICALLY a new nervous disease of which only six cases had been reported under various names previous to his own observations, is described by S. A. Kinnier Wilson in the *Lancet*, April 27, 1912. The first case was reported in 1888 by Gowers under the name of "tetanoid chorea, associated with cirrhosis of the liver." The author has had the opportunity of studying four cases of this disease, in three of which he made a post-mortem examination. Progressive lenticular degeneration is defined as a "disease which occurs apparently only in young people, which is often familial, but not congenital or hereditary; it is essentially and chiefly a disease of the extra-pyramidal motor system, and is characterized by involuntary movements, usually of the nature of tremor, dysarthria, or anarthria, dysphagia, muscular weakness, spasticity or hypertonicity, and contractions, with progressive emaciation; with these may be associated emotionalism and certain symptoms of a mental nature. It is progressive, and, after a lapse of a longer or shorter period, fatal. Pathologically it is characterized predominantly by bilateral degeneration of the lenticular nucleus, and in addition cirrhosis of the liver is constantly found, the latter morbid condition not giving rise to symptoms during the lifetime of the patient."

The most remarkable feature of this disease is the occurrence of advanced cirrhosis of the liver, in the causation of which alcohol and syphilis can be definitely excluded. The cerebral lesion is "a bilateral symmetrical softening of the lenticular nucleus, involving more particularly the putamen; the globus pallidus is implicated to a less extent. Sometimes the external capsule is partly included in the area of disease, whereas the caudate nucleus is scarcely touched directly, and the optic thalamus escapes. Most important of all, in a pure case, the internal capsule is absolutely intact." The bilateral involuntary movement of the extremities in this condition is of the nature of rhythmical tremor which increases with volitional movement. The pronounced spasticity of the muscles is partly expressed in the spastic smile and the contracture of the limbs, and also accounts for the dysphagia and dysarthria. There is little or no true paresis or paralysis. As regards the mental symptoms it is noted that there is a certain narrowing of the mental horizon, but within its limits the powers of perception and recognition are unimpaired. Increase of emotional reaction is not infrequently observed. This combination of symptoms forms what the author designates "the syndrome of the corpus striatum."

Wilson believes that progressive lenticular degeneration is the first definitely established morbid entity whose most striking characteristic is a specific association between disease of one of the viscera and disease of a particular part of the gray matter of the central nervous system. It seems that the disease is not due to a congenital or abiotrophic defect, and the presumption is strong that it is acquired. There is evidence that the disease is of toxic origin, and it is possible that the toxin is elaborated in the liver. Of peculiar significance is the fact that the toxin has a specific action on the lenticular nucleus.

THE SIGNIFICANCE OF THE PULSE RATE IN CARDIAC AFFECTIONS.

VIEWS as to the significance of the pulse rate in the diagnosis and prognosis of heart affections have undergone considerable change during the past few years. The teachings of Mackenzie, Einthoven, Lewis, and others of the so-called new school are mainly responsible for many new conceptions regarding the action and diseases of the heart and, of course, their studies have included investigations into the significance of the pulse rate. Recently, Sir T. Clifford Allbutt created somewhat of a stir in medical circles in Great Britain, by an address he delivered before the Chelsea Clinical Society (*British Medical Journal*, March 16). The Cambridge professor's address was deemed, at any rate by members of the new school, to be quite unduly pessimistic, and especially did he express himself as sceptical with regard to the significance of the pulse rate. In fact, he concluded that even marked changes in the rate and rhythm of the pulse have no constant significance in relation to myocardial damage. Einthoven also, who recently demonstrated the electrocardiogram before the Royal Society of Medicine (*Medical Press and Circular*, April 3, 1912), expressed the opinion that the work of the heart cannot be judged by the pulse.

On the other hand, Thomas Lewis (*British Medical Journal*, March 23) objects strongly to the statement of Allbutt that in the pulse we have no guide to myocardial damage and contends that irregularity of pulse is in itself evidence that the cardiac muscle has suffered functional change. He further states that heart block, extrasystole, auricular fibrillation, pulsus alternans, and so on can be identified with certainty and their pathological significance will soon be fully known, if the analysis is made in all cases of irregularity. No doubt in this connection, reference was made to the analysis of venous pulse curves rendered possible by the results of the studies of Mackenzie. Mackenzie himself speaking at the meeting of the Royal Society said that he regarded the pulsus alternans as a condition which is not rare but always of very grave significance.

Mackenzie and Lewis then, at any rate, seem to believe in the significance of pulsus alternans. Indeed Lewis goes further and appears to hold the

view that the pulse rate when properly analyzed is a fairly reliable criterion from which a diagnosis and prognosis of heart affection can be drawn. Mackenzie insists that a rational prognosis of heart disease must be based on a close idea of the manner in which any given symptom is produced. The physician must intelligently recognize the significance of a symptom ere he passes an opinion. The new school may claim more for its methods than as yet experience has justified. But it must be borne in mind that these methods are founded on discoveries which are now accepted generally. Even if all their claims may not be allowed it cannot be denied that they have pointed the way to newer conceptions and to a more rational treatment of heart affections. On the whole, Mackenzie and his followers are more likely to be correct when they give significance to the rate of the pulse in the diagnosis and prognosis of heart affections than those who minimize such significance.

SEX PEDAGOGY IN THE HIGH SCHOOL.

Questions relating to sex are very freely discussed at the present time, and it is well that they should be. The voluntary infertility of the women of the well-to-do and educated classes in this and other countries which is said to prevail is arousing much alarm. Also the spread of sexual immorality among the young is giving rise to grave misgivings. It is pointed out that in the history of defunct civilizations as of Rome and Greece, among the most significant signs of decadence were the restriction of the birth rate of the rich and cultured population and the omnipresent immorality.

By many the argument is made that so far as lack of morality among the members of the rising generation is concerned, if it does exist so widely as is confidently stated, it is largely due to existing modes of education. Dr. A. S. Warthin, treating of sex pedagogy in the high school, in Johnstown's High School Education, recently published by Charles Scribner's Sons, takes this view of the situation, at least as regards the Anglo-Saxon race. He asserts that the great failure of parents to teach the problems of the sexual life to their children has been all the more paradoxical in a generation which has so vaunted the value of knowledge and education along all other lines of thought. From this one path modern society, particularly the Anglo-Saxon, has continually turned away in foolish fear and prudery, hesitating to call things by their proper names and avoiding the main issue at all hazards. Modern medicine has, however, been the first to herald the new era, that of plain speech and frank education in sex matters. It has drawn attention to the diseases which must necessarily go hand in hand with sexual promiscuity, and to the menace of gonorrhea and its obvious relationship to pelvic diseases in women, chronic invalidism, sterility, and so on. The profound influence exerted by syphilis on public health generally has become so patent that even the laity are now fairly well acquainted with the ravages wreaked directly and indirectly by this dread malady.

According to Warthin the time is now ripe when the primary and secondary schools must include in their curriculum earnest and definite methods of teaching the ethics and hygiene of sex. Emphasis is laid on the point that the schools must imitate and carry out such teaching because something must be done and parents have acknowledged their weakness and inability to take upon themselves the role of teachers. The writer advocates that education in sexual ethics and hygiene be begun in high schools, for the reason that his experience has shown him that after this period of scholastic life it is too late. The harm has been done already. As for the nature and amount of such teaching Warthin is of the opinion that sex instruction should be constructive as well as negative and preventive. Not only must the moral and physical evils of vice be shown, but the ideal side and the higher significance of the sex relationship must be given with equal emphasis. A scheme of teaching is drawn up by the author which deals with the whole matter exhaustively on the lines indicated above.

There is no doubt that steps should be taken to remedy the existing state of affairs relating to sexual questions in this country. The evil is deep rooted, and doubtless the only effective manner of grappling with the problem is to point out plainly to the young the error and the folly of sexual vice and to prove to them that transgressions of this kind will inevitably lead to physical and moral shipwreck.

Intrauterine Respiration.

The relations between the fetus and amniotic fluid have always been the source of speculation, and the claim that the fluid collection in question has only a mechanical function has been received with more or less scepticism. The orifices of the nose and mouth are constantly bathed in it, and to a certain extent must admit it. This is not only evidence *a priori* but traces may be found in both the lungs and stomach under certain circumstances. The fetus is known to make inspiratory movements *in utero*, whether these be truly respiratory or merely uncoordinated anabolous acts; further, during the violent death of a fetus at term with unruptured membranes, the death agony should cause the inspiration of amniotic fluid. The presence of the latter in the lungs of the newly born has been commonly accepted as indicating the possibility of feticide. Haberda, in an analysis of over 200 cases of alleged infanticide, found amniotic fluid in the lungs in 25 per cent. It is doubtful, however, if this fluid means anything at all. Ahlfeld believes that the presence of the fluid as low down as the tracheal bifurcation has no significance whatever. Leaving this point out of consideration, the question arises, Is the entrance of amniotic fluid into the nose and mouth physiological or nonphysiological? It has often been alleged that the fetus derives some of its nutriment from this secretion. But how does it enter the upper air and food passages in bulk? At a meeting last December of the Niederrheinische Gesellschaft für Natur und Heilkunde, in Bonn (*Deutsche medizinische Wochenschrift*, April 4), Ungar read a paper on intrauterine respiratory movements. He stated that the old claim concerning the existence of physiological periodic respiratory movements of the fetus, defended for many years by Ahlfeld, had not been proved beyond doubt with the kymographion by Reifferscheid. If, as is alleged, the glottis closes during these coordinated movements, the fluid is

doubtless swallowed. The speaker added this inspiratory movement with closed glottis might disarrange the circulation of mother and fetus, causing in theory a disturbance of the placental circulation. Reifferscheid believes that the friction resistance of the amniotic fluid in the narrow fetal passages is too great to permit of much aspiration of the latter, which explains why as a rule it is not found below the bifurcation. The inference seems warranted that while intrauterine respiration actually occurs, we know little or nothing as to its significance.

Paranephritis and Perinephritis.

Medical literature appears to contain an increasing number of cases of abscess and free suppuration about the kidney. A number of cases are upon record in which small metastatic abscesses of the kidney, seated close beneath its capsule, have constituted the sole metastasis from ordinary furuncles, irrespective of their site and number. These abscesses may break through the fibrous capsule of the kidney and cause suppuration in the fatty capsule, which is followed by symptoms out of all apparent proportion to the infected area. In view of this singular sequence we are forced to believe that the common boil may infect the kidney, and that alone, more frequently than is commonly believed; but that in any case perforation of the capsule rarely occurs. Unless operation is performed very soon after the perforation, these cases are said to end fatally. On the other hand, suppurative paranephritis due to extension of a local infection in some other viscus is an equally important affection. As shown by a case very recently reported by Zondek before the Berlin Medical Society (*Deutsche medizinische Wochenschrift*, November 23), it may be difficult, supposing that the ordinary conditions of renal abscess can be excluded, to differentiate between such a paranephritis and a perinephritis due to perforation of a metastatic abscess, or direct infection by the hematogenous route. To complicate matters the *x*-ray showed the presence of a stone in the kidney. This, however, was deemed to be non-participating in the process. The urine was for all practical purposes normal and sterile, which seemed to exclude a process in the kidney itself. There was some history pointing to an affection of the stomach or pancreas. Operation showed that kidney and capsule were intact, and that the paranephritic tissue was the seat of suppuration traceable to the tail of the pancreas. The patient made a hard recovery. The calculi had to be left in the pelvis, which could not have been incised without grave danger of infection. The nature of the pancreatic infection could only be surmised.

News of the Week.

Cholera in Spain.—Three suspected cases of cholera have been reported in Barcelona, Spain, and energetic measures are being taken to prevent an epidemic. An intense heat wave has aggravated the situation.

Canal Zone Report.—The Department of Sanitation of the Isthmian Canal Commission reports that during the month of February, 1912, the total number of deaths from all causes among employees was 40, of which 29 were due to disease and 17 to violence, giving an annual average per thousand of 6.00 and 3.01 respectively. Among employees during the month the deaths from the principal diseases were as follows: Nephritis, acute and chronic, 5; dysentery, 1; hemoglobinuric fever, 1; lobar pneumonia, 5; malarial fever, 1; tuberculosis, 4; typhoid fever, 1. No cases of yellow fever, smallpox, or plague originated on or were brought to the Isthmus during the month.

Associated Out-Patient Clinics.—In response to a call issued at the suggestion of a representative of one of the dispensaries of New York City, a meeting was held in the Academy of Medicine on February 29 last, for the purpose of discussing general problems connected with dispensary work. As a result of the meeting a committee of five was appointed to consider the formation of a cooperative dispensary association having for its object the coordination and improvement of the work of existing dispensaries and out-patient departments in the Borough of Manhattan. This Committee on Temporary Organization, consisting of Mr. George L. Rives, chairman, representing the New York Hospital; Mr. Henry S. Van Duzer, Presbyterian Hospital; Rev. R. S. W. Wood, St. Bartholomew's Clinic; Dr. George L. Peabody, Northern Dispensary; Dr. S. S. Goldwater, Mt. Sinai Hospital, now invites the dispensaries and out-patient departments of the hospitals in this borough to join in an association to be known as the "Associated Out-Patient Clinics of the City of New York," and having the following general aims and purposes: (1) The coordination of the work of existing dispensaries and out-patient clinics. (2) The elimination of unworthy applicants for treatment. (3) The promotion of proper standards of treatment. (4) The promotion of economy and efficiency in dispensary management. Each member of the association will be represented at the general meetings by one delegate entitled to vote. The plans for the association already formulated include a long series of investigations into present conditions which will be of service in accomplishing its ends.

Quarantine Matters.—The Health Officer of the Port of New York announces the appointment of Dr. James F. Donnelly as boarding officer at the Quarantine Station, and the advancement of Dr. John M. Hall to the position of second deputy health officer, recently made vacant by the resignation of Dr. E. S. Rimer.

Health Officer of Boston.—A vacancy will soon exist in the position of chairman of the Board of Health of Boston, and the Mayor announces that he will consider applications from physicians, sanitary engineers, or other persons who are experienced in this field, irrespective of their present residence, provided only they are American citizens. The salary of the position is now $4,500 per year but the Mayor has recommended an increase to $5,000, and is willing to recommend more. The appointment is made by the Mayor, subject to confirmation by the Civil Service Commission and the new appointee will serve out two years of an unexpired term. The full term is three years. Applications should be addressed to Hon. John F. Fitzgerald, Mayor, Boston, Mass.

Another Centenarian.—Mrs. Winifred Farrell of East Orange, N. J., died on May 9 at the age of 104 years, never having known a day of sickness until she had passed her 102d birthday, and up to a few months ago retaining her eyesight and hearing unimpaired.

Fire in Laboratory.—A fire in the basement of the Carnegie Laboratory near Bellevue Hospital,

New York, recently caused some excitement in the neighborhood but was extinguished without much damage and without creating any disturbance among the hospital patients.

Graduates in Pharmacy.—At the eighty second commencement of the College of Pharmacy, Columbia University, New York, eighty-four graduates in pharmacy received their degrees, and eight other students received certificates of proficiency as food and drug analysts. The exercises were conducted by Vice-President Charles F. Chandler, and the address to the graduates was delivered by Rabbi Stephen Wise.

Insane Aliens.—The New York State Hospital Commission in a recent announcement places the annual cost to the State of the care of foreign born insane patients at $3,448,700. The State is now caring for 31,452 insane patients, of whom 42 per cent., or 13,163, are foreign born. In addition to these there are in the State hospitals for the criminal insane 1,230 patients, of whom 44 per cent., or 540, are of foreign birth. Since 1903 the number of foreign born patients in all the State hospitals has increased by 2,098, or 18 per cent. Nearly one-fifth of these patients were admitted to the hospitals before they had been in this country long enough to become citizens; they came principally from Austria-Hungary, Russia, and Italy.

University of Nebraska Medical Laboratory Building.—The Supreme Court of the State of Nebraska has recently handed down a decision confirming the act of the Legislature appropriating $100,000 for a laboratory building for the College of Medicine of the University of Nebraska, to be located in Omaha. This will permit of the removal of the first two years of the medical course from Lincoln to Nebraska, a plan which is in harmony with the report on the condition of medical education in Nebraska issued by the Carnegie Foundation, and which will establish the College of Medicine of the University of Nebraska in line with those of the Universities of Michigan, Iowa, and Minnesota.

Conference on Industrial Diseases.—The second National Conference on Industrial Disease will be held at the Hotel Marlborough, Atlantic City, on June 3 to 5, 1912, in joint session with the American Medical Association. The preliminary program which has just been issued includes series of papers and discussion on the investigation of industrial diseases, on health problems in modern industry, on State promotion of industrial hygiene, on industrial diseases, and on the preparation of an immediate legislative program for the promotion of industrial hygiene. A special feature will be an exhibit of photographs and charts illustrating the industrial processes dangerous to health as well as the effects of those work hazards known as diseases of occupation.

Health of New York.—For the week ending May 4, 1912, the death rate in New York City was 15.55, the total number of deaths being 1,542, a considerable decrease as compared with the corresponding week in 1911, when the rate was 16.76 and the total 1,661. Comparing the details of the two periods, it may be noted that the number of deaths from lobar pneumonia fell from 121 in 1911 to 112 in 1912, those from bronchopneumonia from 140 to 131, from pulmonary tuberculosis from 215 to 188, diarrheal diseases from 61 to 51, diarrheal diseases, under five years of age, from 60 to 45, and scarlet fever from 27 to 20. Deaths from diseases of the kidneys, on the contrary, increased from 89 to 128, from heart disease from 199 to 201, and from measles from 19 to 25.

Clinic at Randall's Island.—The Scientific Committee of the Medical Board of the New York City Children's Hospitals and Schools, Randall's Island, has arranged a public clinic at the island on May 20 at 2.30 P. M., which the members of the medical profession are cordially invited to attend. The program includes the presentation of a number of interesting medical and surgical cases as well as the results of statistical and other studies by the members of the attending staff.

Typhoid Epidemic.—The New York State Department of Health is investigating an epidemic of typhoid fever at Corning, N. Y. Over sixty cases had been reported up to May 7, and it is feared that an impure water supply may be the cause.

Charity Ball.—The Barlow Sanatorium of Los Angeles, Cal., an institution for the treatment of tuberculosis among the worthy poor of Los Angeles County, benefited by over $47,000 as a result of a charity ball benefit given recently. The institution will now be able to open ten additional beds which have been closed for two years, and thus increase the capacity of the sanatorium to forty.

Examination for Dental Interne. The United States Civil Service Commission announces an examination on June 5, 1912, to secure eligibles for the position of dental interne (male) in the Government Hospital for the Insane at Washington, D. C., at a salary of $600 per year and maintenance. Applicants for admission to the examination must be graduates of at least eighteen months' standing of a regularly incorporated dental college, and must be twenty years of age or over and unmarried. Further details may be obtained from the United States Civil Service Commission, Washington, D. C.

Animal Hospital.—The New York Women's League for Animals has purchased the property on the southwest corner of Lafayette and Bond Streets, New York, and will erect thereon a building to be used as a permanent hospital for animals.

Sanitary Aid for Chile.—The Government of the United States through the State Department has signified to the Chilean Government that it will be glad to aid the latter in any way in putting down the yellow fever epidemic at Tecopilla. The suggestion had been made that some of the sanitary experts employed in the Canal Zone might be allowed to advise in the matter of sanitation in Chile, but this may not be possible, as the Panama experts are army officers and can not be sent to a foreign country except by special act of Congress. The matter of sanitation in all the South American countries, however, becomes of greater importance to the United States as the Canal approaches completion.

Health Week in England.—The week beginning April 28 was celebrated in England as "health week," that is, a week marked by organized public advocacy of the simple rules of health. The program began with sermons in many churches on the importance of cleanliness, and during the week lectures were given in forty towns throughout the country. It is proposed to repeat the experiment next year.

New Typhoid Serum.—Professor Metchnikoff announces the discovery as a result of his investigations with Dr. Broughton Alcock of a new vaccine against typhoid fever which is prepared with

living instead of as formerly with dead cultures of the bacilli. The bacilli are impregnated with the serum of animals immune against typhoid fever. The serum has proved very successful in protecting both human beings and chimpanzees. The first injection consists of about 500 million typhoid bacilli, and the second, which is given eight or ten days later, is two or three times as large.

Gifts to Charities.—By the will of the late Henry Iden of Pelham Manor, New York, a bequest of $10,000 is left to the New York Society for the Relief of Ruptured and Crippled. St. Christopher's Hospital of Brooklyn receives a bequest of $5,000 under the will of the late Henry C. Hulbert of that city. By the will of the late John Torrance Bannock of New York, who died recently at Cannes, France, the sum of $50,000 each is left to the Post-Graduate Hospital of New York and the Montreal General Hospital.

Col. William C. Gorgas, chief sanitary officer of the Isthmian Canal Commission, reached New York recently on his annual leave. He will deliver lectures in several places on the sanitary work and conditions in the Canal Zone.

Dr. David Linn Edsall, professor of hygiene and preventive medicine in Washington University, St. Louis, has been elected Jackson professor of medicine in the Harvard University Medical School, Boston, and chief of one of the two medical clinics at the Massachusetts General Hospital.

Dr. William F. Verdi of New Haven, Conn., has been reappointed surgeon-in-chief to St. Raphael's Hospital, in that city, a position which he formerly held but resigned two years ago.

American Medico-Psychological Association.—The annual meeting of this association will be held at the Marlborough-Blenheim Hotel, Atlantic City, on May 28-31, under the presidency of Dr. Hubert Work of Pueblo, Col. The secretary is Dr. Charles G. Wagner of Binghamton, N. Y.

Central Illinois District Medical Society.—At the annual meeting held in Pana on April 30, the following officers were elected: *President*, Dr. C. E. Munson, Springfield; *Vice-Presidents*, Dr. A. F. Turner, Taylorville, and Dr. L. C. Littlejohn, Oconee; *Treasurer*, Dr. J. N. Nelms, Taylorville; *Secretary*, Dr. Walter Burgess, Pana.

Houston County (Texas) Medical Society.—The following officers were elected at the annual meeting held in Crockett on April 30: *President*, Dr. R. W. Skipper, Lovelady; *Vice-President*, Dr. J. S. Wooters, Crockett; *Secretary*, Dr. W. W. Latham, Porter Springs.

Wyandot County (Ohio) Medical Society.—At the annual meeting officers were elected as follows: *President*, Dr. I. N. Bowman; *Vice-President*, Dr. G. O. Maskey; *Secretary-Treasurer*, Dr. Frederick Kenan, all of Upper Sandusky.

Ninth District (N. C.) Medical Society.—At the organizing meeting held in Salisbury on May 2 and 3, the following officers were elected: *President*, Dr. Isaac M. Taylor, Morgantown; *Vice-President*, Dr. C. M. Van Poole, Craven; *Secretary-Treasurer*, Dr. C. B. McNairy, Lenoir.

Kansas State Medical Society.—At the annual meeting held in Hutchinson recently, officers for the ensuing year were elected as follows: *President*, Dr. George M. Gray, Kansas City; *Vice-Presidents*, Dr. Clemens Klippel and Dr. Horace G. Welsh, Hutchinson, and Dr. G. A. Blaisdell, Garnett; *Treasurer*, Dr. L. H. Munn, Topeka.

Louisiana State Medical Association.—The following officers were elected at the annual meeting which, in spite of reports to the contrary, was held as arranged on April 24 and 25: *President*, Dr. B. A. Ledbetter; Vice-Presidents, Dr. E. G. Chandler, Shreveport; Dr. George F. Bel, New Orleans, and Dr. J. Adams, Monroe; *Secretary*, Dr. J. D. Martin, New Orleans; *Treasurer*, Dr. Maurice Gelpi, New Orleans.

Obituary Notes.—Dr. William S. Cheesman of Auburn, N. Y., a graduate of the College of Physicians and Surgeons, New York, in 1879, a member of the American Medical Association, the New York State and Cayuga County Medical Societies, and the Auburn Medical Society, and attending surgeon to the Auburn City Hospital, died at his home after a long illness on May 7, aged 59 years.

Dr. Dwight B. Neal of Little Rock, Ark., a graduate of the Hahnemann Medical College and Hospital of Chicago in 1887, died at his home suddenly on April 17, aged 55 years.

Dr. Jacob F. Hudson of Canton, Ohio, a graduate of the Western Reserve University Medical College, Cleveland, in 1882, and a member of the American Medical Association and the Ohio State and Stark County Medical Societies, died at his home after a long illness on April 24, aged 50 years.

Dr. Lindsey T. Lowder of Bloomington, Ind., a graduate of the Medical College of Indiana, Indianapolis, in 1874, and a member of the American Medical Association and the Indiana State and Monroe County Medical Societies, died at his home on April 21, aged 66 years.

Dr. Robert Tracey of Belleville, Ontario, Canada, a graduate of the Faculty of Medicine of Queen's University and Royal College of Physicians and Surgeons, Kingston, in 1862, one of the founders of the Belleville Hospital, and for many years Medical Health Officer of the city, died at his home after a long illness on April 20, aged 70 years.

Dr. Tomes Thams of McVille, N. Dak., a graduate of the University of Christiania, Norway, in 1873, died at his home on April 23.

Dr. John S. Kennelley of Longmont, Col., a graduate of the College of Physicians and Surgeons of Keokuk, Ia., in 1880, died at his home on April 23, after a long illness, aged 59 years.

Dr. Daniel McLaren Miller of Oconomowoc, Wis., a graduate of the College of Physicians and Surgeons, New York, in 1856, surgeon of the Twenty-eighth Wisconsin Regiment during the Civil War, and a member of the Wisconsin State and Waukesha County Medical Societies, died at his home on April 25, aged 76 years.

Dr. John W. Logan died at Marion, Pa., on May 4 at the age of 75 years. He was graduated from the Medical College of the State of South Carolina in the class of 1859.

Dr. Jacob M. Lipschutz of New York, a graduate of the College of Physicians and Surgeons, New York, in 1905, assistant laryngologist to the German Poliklinik, radiographer to Lebanon Hospital, and visiting physician to the Sanatorium for Hebrew Children at Rockaway Park, and a member of the Eastern Medical Association and the Medical Society of the Borough of the Bronx, died suddenly at his home on May 8, aged 28 years.

Dr. William Bennett Pierson, formerly of Brooklyn, N. Y., a graduate of the College of Physicians and Surgeons, New York, in 1852, died suddenly at his summer home in Huntington, L. I., on May 10, aged 86 years.

Correspondence.

PROFESSOR AGRAMONTE AND THE ETIOLOGY OF YELLOW FEVER.

To the Editor of the Medical Record:

Sir:—In the Medical Record for March 30, 1912, Professor Agramonte has attacked me and my recent paper on the etiology of yellow fever ("Yellow Fever Bureau Bulletin," November, 1911) in terms which ought not to enter in a scientific discussion, and which I therefore prefer to leave unanswered. With regard to the question, whether I have discussed in a fair manner or otherwise the work of the U. S. Army Commission, I would simply ask readers to compare the statements in my paper with those of Agramonte. Leaving aside non-essential discussions, two points remain to be considered.

Agramonte is offended because I have said that the experiments of Reed, Carroll, and Agramonte are not absolutely conclusive, not having been carried out in a non-infected country, as were the corresponding experiments in malaria and pappataci fever. In this opinion I do not stand alone, as Agramonte well might know. The question cannot be resolved by an appeal to authorities, nor can it be modified by the objections which can be raised against a repetition of the experiments. Agramonte says that the danger of such experiments should restrain experimentation within certain limits, a quite unnecessary remark as directed against me, since I already said just the same in my paper which Agramonte criticises. But if moral objections prevent conclusive proof from being obtained, relative proofs do not become as a consequence conclusive.

The remark that the prophylactic results "stare the least observing in the face" is of a similar nature, namely entirely superfluous and misleading as giving the impression that I had not emphasized this important fact in my paper. The truth, however, is that I mentioned the results obtained by antimosquito measures as constituting the most important corroboration which the theory has received.

Next, as to the bodies which I have described as blood parasites in yellow fever cases and therefore presumably the pathogenic germ in this disease. The question of their existence cannot be resolved by Agramonte nor by anybody else on the strength of *a priori* reasoning as to the period during which the parasites ought to be present in the blood, or the like. It is simply a question of observation, and here we arrive to the only real point in Agramonte's criticism. He did not feel convinced by examining the specimens which I showed him: this opinion I must respect, though still preserving the hope that he may change his opinion on some future occasion. I must, however, at the same time claim respect for my statements also. Agramonte may differ in his opinion as to the significance of the bodies demonstrated, but he has seen these bodies and he has no right whatever to throw doubt on my statements about the numbers of cases in which similar bodies have been observed.

When mentioning the demonstration in Havana, it does not seem fair to convey the idea that the impression which Agramonte, according to his paper, received was that of all gentlemen present. Agramonte might have added that at least one distinguished colleague, who had been present during the whole time of the demonstration and had seen all the specimens demonstrated and not four only, as Agramonte declares that he saw, gave as his opinion that the bodies presented were decidedly parasite-looking, but with regard to their importance suggested the possibility that one might have to do with innocent parasites living in the blood of the inhabitants of Yucatán. I may possibly be wrong in my interpretation of my observations, but as to the existence of the bodies there can be no doubt, and during my present investigations in Yucatán I have found them again and again.

Harald Seidlin, M.D.

(From Our Regular Correspondent.)

DISCUSSION ON ALCOHOL IN THERAPEUTICS—RHEUMATOID ARTHRITIS — NURSING EXHIBITION — AMEND-THE-ACT LEAGUE — OBITUARY.

London, April 26, 1912.

A discussion on alcohol in any of its numerous aspects holds out little promise of novelty. Even the question whether it has any value as a remedial agent is a subject on which many will despair of finding new arguments. Yet most practitioners seem to hold a distinct opinion, one way or other. Sir Victor Horsley has a very strong opinion on the subject which he expressed with considerable decision in opening a discussion at the Hunterian Society. He remarked on the great decrease in the use of it in hospitals that he had observed and which he attributed to our increased knowledge. But, he said, it is still prescribed—sometimes as a stimulant, whatever is meant by that, sometimes as a narcotic, and now an then as a tonic. The stimulation he looked upon as merely the lowering of the control of the highest centers. The narcotic action was undoubted.

He could not speak from his own experience of its effect in pneumonia, but believed it was regarded as a sheet anchor some twenty-five years ago. He might have said twice as long, for medical history tells of the way in which it was poured into patients by Dr. R. B. Todd and his followers in this and other febrile and inflammatory conditions. The effect in pyrexia, Sir Victor said, was the sum of the effects on the infective process and on the increased catabolism. There was abundant evidence that resistance to infection was lowered by alcohol. It diminished the complement in the blood, inhibited phagocytosis, lessened the resistance of the red corpuscles and the bacterial power of the body fluids. All this it did in very small quantities. As to nitrogenous destruction, Max Gruber had shown it increased destruction of proteid at first, but after a fortnight or more immunization occurred and it acted as a proteid sparer. But even so it was of no therapeutic advantage, for as the metabolism was lowered so would be the resistance to disease. The net result, therefore, would be unprofitable and the clinical experience of fever hospitals shows this to be the case. He supposed most surgeons had given up its use in shock. The experiments on the isolated heart were not uniform. Though some had reported an initial increase of work with minute quantities and a paralysis with larger dosage others had found a fall from the very first. Normal contraction was restored by replacing the alcohol with dextrose, proving the superiority of the latter as a foodstuff for the heart. The use of sugar in armies had illustrated this fact. Sir Victor objected to alcohol as a remedial agent on account of its tendency to set up the habit.

Professor Cushny made the statement that he had no very strong conviction against the use of alcohol. As a drug he knew it had no specific action, but it often gave relief to sufferers. He looked upon experiments on the isolated heart, unprotected as it was by the plasma, as of uncertain value. He had always found weakened pulsation from the outset in animals, and in man they must dismiss the idea of alcohol being a stimulant of any value. But he could not agree that it was a deadly poison in infective processes. Intoxicant doses rendered rabbits more liable to infection and he thought all must admit the same was the case with man. Perhaps very moderate drinking could not be shown to lessen resistance to infective agents. He thought alcohol, chloral, opium, and so on were of use to patients in making their lives more comfortable, and he did not think many cases of alcoholism were the result of its medically prescribed use.

Dr. F. J. Smith used it sparingly in hospital, though he had seen it given in the old excessive style. Moderately it induced hope, in some cases restored appetite and thus was a distinct tonic. In the experiments quoted the hearts were not in normal conditions. Moreover animals before experimentation were abstainers.

Dr. T. B. Hyslop, as President of the Society for the Study of Inebriety, with great experience in lunacy, had often had the question before him. He said alcohol, chloral, aromatics, and other drugs exerted a deleterious effect on brain cells. The so-called "night cap" he regarded as specially injurious. The hypnosis produced by alcohol was in the nature of autointoxication for the oxygen used to eliminate it was taken from the supply available for oxidizing the waste products of metabolism. This accounts for the fact that after a sleep induced by alcohol the person feels very tired on waking. In asylum practice alcohol had been practically eliminated from therapeutics and also from the dietary.

One member after 30 years general practice found something to say for whisky or brandy in a few cases. Another asked if the local stimulant effect on the mouth, gullet, etc., might not have an influence, but this Sir V. Horsley replied must be very fugitive.

Rheumatoid arthritis has been discussed at the West London Medical Chirurgical Society and various views put forward. The President, Mr. McAdam Eccles, offered as a definition of this troublesome disease—arthritis of many joints, chiefly the smaller, due to absorption of a toxin, and usually affecting females more than males. A cause must be sought in the blood stream which carried the infective agent to the joints. Dr. Poynton took up one point—the demonstration that a micrococcus which he held to be the cause of acute rheumatism would produce in animals different types of arthritis. He showed lantern slides of acute transient arthritis, osteoarthritis, and periarticular arthritis, and emphasized the fact that suppuration had not occurred in any of these examples. The different lesions depended on the severity and duration of the arthritis which was set up by intravenous inoculation. The joint lesions could not be made to differentiate a case from acute rheumatism. The lesions he showed were not produced by direct infection of joints (a plan, he thought, of little value) but of intravenous inoculation. There was a perivascular fibrosis in the capsule of the joints to which he attributed the tendency to atrophy and consequent stiffness. From numerous examinations he inclined to the view that organisms of the streptococcal and also of the staphylococcal groups might produce the lesions, but cultures from diseased human joints were hitherto negative and so progress was slow. On the whole he thought rheumatoid arthritis was the result of many infections.

Mr. Jones Llewyllen had seen cases which had been preceded by vasomotor phenomena identical with Raynaud's disease.

Dr. Lloyd-Williams had much to say on oral sepsis as a source of arthritis and a condition which, if removed, often alleviated the joint affection. Pyorrhea alveolaris is a form of osteoarthritis itself from many points of view. Dr. Middleton submitted a paper in favor of counterirritation as the most effectual mode of treatment. Blisters, croton oil, acetic acid, acupuncture, galvanocautery, the whole armory of counterirritants had no value for him, and he gave few drugs. He had used thyroid, however, and also found baths and massage do good. He did not approve of breaking down adhesions or of encouraging early movements when improvement began. He had treated hundreds of cases by spinal blistering. This plan required experience to make the best of it. Dr. Horder sent a contribution on vaccino-therapy in this disease, which he thought had recently given favorable results. He objected to the ordinary name and would call it multiple arthritis. In this he is supported by Dr. P. King, who had stated that the disease was microbic before the bacillus had been discovered. Dr. E. H. Shaw did not believe in a single bacillus. He had used different vaccines successfully. Organisms from the joints and also from other regions (mouth, nose, cervix, rectum, etc.) could be employed. Dr. Rice Oxley related a case benefited by inoculations. Dr. Dauber remarked on the fashion of blaming oral sepsis for many diverse conditions. He had examined the mouth of every patient at the woman's hospital for five years and not 1 per cent. could be called clean. A yeomanry regiment he examined gave a cleaner average with general good health, but there were many foul mouths and there had not been a case of rheumatoid in the regiment for five years.

Dr. Kidd objected to experiments on animals being put forward as applicable to the question. The effect on infectivity had been considered, but he asked would it diminish the vitality of the pneumococcus? He knew it did of gonococci.

The fifth Nursing and Midwifery Exhibition has been held this week, closing to-day. Instruments, appliances, and contrivances of every kind useful to the modern nurse have well illustrated the progress that has been made. A folding cradle for a crippled child made out of a box gained the first prize in the inventions. The second was awarded for a leg-rest which permits a change of the bandages without moving the leg. The third prize was won by an arrangement for carrying two trays. Cinamatograph illustrations of nursing work were shown as helps in teaching. A model day and night nursery attracted much attention. It showed how an infective child could be nursed in isolation and provided with all necessaries and even amusements.

The Amend-the-Act League is in full swing. In the first nine days 10,000 members were enrolled, and the offer to send speakers into the country accepted by 250 places.

Col. F. Casement Reeves, late of the Indian Medical Service, has died suddenly at the age of 50. He entered the army Medical Department in 1870 and took part in the Afghan war in 1880, for which

he was awarded the medal. He was employed in various ways until 1885 and afterwards in the Assay Department of the Bombay mint as well as other official posts. He qualified at the Irish Royal Colleges in 1878.

OUR LETTER FROM PARIS

(From Our Regular Correspondent)

ACTION OF ALCOHOL ON THE ORGANISM — THE MECHANISM OF RETENTION IN PROSTATICS — TREATMENT OF VESICOVAGINAL FISTULÆ BY SUTURE OF THE BLADDER THROUGH THE SUPRAPUBIC ROUTE — RADIOGRAPHY OF TUMORS OF THE BLADDER — OBITUARY.

PARIS, March 23, 1912.

GOUGET has made an interesting study of the action of alcohol on the organism. Alcohol has no exciting influence on the kidneys, whether it be employed in small or large dose. On the contrary, it produces a vascular spasm and paralysis of the secretory function of the renal epithelium. It does not favor diuresis but rather diminishes it. The increase of the amount of urine consecutive to the introduction of alcohol into the stomach along with a large amount of water does not depend on renal stimulation, but on the acceleration of action caused by the rapid passage of so much water into the blood. Alcohol accelerates the absorption of water by stimulating gastric and intestinal peristalsis. Thus the use of alcohol should be discouraged in alimentation, while its employment as a medicine is perfectly justifiable. In small doses alcohol stimulates the heart and raises pressure in such a way that it is indicated in conditions of collapse and in certain infectious maladies.

At the Paris Society of Surgeons there was discussed an interesting question as to the mechanism of the retention of urine in prostatics. Bonneau thinks that there are several different forms of the disease classically called hypertrophy of the prostate: hypertrophy of one of the two lateral lobes of the prostate, hypertrophy of the median lobe, paraureteral adenoma, and old sclerotic prostate. Besides the anatomical causes that prevent the passage of urine there exist still other dynamic causes not well known, aside from true mechanical obstacles, which in a reflex way disturb the function of the posterior urethra. Nogués thinks that the essential cause of retention is the loss of extensibility of the walls of the urethra under the influence of the hypertrophy. The walls of the prostatic urethra have no pliability and cannot stretch under the effect of the jet of urine. Pasteau thinks that in the pathogeny of retention in prostatics we should study three factors: (1) Mechanical causes which depend on the hypertrophy itself, and which increase the retention of the canal; (2) local congestion which results from the preceding causes; (3) diminution of the expulsive force of the bladder due secondarily to the prostatic lesions. A relative inhibitive action is certain as is proven by the integral return of function after prostatectomy. As to the retention by the mechanism of the ring in hypertrophy of the median lobe of the prostate, Lance believes that this mechanism can rarely be invoked. Lefur thinks that aside from the mechanical lesions of the prostate there are other reflex and inhibiting causes very numerous, which explain the mechanism of retention in prostatics. The affections in which we may observe vesical retention from purely reflex and inhibitive causes are the following: Hemorrhoids, obstinate constipation, interrupted coitus, and prolonged coitus. The very important congestion in prostatics provokes consequences which bring to the fore the reflex and inhibitive influences causing retention.

Genouville thinks that the obstacle in the prostate is the only primary cause of prostatic dysuria. Enfeeblement of vesical contractility is only a secondary prostatic obstacle. The bladder is susceptible of taking up again its function when the condition is suppressed which constitutes for it an insurmountable obstacle. With reference to the treatment of vesicovaginal fistula by suture of the bladder by the subpubic route, Chevassu presented a patient in whom he obtained a cure of a rebellious vesicovaginal fistula by a transvesical operation. Suture by the transvesical route can only be an exceptional method, but we can make use of it with advantage in case of fistula of the upper part of the bladder. The height of the bladder allows us to see the fistulous orifice. Considering the published cases, out of 20 cases of complex vesicovaginal fistula, there have been 16 cures. Hartmann thinks that it is nevertheless easy to operate with success by the vaginal route in vesicovaginal fistulæ.

Radiography of tumors of the bladder was considered by Legueu, who has applied the principle of the radiology of the stomach to the pathological exploration of the bladder. By filling the bladder with bismuth milk we may follow its contours with radiography. We may thus obtain the radiograph of tumors of the bladder if large. On the black medium of the bismuth bladder the vesical tumor appears light; we can see its volume, the irregularity of its contours, and its point of implantation. Here we have a new application of radiography which is destined to extend advantageously the actual results of clinical and cystoscopic research, especially in what concerns the volume of tumors.

Eugene Caventou died recently, a member of the Academy of Medicine, who was a chemist, modest but very distinguished, and who had made important discoveries in organic chemistry. He belonged to the section of pharmacy of the Academy from 1870. In 1879 he was elected treasurer, and in 1897 he was made president. Most of his experiments were in the laboratory of Wurtz, of whom he was a most zealous collaborator in the Dictionary of Chemistry, in which he signed a large number of articles.

Progress of Medical Science.

1. The Influence of Antivivisection on Character. W. W. Keen.
2. Dr. Samuel Sheldon Fitch, a New England Consumption Specialist of Seventy-five Years Ago. By H. F. Stoll.
3. Cerebrospinal Meningitis Caused by Acti in the Blood. D. G. Hall.
4. Remarks on a Series of One Hundred Cases of Vaginal Hysterectomy for Uterine Fibromata. C. G. Cumston.
5. Medical Gymnastic Treatment in Certain Circulatory Disturbances. G. Sundelius.

1. **Antivivisection and Character.**—W. W. Keen states that the policy of vituperation indulged in by the antivivisectionists cannot but have a debasing effect upon the character of these partisans, who are thereby ill fitted to form a sound and safe judgment upon the subject about which they preach. Much of their fervor is the result of ignorance. A second reason for believing that antivivisection injures character is that, by putting a greater value on the well-being and the lives of monkeys, guinea-pigs, rabbits, dogs, cats, mice, and frogs than on the lives of human

beings, it fosters a spirit of cruelty to human beings.

3. **Meningitis and Acidity of the Blood.**—D. G. Hall states that one of the etiological factors in the production of epidemic meningitis is an excessive acidity of the blood. In this respect meningitis bears a striking resemblance to rheumatism. Both diseases were equally prevalent in Texas during the past winter.

4. **Vaginal Hysterectomy for Uterine Fibromata.**—C. G. Cumston states that in uterine fibroids the principal factor in the selection of the route to be resorted to seems to be the size of the growth and the roominess of the vaginal canal. When the uterus is larger than a fetal head the abdominal route is to be selected, for otherwise morcellation of the growth must be resorted to when vaginal hysterectomy is undertaken, an operative procedure which is always to be avoided when possible. If, for certain reasons, vaginal hysterectomy is to be preferred and the birth canal is narrow, one may resort to a deep lateral vaginal incision on either side of the rectum. After the hysterectomy has been done, these incisions are closed with sutures, and apparently do not complicate the operative results. Postoperative hemorrhages from the small arteries of the vagina have been occasionally reported, but the author has never observed this complication. To those familiar with both the abdominal and vaginal route it cannot be denied that the shock is much greater when the former is used. Perfect freedom in mobility of the uterine growth and uterus is absolutely essential when the vaginal route is to be resorted to. The author has always used the clamp-method. There is less shock in the vaginal than in the abdominal operation.

New York Medical Journal.

May 4, 1912

2. **Salvarsan and the Wassermann Reaction.**—M. L. Heidingsfeld states that salvarsan, though not an unfailing remedy, is by far the most effective present day agent for the treatment of syphilis. It effects an apparent clinical cure, with negative Wassermann reaction, in about 80 per cent. of the cases treated. A fair share of the remaining 20 per cent., with the aid of mercurials and repeated administrations, give promise of still proceeding to a negative Wassermann test in due course of time. Salvarsan fails utterly in probably more than 1 per cent. of the cases. From the author's personal experience, salvarsan cannot effect any material harm and can be safely administered in ambulatory practice; the administration of salvarsan has not been followed by complications on the part of the ocular and auditory apparatus, with possibly one exception. In this instance, it is probable that syphilis, and not salvarsan, was the causative factor, inasmuch as the Wassermann test remained strongly positive in character. Readministration of salvarsan did not aggravate but apparently cleared up the condition. The diagnosis and treatment of syphilis without Wassermann control and other specialized aid must be unscientific and, in a large degree, unsatisfactory in character.

3. **Diagnosis of the Prolonged Fevers.**—M. Manges states that twenty years ago, given a case of prolonged fever, the diagnosis would lie between malaria, typhoid fever, tuberculosis, obscure suppuration, and if one wished to be ultrascientific, cryptogenetic sepsis. Today, in spite of the differentiation of many clearly defined types of prolonged fever, there are still many unexplainable cases. These are not infrequently the cases in which irregular fever persists for years without any cause being discovered. The more the fever problem is studied, the more complex it becomes. Thus Ehrlich would explain the occurrence of fever in some salvarsan injections as being due to the liberation of endotoxins of the bacteria during the sterilization of the water which was used in the injections. Hale White has reported cases in which the taking of carbohydrate food brought on attacks of fever of 102 and 104 F., lasting almost a week, until the temperature gradually returned to normal. Finkelstein's alimentary fever is mentioned. Finally, there remain those mysterious cases of nervous and hysterical fever, the authenticity of which cannot be doubted. In some of these cases of supposed nervous fever, especially in neurasthenic blondes, the fever may be the prodromal symptom of tuberculosis. The first disease to be thought of in the differential diagnosis of any continued fever is typhoid fever. When the Widal reaction remains negative two possibilities should be considered, namely, trichinosis and acute miliary tuberculosis. Next to be considered is chronic infective endocarditis, the recognition of which in the majority of cases affords striking evidence of the great advance in our knowledge of obscure febrile conditions. The prolonged irregular fever, the cardiac changes, leucocytosis, petechiæ, infarcts, the positive blood cultures, etc., are familiar to all. Osler has laid stress upon ephemeral nodules which appear irregularly in the skin of the hands and feet. It has been largely overlooked that syphilis may give rise to irregular prolonged fevers. Neoplasms, especially if their growth is rapid, may be accompanied by fever. The fever of gallstones, with few ill-defined local symptoms, is well known. So, too, abscess of the liver may run a latent course for a long time until the upward enlargement and the local tenderness appear. Another cause of obscure hepatic fever of long duration is acute hepatitis without suppuration. This is cured by multiple aspiration. Hodgkins' disease is frequently accompanied by irregular attacks of more or less prolonged intermittent fever. Leucemia is accompanied by fever, which may be quite prolonged in duration. Pernicious anemia may be associated with such marked fever that erroneous diagnoses of typhoid fever have been made. The possibility of the colon bacillus being the cause should be considered in every case of obscure prolonged fever. The systemic or hemic infections with the colon bacillus may be divided into three groups of cases: (1) Those which run a course somewhat resembling typhoid fever; (2) those with secondary abscesses or pyemia, and (3) the terminal infections. Of the other innumerable conditions giving rise to prolonged and obscure fevers the author mentions the following commoner ones: Tuberculous peritonitis of a low grade with few signs; localized pleural empyemata, deep seated small foci in the tonsils and lymphatic glands, oral sepsis, etc. Subphrenic abscesses which are indefinitely defined without any antecedent etiological factors may tax one's skill to the uttermost. Even with definite signs of suppuration such foci may escape detection, in spite of frequent and searching aspiration. Another type deserving mention is the unilateral hematogenous infection of the kidney.

6. **Deep Pétrissage of the Abdomen in the Diagnosis of Tapeworm.**—R. J. Cyriax states that by deep abdominal pétrissage is meant a series of circular movements executed in the direction of the large intestine with sufficient energy to cause a thorough kneading of the abdominal contents. In carrying it out, it is essential that the abdominal parietes and the fingers of the operator move as one over the underlying viscera, otherwise the process is resolved into a mere superficial effleurage, which hardly influences the viscera. It is not necessary for the pétrissage to be

executed very hard in order to achieve the desired end, and unless the technique is defective, it should cause no pain. When properly performed it presumably effects the dislodging of the proglottides in two ways: by promoting peristalsis and by mechanically separating segments of the distal end of the parasite by tearing through their attachments. Of these two actions, the latter is probably by far the more important. The increased peristalsis seems to act only as an adjuvant in expelling the separated segments, and probably no intensity of it can actually dislodge the head of the worm; nor does it seem possible to reach the point of achieving this by the merely mechanical effect of the petrissage. The latter is, therefore, only a means of diagnosis as regards tapeworm infection, and cannot replace the usual curative treatment. The advantages maintained for this method of establishing a diagnosis of tapeworm are as follows: (1) It is entirely harmless, and reveals worms in some cases in which purgatives alone have apparently not been successful; (2) it does not interfere with the patient's regular work, and causes no discomfort worth mentioning. As a general rule, only about three or four applications of deep abdominal pétrissage, each of fifteen minutes, duration, are required to establish a definite diagnosis; (3) it abolishes the unnecessary administration of purgatives, alone or in combination with anthelmintics, in cases where they are contraindicated; (4) it is apparently uniformly successful.

Journal of the American Medical Association.

May 4, 1912.

1. **Treatment of Fractures.**—M. L. Harris states that the first thing in the treatment of fractures is to bring about a perfect reduction or adjustment of the ends of the bone, and it is only by the *x*-ray that this can be certainly demonstrated. It should not be forgotten also that this readjustment may not be permanent, even with a suitable fixation dressing, and constant vigilance is required. In many cases perfect reduction is impossible, and the question of an open operation arises. Formerly this was considered a serious procedure, but improved methods of technique have changed this. The technique of opening the peritoneum is a simple matter compared to the opening up of a fresh fracture, and the utmost care should be taken to insure proper technique and perfect asepsis. While, as a rule, the metal plate is the best mechanical device, there are exceptions, as in the case of fractures of the patella and the olecranon, in which passing wires around the fragment is better. In some cases also traction apparatus is required. Fractures of the neck of the femur are generally hopeless as regards perfect union, but in some cases this may occur, and the Whitman method of traction and fixation in marked abduction is undoubtedly the most important improvement in the non-operative treatment of these cases, and next in importance is the Maxwell method of longitudinal and transverse traction. Even these improved methods have not been as successful as desired, and the author describes the open method of treatment of these cases by nailing the detached portion of the neck of the bone. In cases of this kind the extension apparatus is also valuable.

2. **Antityphoid Vaccination.**—F. F. Russell concludes that: 1. Antityphoid vaccination in healthy persons is a harmless procedure. 2. It confers almost absolute immunity against infection. 3. It is the principal cause of the immunity of the troops against typhoid in the recent Texas maneuvers. 4. The duration of the immunity is not yet determined, but is assuredly two and one-half years, and probably longer. 5. Only in exceptional instances does its administration cause an appreciable degree of personal discomfort. 6. It apparently protects against the chronic bacillus-carrier, and is, at present, the only known means by which a person can be protected against typhoid under all conditions. 7. All persons whose professions or duty involves contact with the sick should be immunized. 8. The general vaccination of an entire community is feasible and can be done without interfering with general sanitary improvements, and should be urged wherever the typhoid rate is high.

5. **Experiments with Bismuth Pastes.**—F. McK. Bell states that bismuth paste as a drainage for acute suppurating sinuses is painless and efficacious, but does not assist in rapidity of cure. When a sinus shows sluggishness, if 5 per cent. iodoform is added to the bismuth paste it is much more stimulating to granulations. As a packing and drainage for localized intraabdominal and pelvic sinuses, bismuth paste is safe, painless, rapidly curative, prevents the formation of pockets of pus, lowers temperature and to a limited extent prevents postoperative adhesions. It may be used as an aid to diagnosis in fecal fistulas as well as act as a curative agent. In large cavities requiring four or more ounces of paste it should be watched carefully for symptoms of bismuth or arsenic poisoning. Unless there is free exit for paste it is dangerous. Bismuth "stones" may form in a closed sinus. In clean wounds or those discharging seropus the application of the bismuth paste retards healing and tends to establish chronic conditions. To get results, the author says, the discharge should be frankly purulent.

10. **Proctoclysis.**—H. H. Trout concludes from his experiments as follows: All patients show less rectal irritation to proctoclysis is given a saline enema before the operation. The patients given water by rectum absorbed nearly 400 c.c. more in the twenty-four hours than did the patients given salt solution, the average for the water series being 2,444 c.c. per twenty-four hours, the average for the salt series being 2,041 c.c. per twenty-four hours. The patients given salt solution by rectum required nearly twice as much water by mouth to relieve thirst, or to give exact figures, in the water cases only 332 c.c. were taken in the first twenty-four hours; in the salt cases 600 c.c. were required in the first twenty-four hours. The amount of urine was practically the same in both classes of cases, there being 2 c.c. more in the water cases for the first twenty-four hours after operation and 3 c.c. more in the salt cases for the next twenty-four hours. In seventeen cases the patients complained of tasting salt without having any idea that normal saline solution was being given by rectum. None of the water series made any such complaint. In drainage cases more fluid may be taken by rectum than in those laparotomies closed without drainage. Proctoclysis should be employed more frequently than it has been in the past and in all classes of cases in which it is possible. Care should be exercised to prevent "water-logging" of the entire system, and this applies to both salt and water. In peritonitis cases with drainage it is possible to have the patients take four or five times as much fluid by rectum as in the cases on which the author's observations are based.

The Lancet.

April 27, 1912

1. **Tuberculin.**—A. Latham states that his experience of the last six years, which includes several hundred cases, has led him to form the impression that the careful use of tuberculin gives valuable results in the treatment of pulmonary tuberculosis. Its use is not attended by any dramatic effect in occasional examples of febrile phthisis or laryngeal tuberculosis, nor does its use tend to hasten the apparent arrest of the disease or shorten the length of treatment required, except in certain instances in which the patient is just holding his own but is making no real progress. On the other hand, tuberculin, in conjunction with ordinary methods, will lead to the disappearance of tubercle bacilli from the sputum in a larger proportion of cases than ordinary methods alone, and in the author's experience diminishes the number of relapses, or, in other words, establishes a higher degree of immunity. In view of these facts, he agrees with those who hold that the best treatment for pulmonary tuberculosis is tuberculin treatment in conjunction with what is called sanatorium treatment, either at a special institution—as is necessary in a considerable proportion of cases—or at home.

2. **Progressive Lenticular Degeneration.**—By S. A. K. Wilson. (See page 946.)

3. **Treatment of Opium Poisoning by the Faradic Current.**—F. Taylor states that in cases of opium narcosis one may apply the faradic current to accomplish the same results as slapping the patient or compelling him to walk the room. The experience of cases shows that the unfavorable condition of somnolence may be increasing some hours after the ingestion of the poison, that it will increase again after temporary amelioration by lavage or "rousing"; and it is not safe to leave a patient semi-comatose until the difficulties of his respiration impel one to perform artificial respiration. He should as soon as possible be aroused or awakened, and kept aroused until it is morally certain that the sleep will not pass again into a serious condition of coma. And this can be done by the faradic current, as efficiently as by any other means. In cases in which the coma has reached a stage threatening life the faradic current should be applied persistently, in spite of the entire want of response during the first 30 or 40 minutes, other than the contraction of muscles.

4. **Treatment of Uterine Hemorrhage.**—B. Whitehouse states that it can indeed be truly said with regard to uterine hemorrhage that the keystone of the therapeutic arch lies in a correct diagnosis. Uterine bleeding must be considered as a symptom only, and no stone must be left unturned to ascertain its cause. With this in view it is not sufficient to limit the examination to the pelvic organs. The abdomen must be examined for evidence of hepatic enlargement, the blood pressure must be accurately measured, and the condition of the vessel walls should be ascertained. Evidences of syphilis or other constitutional disease should be looked for, and if possible the calcium index should be estimated. The condition of the heart, lungs, and thyroid gland must be noted, and if circumstances permit, a bacteriological examination of the uterine blood should be conducted. If the uterus is sterile, and no other cause is found to account for the bleeding, then one may confidently recommend curetting as a therapeutic measure. Individual treatment will, of course, depend upon the condition diagnosed. Thus, where the bleeding is due to a high arterial blood pressure the tension must be reduced by purgation, nitroglycerine, and dieting. Purgation will also have its place in depletion of the portal circulation where hemorrhage is due to hepatic cirrhosis. If the calcium index is low menorrhagia will probably be benefited by the administration of this agent, preferably in the form of the lactate. In the case of bacterial infections the author has obtained good results by intrauterine applications such as peroxide of hydrogen, Churchill's iodine, or protargol. Treatment in these cases must be thorough and prolonged. The curette under such circumstances should be absolutely tabooed. Finally, in cases in which hemorrhage is due to rupture of degenerated vessels in the uterine wall, hysterectomy appears to be the best and safest procedure. Howard Kelly devised a partial hysterectomy for similar cases, and it was introduced into England by Victor Bonney under the name of "utriculoplasty." So far the operation, in London at least, has received but little support, the general opinion being that if hysterectomy is required to relieve severe bleeding, it is preferable to perform the complete operation. If all patients suffering from excessive uterine bleeding could receive the benefit of a detailed examination before resort is made to the curette, the author feels sure that it would lower the 20 per cent. of failures found in these cases, and help to prevent the operation of curetting from falling into discredit.

2. **Mechanism of Shock.**—H. T. Gray divides surgical shock into three stages: (1) The stage of stimulation, or the pressor stage; (2) the stage of depression, or the depressor stage; (3) the stage of equilibrium, when active abnormal afferent impulses are in abeyance. It has been shown that every sensory nerve contains pressor and depressor fibres to the vasomotor center, stimulation of the pressor fibres only, induces reflex vasoconstriction and cardiac acceleration, while stimulation of the depressor fibres only induces reflex vasodilatation, and at the same time inhibits vasoconstrictor impulses. Stimulation of such a mixed sensory nerve usually induces domination of the pressor group. Domination of the depressor group only occurs when the depressors are fatigued. Prolongation of the stimulus during the depressor stage leads to: (1) Continuous lowering of blood pressure, which lowering renders inadequate the blood supply to the cardiac muscle through the coronary arteries, and this fact, combined with the lack of peripheral resistance, leads to delirium cordis, and (2) anemia and starvation of the central nervous system, which if carried to a sufficient degree render impossible the recovery of the centers.

3. **Estimating the Strength of a Vaccine.**—J. A. Braxton Hicks states that one may obtain a Gram-positive and Gram-negative "standard" by diluting and plating out processes which he describes. These "standards" keep good for at least six months. One should then take equal parts of the emulsion of "unknown" strength and a "standard" of opposite Gram-staining properties and mix thoroughly. A film is then made, fixed carefully, and stained by Gram's method, using a counterstain. One should count 200 or 300 bacteria, using a "counting square" and a one-twelfth objective and noting the Gram-negative and Gram-positive organisms in the squares counted

knowing the strength of the "standard" and the proportion of Gram-negative to Gram-positive organisms, the strength of the unknown emulsion is easily worked out by proportion.

Generalizations Concerning Tuberculosis.—Romer as a combined result of experimental and epidemiological study gives five fundamental generalizations in regard to tuberculosis. (1) Nearly every member of a given community becomes infected with the disease in childhood, but the great majority withstand its effects. This great truth, long held on insufficient evidence by some authorities, has been demonstrated by the introduction of the newer diagnostic tuberculosis tests. Localities with high tuberculosis mortality show hardly any higher percentages in this respect than those with reverse conditions. (2) Tuberculous animals show relative immunity to subsequent infection with the disease. The author refers here to experimental tuberculosis caused by the human bacillus. (3) Tuberculous human beings are similarly resistant to repeated infection. This should be the case *a priori* because no exceptions have thus far been found in the animal kingdom. It has been shown in a few cases of inoculation of cancerous patients. Finally it is in harmony with clinical and epidemiological finds, evidence of immunity being everywhere apparent. What was once believed to be natural immunity is now known to be very largely acquired immunity. (4) The less widely distributed the disease in a given community, the greater is the relative mortality. For example, in troops who come from localities where tuberculosis is uncommon, we note a much higher deathrate than in those who come from well infected localities. (5) Pulmonary consumption is due to a massive autoreinfection of a relatively immunized organism originally infected in childhood.

Recent Developments in the Treatment of Eczema.—Alexander states that radiographic treatment of chronic eczema has been proved to be the most efficacious and most convenient of all plans. The quartz lamp is also valuable in certain obstinate cases. The old ointment treatment is still useful as an adjunct, and the tarry oils both in salves and lotions are used largely in all obstinate cases. In late years the tar of the distillation of anthracite coal has been largely used. There is a tendency to polypharmacy in some quarters, and a combination of wood tar, coal tar, resorcin, sulphur, camphor, menthol, borax, etc., in a lanolin base is recommended especially in obstinate eczema in childhood. While it is admitted that eczema stands in a causal relation with diathesis, metabolic disturbance and autointoxication, it cannot be said that attempts to reach the condition through internal medication and diet are as successful as might be expected. Finkelstein's attempts to cure the eczema of nurslings by special milks have thus far done little to usurp the position of external therapy.

Clinical Results with Thorium Emanations.—Plesch has reached a number of positive results with this substitute for radium emanations. Cardiac dyspnea is said to be at once relieved, and this relief persists for a long period. The emanations lower the blood pressure, but we do not yet know the mechanism of this action. The relief from dyspnea has been seen in pneumonia, angina pectoris and other conditions. Among other affections favorably influenced were such varied conditions as gouty paroxysms, suppuration in the accessory nasal sinuses, leucemia and certain cases of rheumatism. The thorium is given in solution only, this being luminous in the dark. The best mode of administration is by intravenous injection of 1 c.cm.

Therapeutics of Cold in the Head and Its Complications.—Lindenmayr for the past twenty years has invariably contracted cold in the head as soon as the winter cold is sufficient for a pronounced temperature difference between the heated room and the external air. The pharynx participates with a vexatious cough irritation. This disturbance lasts throughout the cold weather, and no permanent relief worth mentioning has been obtainable. The measures tested have been cocainizing the nose and throat, insufflations of powders and solutions containing borax and menthol, inhalations, etc. The only relief secured was through opiates—morphine and codeine. These mitigated the unpleasant sensations in the head and lessened the profuse secretion, without, however, affecting the course of the disease. The inflammatory symptoms, furthermore, always left in their wake the impulse to cough, and even the slightest fluctuations of temperature caused convulsive paroxysms, to control which several daily doses of morphine were sometimes required. Enough morphine was used to cause unpleasant effects, such as insomnia. Codeine had not these drawbacks but its action was much more feeble. Volland, of Davos, who has warmly recommended morphine for cases of this sort, gives from 10 to 15 drops of a 1 per cent. solution. Apparently some of the newer synthetic derivatives of morphine and codeine are indicated naturally in cases of this character; the author, however, does not appear to have made any systematic trial of any of these substitutes.

Metaparalytic Psychogenous Akinesia.—Toby Cohn uses this term to throw light on the nature of certain cases of facial palsy. He has already made public that in many cases of this affection, notably in childhood, complete return of electric conductivity is not attended by return of function or by complete return of the same. The condition is not quite the same as akinesia from disuse, although very similar. An analogous state of affairs is seen in certain cases of acquired deafmutism which persists without adequate reason. In all such cases the return to the normal is effected by reëducation. It does not follow that in all these cases there is a psychogenous inhibition for there are many mild cases of facial palsy in which nothing of this sort can be placed in evidence. These cases recover in a short time. Such cases are by no means peculiar to the facialis, and in fact may occur in any peripheral nerve. The psychogenous form described by the author appears to be peculiar to the facialis. Since the latter is the chief mimetic nerve and in intimate relationship with ideomotor manifestations it should be very largely dominated by psychogenous influences. This, however, does not appear to be the author's rationale for the existence of the phenomenon, but rather that of one of his critics.

Treatment of Acute Spastic Bronchitis in Early Childhood.—Goppert states that this affection is often looked upon as practically an infantile asthma, in which the inflammatory factor is naturally more in evidence than in older subjects. The infant after developing a slight catarrh in the bronchi is seized suddenly with dyspnea and impending suffocation. Instead of cyanosis, however, a death-like pallor supervenes. Cyanosis may be present before the age of four months but not afterwards. The spastic phenomena may persist for one or two days and when they finally subside only a slight bronchitis still persists. To relieve the spasm the author depends on a clysma containing chloral but always with the fear of overaction of the remedy. The patients are spasmophilic by nature and a milder antispasmodic is desirable. Of possible substitutes the author only mentions urethan for which antiasthmatic properties were once claimed. He has used it once with favorable effects and it is believed to be safe.

Chemotropism in Neoplastic Tissue.—Von den Velden's researches have shown the existence of a tropism

on the part of neoplastic tissues to arsenic, and it remains to be demonstrated whether or not this fact can be utilized in therapy. We know that cancerous tissue in the animal organism holds a special position in virtue of its altered chemical composition, of the presence of heterolytic ferments, of its feeble resistance to various chemical and physical irritants. Hence there are present chemical reaction possibilities and affinities which are not to be encountered in normal tissues. It is the province of chemotherapy to learn these affinities. In this connection, however, results have been obtained with potassium iodide which show how slight the differences are between the organotropy to tumors and that to normal tissues. This fact is becoming more and more corroborated, and seems to militate against the employment of many substances which in theory should possess the greatest significance. It is beginning to be held that chemotropism may be only a biophysical property due to alterations in diffusibility, which in turn depend on the texture of the colloid envelopes of the cells. Ostwald terms this subject the "membrane problem."

Radiotherapy of Uterine Myomata.—Falk states that if myomata, even large ones, show no marked tendency to hemorrhage they do not require treatment of any sort, but only close watching. In rapidly growing myomata the *x* ray treatment is contraindicated. The knife is indicated, irrespective of the condition of the heart. Neither are submucous myomata suitable for *x*-ray therapy. In young women myomata which bleed profusely should be subjected to operation and only exceptionally treated with *x*-rays. The latter act upon the tumors only through their effects upon the ovaries in causing artificial climacteric. In a surgical operation the ovaries may be left intact. In myoma with adnexa disease the rays must be used very cautiously, for they are contraindicated if inflammation sets in. Specially suited to *x*-ray treatment are interstitial myomata in women over fifty years of age. Gräfenberg, whose article follows Falk's, dissents from the latter's view of the indirect action of the rays. He claims that the latter directly affect the myomatous tissues. The indirect procedure is indeed the one to employ first, but it may fail to affect the ovary. Again, operative castration does not always cure myoma. This appears to show that the rays have a direct action on the tumor cells, a fact in harmony with what is already known concerning the direct radiography of neoplasms.

Ratbite Disease in the New World.—Proescher of Pittsburg, who has made an extensive research into the older literature of this affection, naturally described without any special designation, finds more cases on record in North America than in Europe. At first the affection was believed to be endemic in Japan and China. Cases appear in American medical literature as far back as 1840 (Wilcox, Watson), and are found again in 1868 (Gilliam), 1871 (Packard), 1872 (Earle), 1885 (Cook), 1886 (Banker), and 1902 (Evans). Others have been reported under their proper designation in the past two years, so that there are now seventeen on record in the United States. In the older literature two cases were reported in France in 1884 and one in Spain (1885). In the past year or two four cases have been reported in England and one in Italy. This makes an even twenty-five cases, which shows plainly that the affection is practically world wide. The author himself reports a personal case.

Münchener medizinische Wochenschrift.

April 23, 1912.

O-Legs and X-Legs.—Francke employs these vernacular terms to designate certain degrees of bowleg and knock-knee. He has long noted that many children outgrow both these deformities and that a large proportion of Bavarian women are knock-kneed to the point of deformity. He cites an expert opinion that these malformations were unknown to the ancient Greeks. In order to obtain light on the subject he made measurements of about 1100 individuals without using any sort of selection. The limbs were classed as o-legs, x-legs, and parallels. In reality, perfectly straight legs are impossible, and what are so called commonly are the mildest degrees of x-legs, while the legs which are technically most nearly straight are the mildest degree of o-legs. The latter always convey the impression of powerful members, well able to support the body, while x-legs sufficiently developed to be noticeable give the opposite impression of weak, insecure members. If in a natural relaxed position of the limbs the knees and ankles touch evenly without forcing, the subject has straight legs. If with the ankles touching there is as much as 2 cm. between the knees, the subject has o-legs in the first degree. If the distance measures 2-4 cm. the second degree is present. If with the knees touching, the ankles are 2 cm. apart, the first degree of x-legs is present, and beyond that the second degree. The author does not consider cases of either extreme with distances above 4 cm. The material measured included practically all ages. The conclusions formed from the measurements are in part as follows: The shape of the legs in respect to lateral deviations varies considerably with the individual's age and development, especially during childhood. Children born with o or straight legs tend to become x-legged while learning to walk. This persists for many years, and as a rule disappears in men up to the twenty-third year, occasionally up to the thirty-eighth year, perhaps in twenty-five per cent. Women, on the contrary, tend to remain x-legged throughout life, as a result in part of their wearing-apparel and partly because they never exercise and have weak muscular development. The absence of x-legs in the ancient Greeks and in savage tribes is due to the opposite conditions. In other words, x-legs in the adults are one of the consequences of civilization. In a general way, the author says, the presence of x-legs tends to imply physical inferiority.

Human Tails.—Schwarz refers to the work of Bartels in 1884 in compiling and digesting all the literature of this subject. He found upon record 116 cases of so-called tailed individuals, of which a considerable number had occurred in the female. The author has sought to extend the work of Bartels to the present day, but is able to find less than half a dozen new cases, including one of his own. It will be recalled that Bartels recognized no less than five different formations described as tails, viz., 1. The true tail, composed of accessory vertebræ, which could be regarded as atavistic outright or as a mere instance of supernumerary bones. 2. An apparent persistence of the embryonal tail, which is composed of soft tissues only. This may be explained by arrested development. 3. The so-called adherent tail—a caudate formation characterized principally by its want of isolation from the underlying sacrococcygeal structures. Like the preceding form, it may be reckoned among anomalies due to arrested intrauterine development. 4. A long, thin, free formation commonly known as a pigtail. A bone component, if present, shows no differentiation into vertebræ. Its existence may be accounted for on the score of embryonal overgrowth, the normal incitation to growth being accentuated. 5. This is a stump tail like class 2, but is characterized by the presence of differentiated and ossified vertebræ. Of the cases reported since Bartels, one by Virchow was an example of adherent tail, while Schaeffer's case was a pigtail and Waldeyer's case seems to have been an example of class 2, the so-called short, boneless tail. Finally, the author's personal case, the observation of which suggested this article, must be included among the pigtails. It occurred in a newly born male child.

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS

BY THE INSURANCE EDITOR.

THE PHYSICAL EXAMINATION.

THE PULSE.—The pulse rate should not exceed 90 according to the requirements of most companies. It should be counted for a full minute, so that the frequency, quality, and rhythm may be determined with accuracy. It is advisable to observe the pulse and the condition of the arteries at the beginning of the examination before the circulation becomes accelerated through nervousness excited by the exploration of the chest.

Rapid Pulse.—The exciting cause in the majority of cases of rapid pulse is pure nervousness and likely to occur in healthy subjects. This nervousness is so pronounced at times that it may even bring on syncope, and it is not a very uncommon event for some robust individual to faint when the stethoscope is applied to his chest during an examination for life insurance.

At other times a pulse will become quickened in consequence of a hurried walk or rapid ascension of the stairs just before the examination. Then, again, the condition may easily arise as the result of the loss of a night's rest, a recent meal, or the drinking of strong coffee or tea.

On the other hand, a *persistently* rapid pulse usually indicates some organic trouble such as tuberculosis, diseased kidneys, arteriosclerosis, exophthalmic goiter, some early change in the brain or nervous system, or the excessive use of coffee, tea, tobacco, or alcohol. These conditions must be definitely excluded even in those cases in which the examiner finally succeeds in getting a pulse rate at 90 or under, but experiences difficulty in doing so.

Slow Pulse.—A pulse rate as low as 45 or 50 is of no consequence unless it is associated with changes in the walls of the heart or blood vessels, or with some cerebral disturbance. While these conditions should be carefully excluded after looking especially for fatty and atheromatous changes, it will be found that the slow pulse in most instances is functional in character.

Intermittent and Irregular Pulse.—Both of these conditions may be attributed to the same causes which accelerate the action of the heart. Many of the companies do not regard an intermittent or irregular pulse very seriously, even if persistent, in an individual under forty years of age and within the normal limits of weight, provided pathological lesions and foci of irritation in all the organs have been eliminated by a rigid scrutiny of the case. When the pulse is intermittent or irregular in an applicant over 40 or one who is a light or heavy weight, the risk should not be recommended unless the examiner is successful in finding a normal pulse later on.

The reluctance of the companies to insure risks with rapid pulse, so different from the attitude adopted in regard to the acceptable cases of intermittent or irregular pulse referred to in the preceding paragraph, is not difficult to understand. The intermittent or irregular action when purely functional, does not indicate any appreciable amount of extra work by the heart, whereas the never ending tax exacted from that organ during persistent rapid action is enormous. Every one would prefer to have the number of his heart-beats average under 80 than at some figure close to the upper border line, though both rates fall within the normal limits. What is to be expected when the rate exceeds 90? A heart averaging one hundred beats a minute will pulsate 14,400 more times a day than if it worked at the already high rate of 90. After making due allowance for the usual compensation for the regular every day labor, it is quite safe to assume that the organ will show the effect of this continuous strain when the supreme test comes during illness or accident.

Taking the Pulse.—The best time to take the pulse is after the questions on the application blank have been answered and before beginning the physical examination. While the examiner is plying the applicant with questions, the latter will be seated and his mind will be occupied in giving the requested information; he will, therefore, have a chance to recover from the effects of any unusual exertion or from the nervousness excited by novelty or dread of the examination. If the taking of the pulse is deferred until after the examination, it will have often become disturbed in consequence of excitement combined with the efforts called for by the examiner. Even when this precaution has been observed the pulse may be still found too rapid, or irregular or intermittent, on account of the nervousness. In this event, the mind of the applicant must be diverted by drawing him easily into conversation on some ordinary topic; this will answer the purpose better than giving him a paper or book which he will apparently read but the chances are that his thoughts will still be running on the prospects of the examination. If the last plan fails to succeed there is no alternative to seeing the applicant again in a day or so when he will have probably become more accustomed to a visit from the examiner. It is usually better if the visit is made unexpectedly instead of giving the subject chance to become apprehensive again.

Nervous applicants with disturbances of the pulse should be handled gently and receive all necessary attention, for if a slower and regular pulse is finally obtained and there is nothing more serious to account for the transient agitation of the circulation, they are acceptable and it would be manifestly unfair and unjust to debar them from the privileges of securing insurance on their lives by sending in an adverse report without making an endeavor to find them in their normal condition. In order to achieve this end, the examiner should be willing to give extra time and not spare any effort in clearing up the case.

When the examiner is finally forced to report a persistently rapid pulse, or one that is continuously intermittent or irregular in an applicant over 40 years of age or outside the normal limits of weight, he should not omit to state whether this finding was based on one or several observations. The home office will invariably ask for a further examination in these cases when there is nothing in the report to indicate that the examiner has made at least one subsequent attempt to find a normal pulse.

The Importance of the Family History.—At a meeting of the life division conference of the Insurance Institute of Hartford, on February 29 last, Dr. Arthur B. Wright, medical director of the Travelers' Insurance Company, discussed medical aspects of insurance and especially the important part played by family history of an applicant in influencing the physician's decision as to his fitness for insurance. In the early days of insurance good

health and appearance in the applicant and no evident tendency to disease were alone required. Family history and remote disease were not considered. At the present time the medical department is an important part of a life insurance company. The home office medical men have charge of the appointment of examiners, indulge in vast correspondence with them in order to elucidate the doubtful features of a life risk, discussing with and trying to pacify the agent in regard to declined risks, making trips to the various agencies, becoming personally acquainted with the field examiners and re-examining many of these cases, which only too often result in corroborating the findings of the original examiner. Many are the borderline cases requiring judgment, and unless the doubt can be dispelled, through correspondence and in every conceivable way, that element must be decided in favor of the company. Great stress is brought to bear by the agent when a penalty is imposed on any of his cases, even to eliciting the aid of the higher officers, and the argument is generally to the effect that the particular risk is a picture of health, is active in his business affairs, is a man of standing in the community and is financially in a good position. Family history plays an important part. One or more deaths from tuberculosis in a family, together with under-average weight, calls for a rejection by some companies or an advance in premium in companies doing a sub-standard business. Also early deaths from degenerative diseases such as apoplexy, Bright's disease, diabetes, arteriosclerosis, and organic heart disease. Where there is a history of two cases of insanity or cancer, a modification is generally called for. Personal history is also important. There appears to be a consensus of opinion that one attack of acute articular rheumatism is not a menace, but a history of two attacks must be taken into consideration. Attacks of appendicitis without operation, past history of syphilis, gall or kidney stones, gout, asthma, pleurisy, fainting spells, colics, fistula, etc., are all important and must be thoroughly investigated. As for the daily use of liquor, many applicants are prone to overestimate and are not liable to strike a mean average, while others are liable to underestimate. In deciding this question, the medical department has the assistance of the inspection report, which is made up by a layman. This lay report also assists greatly in determining the hazard as to occupation, financial responsibility, standing in the community, reputation, morals, whether the home life is pleasant and so on. An important aid in passing on medical examination reports is having a personal acquaintance with the examiner, particularly as to his competency. Too often the reports are meager. Therefore the necessity for correspondence and delay. There is no grave objection to using the family physician as an examiner except that occasionally he feels he is divulging confidential information regarding his patient. Wright says that it has been the experience of the medical department of the insurance company with which he is connected that the family physician not only makes a good examiner but is willing to give the company the benefit of all the inside facts pertaining to the case.

At the present time there is being worked out a mortality experience. It is the result of the combined efforts of the medical directors and the actuaries, about forty-five companies now working along these lines. The object of the organization is to promote medical science as applied to life insurance by presentation of papers, discussion and other methods.

A Clearing House for Health Departments.—Robert Lynn Cox says that life insurance companies are now realizing that they have greater responsibilities to the public than formerly. Consequently it has seemed that if they are to take part in the public affairs of the country at large, they might give consideration to the question of the death rate. So discussion of the question was begun, and one year ago it led to the establishment of a Health Bureau in the Association of Life Insurance Presidents. The health question is made part of the regular work. It was thought desirable to have information at first hand from the men looking after the health of the country. It was further thought that the way to obtain this information was to write to ask for it. Copies of annual reports were requested and any information concerning the activities and accomplishments of these men. Letters to this effect were confined to cities of over 5,000 in population, which made up a list of 540. To the surprise of the bureau only 126 replies were received. As it was imagined the purpose for regulating this information might have been misunderstood, further letters were sent explaining that the general interest of the bureau was more or less identical with that of health officers and asking if they would inform the bureau what they were doing in this line. Eighty-three replies were received to the follow-up letters. So the bureau heard from 209 health departments representing cities of 5,000 population or upward in the attempt to organize what might be termed "A Clearing House for Health Activities." The answers received were wholly unsatisfactory, and seemed to show that the chief thing to be said about the health work throughout the country is that the majority of health departments are inadequately equipped; that the men are inadequately paid, and are expected to do much more than they can do with the funds given to them. The speaker was of the opinion that a clearing house is not so much needed for the dissemination of information, as for stimulating interest and activity.—*Report of the Eleventh Annual Conference of Sanitary Officers of the State of New York.*

Mortality in Switzerland.—Bohren gives some data from the last census report for Switzerland. He says that decrease in mortality, which has been noted in Germany during the last half of the last century, is also marked in Switzerland. The following table gives the comparative figures of expectation of a life for children born in one of the three periods named:

	1876–1880	1881—1888	1889—1900
Males	40.6 years	43.3 years	45.7 years
Females	43.2 years	45.7 years	48.5 years

The lowering of mortality is especially marked in youths and young adults. Infant mortality, which is very high in Germany, is more favorable in Switzerland and has shown a tendency to become lower with each period.—*Zeitschrift für die gesammte Versicherungs-Wissenschaft*, March 1, 1912.

Italy's Ban on Foreign Insurance Companies.—The officers of the Paris Bourse have refused to list any Italian securities so long as that Government continues its repressive measures against foreign life insurance companies.

Book Reviews.

Pleurisy, Including Empyema and Bronchiectatic Conditions. By Alex. James, M.D., F.R.C.P.E., Consulting Physician to the Edinburgh Royal Infirmary and to the Edinburgh City Hospital. With Illustrations. Price $2.25. New York: William Wood & Company, 1911.

Dr. James states in his preface that he is "one of those who maintain that while the detection of a germ in a disease process is important enough the interpretation of the conditions which have permitted it to invade a tissue and to carry out there its morbid effects is immensely more so." In accordance with this thought Dr. James considers much more fully than is usually done the etiology of pleurisy, the anatomical and physical environment in which the disease occurs, and its predisposing and immediate exciting causes. Previous lung disease and such accidental causes as exposure to cold, trauma, disease of the neighboring structures, etc., are fully considered. A statement of physical signs and symptoms follows, numerous original observations or explanations being given by the author.

Similar presentation of empyema and of bronchiectatic conditions is given, such rarer conditions as streptothrix and leptothrix empyemata being described. A very conservative chapter on the medical and surgical treatment of pleurisy and empyema closes the book. Dr. James's volume is more the expression of one man's knowledge and observations than an exhaustive statement of other people's work. Its value, therefore, lies in stimulating original observation, and it should prove of greater worth to the advanced student of pulmonary disease than to an undergraduate.

Surgery and Society, A Tribute to Listerism. By C. W. Saleeby, M.D., F.R.S.E., Fellow of the Obstetrical Society of Edinburgh; formerly Resident Physician Royal Infirmary and Resident Surgeon Maternity Hospital of Edinburgh. Price $2.50 net. New York: Moffat Yard and Company, 1912.

The recent death of Lord Lister increases to a large extent the interest in his work at this time. This book reviews the progress of modern surgery and explains in detail its great debt to Lister. The work is a commendable addition to the list of publications designed to inform the general public on medical topics and is executed in quite an interesting and entertaining manner. The author has succeeded in restraining his enthusiasm to a large extent, though it still is irritating at times. The book is one of his best.

Manual of Practical Physiology, Designed for the Physiological Laboratory Course in the Curriculum of the American Association of Medical Colleges. By John C. Hemmeter, M.D., Ph.D., LL.D., Professor of Physiology in the University of Maryland, Baltimore; Member of the Deutsche Physiologische Gesellschaft. Price $2.50 net. Philadelphia: P. Blakiston's Son & Co., 1912.

This manual is designed to furnish the largest possible amount of practical physiology to the medical student in the limited time allotted and yet to cover that ground with the necessary thoroughness. The author has succeeded in devising a logically graded course which covers the ground in excellent fashion. The directions are adequate and the discussion is well advised. The illustrations as a whole are well selected but the general attractiveness of the volume is marred by the numerous typographical errors.

A Treatise on Tumors. By Arthur E. Hertzler, M.D., Ph.D., Associate Professor of Surgery in the University of Kansas, formerly successively Professor of Histology, Pathology, Experimental Surgery, and Gynecology in the University Medical College, Kansas City, Mo.; Attending Surgeon to the Halstead Hospital, Halstead, Kan.; and Consulting Surgeon to the Swedish Hospital, Kansas City, Mo., and St. Margaret's Hospital, Kansas City, Kan.; Member of the Western Surgical Association, the American Academy of Medicine, the American Anatomical Society, etc. Illustrated with 538 engravings and 8 plates. Price $7.00 net. Philadelphia and New York: Lea & Febiger, 1912.

There is no lack in the literature of medicine of books on tumors, but in many such the attitude of the writer has been that of a specialist in pathology and the clinical side has not been emphasized sufficiently to make the volumes directly useful to the practising surgeon. The only general treatise of this sort has been that of Bland-Sutton, which was, however, concerned chiefly with the clinical aspect of tumors in relation to their etiology and occurrence in both man and animals, and though revised through several editions no longer represents the modern standpoint of tumor pathology. On the other hand, the texts of Borst and Ribbert are mainly valuable to those who read German and are interested in the purely scientific side, and hence there has been a need for a clinical-pathological text which would bring together the important points in diagnosis. This need is admirably filled in many ways by this treatise of Hertzler's. Typographically the book is a credit to the publishers. The illustrations are numerous and on the whole satisfactory, though many of the microscopical drawings do not show all that their legends state and would hardly be valuable in teaching the microscopical appearances seen in the original sections. The photographs of patients, on the other hand, are especially good.

The volume opens with a general chapter on the biology of tumors. This is followed by a portion discussing the different types of new growths and including cysts and inflammatory tissues. The third part is devoted to an original consideration of various forms of neoplasms. The writer has evidently had considerable training in tumor pathology; but few will agree with him that the removal of a diagnostic section before operation is not justifiable, and we would like a fuller statement of the evidence that the chances of cure are lessened by the removal of such diagnostic material. From the patient's point of view it would seem that the removal of a small fragment of tumor for diagnosis is less likely to be followed by distribution of the tumor cells throughout the tissues than the constant handling and pressure on the tumor which occurs during its removal, by which process cells must certainly be impelled along the lymphatics. Recent studies have shown that large numbers of cells undoubtedly do escape into the lymphatics and tissues, but are promptly cared for by the phagocytic and cytolytic activities of the body, and there are many cases in which the removal of a small fragment for diagnosis will save the patient from a prolonged operation and even death from shock and hemorrhage, since the tumor may ultimately prove to be a benign growth, in which an extensive operation is unwarranted. The surgeon who has not met with such cases has done but little surgery. Examples will arise in the mind of any pathologist of even limited experience. The time required for making sections is overstated also. It is perfectly possible to make satisfactory frozen sections in two or three minutes, and rapid paraffin sections in four to six hours. The writer is correct in stating that a poor pathologist is as bad as a poor surgeon, but that a good pathologist may often be of great value to an operator who is untrained except in the technique of his trade if the latter will rely on the diagnosis furnished him from sections. There is little to criticise in any portion of the text of this book. About minor points there may be considerable difference of opinion, but such differences do not interfere with the successful operative removal of tumors. It is, for example, certainly not generally believed at present that the mixed tumors of the parotid are of endothelial nature. Nor is the difficulty in making a diagnosis of tuberculosis of the breast, even under the microscope, sufficiently emphasized, for many of the chronic inflammatory lesions of the breast simulate tuberculosis very closely, an inflammatory reaction about masses of retained fat with the production of typical Langhans' giant cells and areas resembling tubercles. There is also at the present time no reason to consider even the possibility of a close relationship between Hodgkin's disease and sarcoma, even though this is supported by "several surgeons." Except for such minor defects the volume is an unusually good one and should be widely useful. Its perusal will perhaps instill a certain caution into the operator who prefers to make his diagnosis on the operating table rather than at the bedside, and should lead to very much greater success in the operative treatment of tumors than now is obtained in this country. No clinic has set a higher standard than that at Rochester, where pathology and surgery go hand in hand, and the results there obtained can be duplicated elsewhere if the same scientific equipment is available.

The Taylor Pocket Case Record. By J. J. Taylor, M.D. Price $1.00. Philadelphia: The Medical Council Co., 1912.

This book supplies in convenient form and pocket size a means for recording the histories of 120 cases. A syllabus provides the important items which are to be considered in each history, and the blank for the first thorough examination, diagnosis, and treatment is followed by spaces for sixteen subsequent visits. The chief virtue of this book is its compactness.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held March 19, 1912.

DR. WALTER L. NILES IN THE CHAIR.

Pneumonia Simulating Localized Peritonitis.—Dr. H. F. L. ZIEGEL reported this case. (See page 942.)

Dr. ROBERT T. MORRIS said that surgeons were often called to operate for abdominal conditions simulating the first stages of pneumonia. He had been caught once, many years ago, and operated for appendicitis which was not present, but had not made the mistake since. He depended chiefly upon two signs for differentiating between abdominal signs of pneumonia and peritonitis. First, if one pressed upon the abdomen deeply and then removed the hand quickly, he did not elicit in pneumonia cases the symptom of pain characteristic of peritonitis. Second, early hypersensitiveness of the lumbar ganglia and semilunar ganglia, so common to peritonitis, did not belong to pneumonia. General disturbance of vital signs was more marked in early stages of pneumonia than in early stages of peritonitis. Recently Dr. Morris had been called to a hotel where two doctors were puzzled over a diagnosis. A third doctor called in had blamed the two for not making an immediate diagnosis of appendicitis with peritonitis; they called the speaker in a hurry, and had nurses and operative arrangements all made by the time of his arrival. Finding the case to be one of pneumonia, it required some diplomacy to disagree with the friend who had called him, and to agree with the two doctors whose feelings had been hurt.

Typhoid Fever Observed During the Incubation Period.—Dr. H. F. L. ZIEGEL reported this case. (See page 942.)

Experimental Demonstration of the Identity of So-Called Brill's Disease and Typhus Fever.—Dr JOHN L. ANDERSON, Director Hygienic Laboratory, and Dr. JOSEPH GOLDBERGER, Passed Assistant Surgeon, Public Health and Marine Hospital Service, presented this communication, which was read by Dr. Goldberger and accompanied by lantern slides. He said that he had the honor to present the results of some experimental work that had recently been completed by Dr. Anderson and himself and their results proved, as they believed, that the disease observed and studied in New York City by Dr. Nathan E. Brill, who described it as "an acute infectious disease of unknown origin" was identical with typhus fever. They had returned from Mexico just after Dr Brill had published his paper based on a clinical study of 221 cases of the disease which he characterized as "an acute infectious disease of unknown origin," and they were struck with the fact that Dr. Brill's description of the disease observed in New York was a splendid delineation of the disease which they had been observing in the typhus wards of the General Hospital in the City of Mexico. The writers were of the opinion that Brill's experiments with monkeys which were particularly susceptible to typhus, though extremely interesting and suggestive, were by no means conclusive. Their reasons for this conclusion were that the blood used for making the inoculations was taken from very mild cases and might have been of very low virulence and again the temperatures of the monkeys were not taken and the observation of monkeys without taking temperatures could not be relied upon to detect even a fairly sharp reaction and certainly not a mild one. About the time that Brill published this paper Louria, in the MEDICAL RECORD, August 26, 1911, published a study of 18 cases of fever, conforming to the type described by Brill, observed at the Jewish Hospital in Brooklyn, and he was disposed to regard these cases as typhus. Through the courtesy of Dr Brill, Dr. Leo Kessel, and Dr. Louria, they had been able to obtain material for inoculating rhesus monkeys, and their experiments demonstrated that it was possible to produce Brill's disease in these monkeys. They showed, as had also Ricketts and Wilder, Nicholle and his colleagues, Gaineo and Girard, and others, that rhesus and capuchin monkeys reacted in a definite way after inoculation with blood of the human cases of typhus. They had also found that fever was the only definite index of reaction, and it was this fact that deprived Dr. Brill's third experiment of any significance. As soon as they were satisfied that the monkey was susceptible to Brill's disease and that they could conserve the virus in passage, they prepared to test its relationship to typhus fever by a series of cross immunity tests. They proceeded to Mexico City where typhus was endemic in order to test the susceptibility to typhus of some of the monkeys that had recovered from an attack of Brill's disease and from there to send to Dr. Anderson in Washington, for a test as to their susceptibility to Brill's disease, animals recovered from an attack of typhus. Following this plan of procedure they had tested the susceptibility to Mexican typhus of seven rhesus monkeys that had recovered from Brill's disease, and the susceptibility to Brill's disease of ten monkeys that they had reason to believe were resistant to Mexican typhus, with the following result: Of the seven Brill's immune monkeys not one had developed typhus, although of nine healthy controls, not one failed to react, the reactions being well marked in seven and abortive in two. Of the ten typhus immune animals, not one had developed Brill's disease, whereas of eight monkeys inoculated as controls only one had failed to react. A diagram of the details of these tests was shown on the screen. They were of the opinion that the results justified the conclusion that an attack of Brill's disease conferred immunity to subsequent infection with Mexican typhus and also that the converse was true. In other words Brill's disease and typhus were identical. If this was true it was then clear that typhus had been endemic in New York City for many years and that this was equally true of other large American and Canadian cities, and there was reason to suspect that this was also true of Europe. Hereafter they must carry in their minds the picture not only of the grave and fatal forms of typhus recognized by their fathers, but also the mild and benign type so patiently studied and carefully depicted by Brill. It might be pointed out that a recognition of these mild forms of typhus gave them a rational explanation of what Osler had characterized as a "remarkable feature of this disease," namely, "the occurrence of a few cases at long intervals of time from other outbreaks and at great distances from any known foci of the disease." In other words, these mild forms constituted the missing epidemiological link between so-called sporadic cases. It might be interesting to learn that they had succeeded in transmitting Brill's disease from monkey to monkey by the bites of body lice and that they had been successful in propagating this disease in the guinea pig. In studying the epidemiology of these diseases they had concluded that the key to the mystery lay in some insect intermediary and they had considered the flea, the bedbug, the louse, the tick, and the mosquito as possibilities. They had been able to rule out of serious consideration all but the louse, and they had found that the louse served to explain all the important facts in the epidemiology of typhus. Transmission by the louse would explain why typhus was peculiarly a disease associated with misery and poverty, why it was a vagabond's disease, why it was a disease of jails and of armies, in brief, why it was a disease of the "unwashed." They believed that from their experiments they were justified in considering the fact as established that Brill's disease was capable of being transmitted by the bite of a louse. They also believed that their experiments justified them in concluding that typhus fever might be transmitted by the bite, not only of the body louse, but of the head louse as well.

Dr. N. E. BRILL said that he would confine his remarks to only the experimental and clinical aspects of the subject. Before introducing the discussion, however, he desired to express his tribute of praise and admiration for the extraordinary and brilliant results of Dr. Anderson's and Dr. Goldberger's investigations. He said that he knew of no other investigators who could have so ably carried on the work, nor of any institution devoted to research work where the work would have been so thoroughly done as it was in the Hygienic Laboratory of Washington. This tribute was due them because, with an abiding faith that Brill's disease and Mexican typhus were identical, they had continued the work after Dr. Brill had asked for other investigators than himself to make further attempts at inoculation experiments. Previous to September, 1909, it was held that typhus was non-inoculable to the lower animals. Nicolle and his collaborators, Comte and Conseil of the Pasteur Institute, went in 1909 to Tunis, Africa, where typhus fever was epidemic, and there studied the subject of the transmission of this disease. Apparently without knowledge of Nicolle's successful work in transmitting typhus fever to monkeys by the inoculation of human typhus-infected blood into such animals, Anderson and Goldberger, and the lamented Ricketts and Wilder proceeded to Mexico City for the purpose of making the same investigations. These investigations were conducted independently of each other, and without the knowledge on the part of either that another set of investigators was doing identical research work. Nicolle of France was the first to find that such an inoculated monkey was immune to further inoculaton tests, he was also the first to show

that the body louse was able to transmit the disease from man to monkey and from monkey to monkey. It was marvelous that the two sets of workers should have undertaken the same work, covered the same ground, and reached results so uniformly identical. This gave strong proof of the truth of these results. Dr. Brill said that he accepted without any arguments the facts of their results. However, he wished to call attention to certain features which made their results lack absolute proof. This was not done in a spirit of criticism, but in the hope that it would further add to the proof that Brill's disease and typhus fever were the same. In the first place all monkeys inoculated with human typhus blood did not respond to the infection. This difficulty applied with greater force to the attempts at inoculation with Brill's disease. In using virulent blood from two patients each suffering with a sharp and pronounced attack of Brill's disease for inoculating monkeys he had met with negative results. In fact Dr. Anderson and Dr. Goldberger succeeded only once in the first four monkeys used. It seemed to be much easier to get a reaction from monkey to monkey than from man to monkey, as shown by the success of Dr. Goldberger and Dr. Anderson in transmitting the fever to fifteen generations of monkeys. Why should this be so? There were no characteristic signs of typhus fever in the monkey after inoculation. He might lose his activity for a day or two and have some fever, but the fever did not run any determinate course nor was it the same in all the monkeys; it varied greatly in duration. There was no eruption which would prove the existence of typhus fever as in man. Fever was the only symptom by which the experimenters determined a successful transmission excepting the immunity test to further reaction by subsequent inoculation with similar virulent blood. This was very thin ice to tread upon as a support of absolute proof that Brill's disease and Mexican typhus were the same. The immunity test, however, admitted of no criticism and undoubtedly showed at least a relationship between the two diseases. He did not believe that it showed that the disease was typhus fever, because in the absence of a proven specific organism, such proof did not seem to him possible. It was well known that under apparently normal conditions monkeys ran a febrile course which might last some days. The handling of monkeys might produce an elevation of temperature. Monkeys in captivity were especially prone to acute and chronic tuberculosis which gave rise to continuous elevations of temperature covering wide fluctuations. The positive results of these experiments were then: (1) The ability by inoculating virulent blood to produce a fever in the monkey. (2) The ability to reproduce a fever successively in a series by transmitting the infected blood from monkey to monkey. (3) Monkeys thus infected were immune to the production of fever on subsequent inoculation. (4) Monkeys so immune showed no febrile reaction to inoculation with blood from Mexican typhus. (5) Monkeys inoculated with Mexican typhus showed no febrile reaction to inoculation with blood from one infected with Brill's disease. In order to complete their proof they should show what the effect of the inoculation of non-virulent human serum was on the monkey; whether the inoculation of human serum from a febrile non-typhus patient would produce a febrile reaction in the monkey, and finally it ought to be shown whether normal human serum was not a toxic factor when inoculated into a monkey and whether it acted as an immunizing agent against human blood from an infectious fever patient. They had furnished no proof of the relationship either of Mexican typhus or of Brill's disease with European typhus. These might bear an analogous position to European typhus, as did the paratyphoid and related infections to typhoid fever. Until these conditions were satisfied one could not say that the identity of Brill's disease and European typhus was absolutely established. He agreed, however, that these authors had undoubtedly shown the closest relationship, if not the identity, between these two diseases. When one viewed the subject from the clinical standpoint he would say that all the recorded knowledge of typhus fever was the result of experiences with typhus fever as it occurred epidemically. One looked in vain in monograph and text book for information of typhus as it occurred sporadically. Even Murchison made a bare mention of typhus in mild form. Dr. Brill then gave a description of typhus fever as he had seen it in the epidemics in New York in 1881 and 1893, and he followed this by a description of Brill's disease. The comparison showed marked differences, such as the absence in the latter of marked nervous symptoms, delirium, stupor, and coma, the absence of extreme prostration and tremor, and the invariable mild course and low mortality. This low mortality was unknown with any form of typhus, Old World or Mexican. He finally stated that there was absolutely no evidence of communicability in any of his cases to others of the same family or in the same house. He further stated that every known writer spoke of the communicable character of typhus fever, most writers stating that it was the most contagious disease. After citing a number of instances showing how the admission of one typhus fever patient to a hospital resulted in a general epidemic in the institution even when conditions were ideal, he stated that no case had ever developed in the wards of Mount Sinai Hospital notwithstanding that they had at least five times as many cases yearly as Murchison mentioned as having occurred in the London Fever Hospital in 1800 and 1801, when the diseases were communicated to so many others in its wards. If lice were the means of transmitting the disease it would seem inexplicable how in a house infected a husband could be afflicted with typhus and his wife escape. In about 300 cases of Brill's disease which he had observed no such family infection had ever occurred. While he thought that the proof of the transmission of typhus by lice was incontestable, he also believed that it could be transmitted in other ways. Finally it should not be forgotten that he had never said that he had pointed out a new disease, nor had he given his name to the disease; his sole object was to point out a disease which every clinician in New York insisted was a modified form of typhoid fever and which he thought he had conclusively proven could not be typhoid. He had been the first to indicate the resemblance of the disease to typhus, and in the absence of demonstrable cause he had called it "an infectious disease of unknown origin." When he reported two cases, one in 1901 and one in 1902, to the Health Department as typhus fever, the department, even after an autopsy, refused to regard it as such. In the light of such circumstances it was no wonder that he had a disinclination to regard the disease as typhus fever. He stated that if Brill's disease were typhus fever, it was entirely different clinically from typhus fever and represented a typhus fever so modified by modern conditions of improved sanitation as to render it a disease shorn of its qualities of a deadly scourge, deprived of its attributes of virulence, of its communicability, and of fatality.

Dr. L. Louria of Brooklyn said that he was thankful for their kind invitation to take part in the discussion of the paper, but that he could hardly add to the comprehensive and admirable description of his predecessors: the detailed experimental evidence adduced by Drs. Anderson and Goldberger, and the clinical picture so ably delineated by Dr. Brill, to whom they were indebted for a most critical observation calling their attention to a set of cases which they were prone to regard and treat as atypical, aberrant typhoids. His personal experience with the so-called Brill's disease was confined to some thirty-odd cases seen in private and hospital practice. And he spoke here this evening, no doubt, because, being a Russian, he had studied and practised medicine in the land where typhus was endemic, and was thus able to draw a comparison between the classical typhus of Russia and the debated Brill's of New York. When he first came to this country he found that even his countrymen who had emigrated some years before, and upon whom he had expected to rely for a clientèle, displayed a hesitancy in calling upon a foreigner to diagnose and treat American diseases. And this attitude, though harsh and at first seemingly unwarranted, he soon recognized as somewhat justifiable, for, though labeled with a common nomenclature, he found that the acute infectious diseases, modified probably by their environment, climatic, hygienic, or sociologic, ran a different course from that which he had learned and observed abroad. They were prone to conjure up the descriptions of typhus fever of the text-books which pictured the disease of fifty or one hundred years ago, and naturally so, for typhus was a comparative stranger to New York. The last visitation dated back some thirty years, and hence it came perhaps as a shock to learn that Brill's and the much dreaded typhus were one and the same, though appearing in an unfamiliar guise. Synonyms of typhus, as jail fever and famine fever, indicated the importance of the conditions favoring the outbreak of the disease. Unhygienic surroundings and privation were responsible for the terrible ravages of this disease in the past, while modern sanitation in peace and war had materially modified the outbreaks of the disease of the present day. Reviewing the literature the speaker ran across numerous reports of recent epidemics of a mild typhus. Thus Beard, in the *Edinburgh Medical Journal*, reported an outbreak in the City of Carlisle and concluded that typhus might be met with in a very mild form. Uttujaminoff reported a series of cases which, following the method of Jovorovsky, were treated with three or four drops of tincture of iodine three or four times daily. In forty-five cases thus treated there

was no fatality. It was inconceivable to ascribe to such small doses of tincture of iodine the property of a therapia sterilisans magna, and it was but rational to conclude that here, too, a mild form of typhus was encountered. Again Verekundoff in *Russkii Vrach*, August, 1911, reported an epidemic of one hundred and twenty cases of a mild typhus varying from the well-known typical picture, having a slower onset, less characteristic rash, etc. And, despite the unfavorable sanitary hygienic surroundings, the mortality had not exceeded 8 per cent. Africa furnished us with an epidemic of mild typhus, and the so-called Manchurian typhus apparently belonged to the same group. Then might one not grant to cosmopolitan New York a like possibility? The clinical picture of Brill's disease following closely that of typhus, was so characteristic that once seen it was never forgotten, so much so that their internes and nurses could readily make a correct diagnosis. It had been asked why it was that Brill's disease was found almost entirely in Slavs, particularly in the Russian and Polish Jews. This might be answered in two ways: (1) that most of the patients were of this nationality; (2) that when these cases came into other institutions they were not recognized as such. He once had had occasion to refer three cases of Brill's disease, the only instance which showed distinct evidence of contagion, to another hospital, and learned that they were not recognized but were regarded as atypical typhoids. It seemed to him that the profession at large was not well enough acquainted with this clinical entity and that Dr. Brill, in justice to the profession as well as to himself, should have his articles, which contained admirable descriptions of the disease, disseminated more widely.

Dr. William H. Park wrote that he had gone over the temperature charts with Dr. Anderson and the proofs seemed to him conclusive that the monkeys suffered from a true typhus fever. He did not see how it was possible to explain the immunity which developed in any other way.

Dr. W. Gilman Thompson said that his excuse for saying a few words in discussing the paper was because he had had some experience with typhus fever and so-called Brill's disease. Some years ago at the New York Hospital they had a few cases of typhus fever. As illustrating the fact that the disease was not always contagious to an active extent one patient came to the hospital with the disease, when there were no known cases of typhus in New York City. The symptoms he presented were those of typhoid fever, and this patient was treated in the general wards of the hospital and handled as a case of typhoid fever. It was only on the tenth day, when the patient made a prompt recovery, that it was learned that he came from a house where there were a number of typhus fever patients. Those in the ward did not contract the disease. Dr. Thompson said he had seen a few of the cases that Dr. Brill had described. Probably many of the cases of typhus fever had been overlooked because of the absence of an active epidemic. He took issue with Dr. Brill; the older writers laid great stress upon the contagiousness of the disease and in those days but little stress was laid upon hygiene. They should remember the contagiousness of yellow fever, cholera, etc., diseases which were the dread of the whole world until modern science and sanitation relieved them of their terrors. The first time Dr. Thompson had seen a case of Brill's disease he regarded it as a mild case of typhus fever. However, in the consideration of typhoid fever one should not overlook the existence of the paratyphoids and the colon bacilli forms which modified the fever, and showed the great variations they had in the disease which they all recognized.

Dr. William H. Thomson said that he began his medical career in 1859. In the previous year the health officer, the general physician of the hospital, and three assistants died of ship fever. Several vessels were boarded and found to be in a dreadfully unsanitary condition. Dr. Thomson took charge of the hospital in 1859. These ships landed batches of patients with true typhus fever or ship fever or contagious fever, and he carefully studied them. They all corresponded to the description of true typhus fever. He left the quarantine hospital in 1862 and had since been connected with Bellevue Hospital. They had an outbreak there of typhus; it was the same fever that he had studied at the quarantine hospital. Four promising internes fell victims to it. One could not confound these cases with the cases he saw at quarantine.

Dr. Matthias Nicoll, Jr., said that in 1893 and 1894 there appeared many cases of typhus fever and he saw about 100 cases at the Hudson Street Hospital. He had seen very few cases of the modified type of the disease, but from the description given the disease seen now compared with the type seen then, although there was not a great deal of resemblance. It seemed rather remarkable that a disease occurring in such an epidemic form in 1893 and 1894, a rather fatal disease, should become so modified in its type as was claimed.

Dr. E. Libman said that up to 1906 blood examinations were made of these cases and showed that they were neither paratyphoids nor typhoids. Dr. Edward G. Janeway pointed out the fact that they should be on the alert in looking out for typhus fever. A supposed case appeared at the hospital, the Board of Health was notified, but no response was made. In 1902 and 1903 the same thing happened. While it was clear that they were dealing with typhus fever, or a modified typhus, the Health Department took no notice of it. If a disease occurred in the wards of a hospital, and if the windows were opened, authorities abroad stated that the disease would not spread.

SECTION ON SURGERY.

Stated Meeting, Held April 5, 1912.

Dr. Lucius W. Hotchkiss in the Chair.

Resection of Elbow for Tuberculous Osteomyelitis.—Dr. Aspinwall Judd presented this patient, one of a series of cases of total destruction of this joint in which he obtained good function. When he opened up the joint he saved the muscles and attachments. The boy was operated upon twice, the first time fifteen months ago, the second time eight months ago, for what seemed to be tuberculous involvement. A radiograph showed the condition very clearly. The joint was about the size of the knee. The boy ran a septic temperature. Since the last operation he had gained thirty pounds in weight.

Sarcoma of the Inferior Maxilla, with Complete Resection of the Right Half—Good Function.—Dr. Aspinwall Judd presented this patient, a woman, whom he saw in January, when she had a tumor mass involving the entire one-half of the inferior maxilla. A diagnosis of osteosarcoma was made. At operation he had to remove the sublingual and the submaxillary glands as well as the entire chain of glands as far as the articular process. All the muscular attachments on the right side were practically gone. There was very little distortion; the jaw was rotated to one side. The patient had very good control. The entire chain of glands was removed.

Sarcoma of the Superior Maxilla, Resection, Recurrence, X-ray, with Recovery.—Dr. Aspinwall Judd presented a man upon whom he had operated seven years ago for sarcoma of the superior maxilla of the left side. The cavity left was filled with paraffin. There followed a recurrence and the patient was treated with the *x*-ray for two years. Splendid results were obtained and to-day there was apparently nothing remaining except a lump which was supposed to be a fibroma. This was, in fact, an *x*-ray and not a surgical case. These spindle-celled sarcomata acted best under the use of the *x*-ray.

Pneumococcus Infection of the Hip and Shoulder.—Dr. Aspinwall Judd reported a case which he considered a novelty. One year ago he saw a patient whom he thought was suffering from a septic arthritis of the hip. At operation he found a pneumococcus infection and the patient left the hospital apparently cured. One month later the patient returned with a temperature of 105° and 106° F. and symptoms of some bone infection. This time he found a pneumococcus infection of the shoulder joint. At no time had he had any pulmonary infection.

Strangulation of Undescended Testes.—Dr. Charles E. Farr presented a baby, seven months old, which was to illustrate his paper. Three days before admission to the hospital the patient vomited and cried and seemed to be in pain. Two days before admission a swelling in the left groin was found. The bowels moved. The pain became so intense the child lay with its legs drawn up. A diagnosis was made of a strangulated bubonocele because of the swelling in the groin. When in the hospital a diagnosis was made of bubonocele and lymphadenitis. The diagnosis, however, was uncertain. When the child was anesthetized they found that the testes did not come down and they made a guess diagnosis of a strangulation of the testes. When an incision was made they found the swelling inside the canal and extending outside the ring. There free fluid and the testes were found at the bottom of the vas completely twisted to 360 degrees. When the testicle was untwisted the color did not at once return. The child was now in perfect health.

The Value of Warmed Anesthetics.—Dr. James T. Gwathmey read this paper. He said that we were indebted to Dr. Seelig of St. Louis for the opportunity to discuss again the value of warmed anesthetics. Dr. Seelig had written an article on "The Fallacy of Warmed Ether

Vapor" which had appeared in the *Interstate Medical Journal*, September, 1911, in which he had stated that one was almost impelled to adopt some procedure by which anesthetics could be warmed, although he disliked to add any further complicated and expensive apparatus to the already complex armamentarium of the operating room. After reviewing Dr. Seelig's experiment the author pointed out that it only proved that the tidal air of the lungs was not changed by the temperature of the anesthetic as given by Seelig's method. The deduction that warmed anesthetics were unnecessary was not warranted by this experiment. In other experiments Seelig had stated positively that he was unable to warm the ether vapor. He had stated that, despite the fact that ether vapor was driven through a temperature approximately 100° C., it radiated its acquired heat so rapidly that at a distance of one meter from the source of the heat it had practically assumed room temperature. And from this he concluded that one need not concern oneself much with securing a special warming apparatus. In order to test the validity of Seelig's experiments a special glass tube was blown with openings 10 cm. apart, into which thermometers were inserted. At the openings and over the thermometers a rubber collar was placed to insure against leakage. A thermometer was also used to determine the room temperature. This glass tube was attached to a heater immersed in a water bath which was heated and kept at the boiling point by an electric hot plate. The Gwathmey vapor apparatus was attached to this heater, compressed air was then passed through the ether bottle, the vapor again passing through the water bottle of the vapor apparatus, and then through the heater, and through the tube to which were attached the thermometers. Readings were made every five minutes for an hour, and from the results it was seen that ether vapor might be heated, and the heat maintained for any length of time and delivered to a patient as determined by the anesthetist. About the same amount of ether was used in this experiment as was usual in practice. In another experiment on another occasion, using a rubber tube of the same length as was used in actual practice, and with a thermometer placed at the end of this tube and also a thermometer for room temperature, and passing compressed air through for one hour, it was found that at the end of 55 minutes the temperature was raised 6° C. higher than room temperature. It was then passed through the ether and water bottle of the vapor apparatus without the heater and readings kept for 45 minutes. These readings showed the desirability of heating the ether vapor. At the end of 45 minutes the vapor was approximately 16° F. below blood temperature. After reviewing his laboratory and experimental work with chloroform, nitrous oxide and oxygen, and ether, and his experiments to determine the value of passing ether vapor through water, which he said had been more than verified by Dr. S. G. Davis of Baltimore, Dr. Teter of Cleveland, and others, he concluded that with warmed anesthetics using chloroform, ether, or nitrous oxide and oxygen, not only was the value of the anesthetic increased as regarded life, but the after effects were reduced to a minimum. Dr. Teter used a lamp to heat the gas and oxygen and had noted a number of times the difference between the warmed gas and the cold. Dr. Davis had made a valuable contribution to the literature of warmed anesthetics by a series of observations on human subjects undergoing surgical operations. In 26 patients anesthetized with warm ether vapor there was a loss of temperature averaging 0.20° F., as against a loss of 1.02 in 140 cases anesthetized under similar conditions with the open drop method. The shortest period of anesthesia in which the temperature was noted was 40 minutes, the longest 4¼ hours. The temperature was taken by rectum immediately before starting and immediately after the removal of the anesthetic. These experiments of Dr. Davis on human beings undergoing surgical operations were more conclusive than the experiment of Dr. Seelig on a dog. With the idea of testing the value of heat in the more rapid recovery from the anesthetic, and of preventing nausea and vomiting, the writer had anesthetized three animals at the same time under glass receptacles for ten minutes, afterwards placing them in receptacles, one at 0° F., another at 100° F., and the third, as a control, in the room temperature to come out of the anesthetic. The animals were changed in position for three successive days. In each instance the animal in the warm chamber made a slightly more rapid recovery than the others. The animal in the cold box came out in chills, while the one in the room temperature came out a close second to the one in the warm box. With reference to human beings, it might be stated that by applying hot towels to the patient's face or aerating the lungs with hot air toward the close of the anesthesia the patient was brought out quickly, and this procedure aided considerably in modifying the unpleasant after effects. The results of the laboratory experiments were emphasized when one took into consideration Dr. Davis's clinical experiments and the fact that the patient's temperature was necessarily lowered in the majority of instances by surgical operation. It was to be hoped that improved technique would be adopted in more clinics. He hoped that the method would be tried out conscientiously. With their knowledge of warmed anesthetics and improved surgical technique it was unnecessary ever to return a patient to bed to have him complain of being cold or uncomfortable.

Dr. A. G. DAVIS of Baltimore said that Dr. Gwathmey must have spent many hours of laboratory work and thought in the preparation of his paper. As to the value of warmed anesthetics, there was no question about it, whether the anesthetic was ether, chloroform, or what not, for this was the proper thing to do. Dr. Davis presented many drawings which were from the laboratory experiments on dogs, showing temperature curves when cold vapor was administered, when warmed vapor was administered, etc. He also showed charts of temperatures when warmed and cold vapor was given in complete amputations of the breast in six cases, three with the cold and three with the warmed, which showed conclusively the value of the latter.

Direct Transfusion of Blood as a Preliminary Step in Certain Surgical Operations.—Dr. A. L. SORREL read this paper. (See page 835.)

Personal Observations on Wassermann's Experiments on Mouse Tumors.—Dr. OTTO G. T. KILIANI read this paper. (See page 789.)

Strangulation of Undescended Testes.—CHARLES E. FARR presented this paper. He stated that the phrase "strangulation of the testes" was rather loosely used to indicate a severe grade of interference with the blood supply of that organ. It might be brought about by torsion, compression, kinking, or stretching of the cord. When one considered the exposed position of the testis, its great mobility, and especially its long stalk or pedicle in which its small and tortuous vessels were conveyed, the wonder was that more cases of strangulation were not more frequently reported. The first recorded case was that of Delasiauve in 1840. Nicoladoni, in 1885, reported two cases of his own and several from the literature. Since that time the number had rapidly increased, and now amounted to about 100 cases. Of these practically 50 per cent. were in frankly undescended testicles, while a considerable proportion of the remainder gave some evidence of late or mal-descent. Many others showed abnormalities of development. In fact, most of the authors had considered abnormal descent or development a necessary condition of strangulation. On the other hand, carefully observed cases had been reported in which no such condition was present. It was well known that the condition of torsion of the cord could not be produced in the normal human cadaver, though it was frequently done to stallions to produce atrophy of the testes and sterility. The probability was then that no one anatomical defect could be called the necessary predisposing cause to strangulation. True strangulation by occlusion at the ring was hardly possible to imagine, although a few cases had been reported of compression of the kinked or looped cord between the body of the testes and the pillars of the ring. A few more were recorded in which the circulation was shut off by excessive stretching of the cord *en masse* when the inguinal testis was forced out of the external ring. The great majority of cases, however, were strangulated by torsion, either of the testes on the epididymis, the epididymis on its own axis, or, by far the more often, the testes and epididymis on the cord. This latter condition might occur within the tunica vaginalis, or very rarely without it, in which case the tunic and testes were both strangulated. In this paper those cases in which a strangulated hernia was present or those cases presenting fully descended testes were not considered. Cases of inflammation without strangulation and unoperated mild cases were also excluded. Strangulation might occur at any age, but it was most common during the ten years following puberty. It might affect either testicle. Undoubtedly it led to aseptic gangrene, abscess, or simple atrophy. In animals the gland was completely lost after 22 hours of strangulation, while in man 75 per cent. of the cases had to be castrated; of the remaining 25 per cent. nearly all sloughed or atrophied. In strangulation by torsion the conditions usually present were: (1) A free-lying testis, like an ovarian cyst on its pedicle. If the twist was of the testis proper the true mes-orchium must be abnormally long. If the testis and

epididymis turned upon the cord, the mes-epididymis must be long and covered on each side with reflections from the tunic. More often the testes and epididymis hung free on the cord. In this case the mes-orchium was said to be absent, but more properly speaking it was abnormally long. (2) The relative size and position of the testes and epididymis varied greatly, the latter lying above, below, or even in front of the testes after the twist was reduced. The two might be quite separate, with separate portions of the cord leading to each. The testis might be, and frequently was, flattened and abnormal in shape and position, as was also the epididymis. (3) The tunica vaginalis was usually well developed and capacious, frequently containing fluid and usually communicating with the general peritoneal cavity. (4) The cord might be abnormally short or long and was usually well developed; but it might be flattened out and even divided into two quite distinct bundles, one containing the vas and its arteries, the other the spermatic vessels. A history of repeated attacks of pain was common and in some cases undoubtedly twists had recurred repeatedly, being reduced without operation, or in a few cases spontaneously. The testes in these cases had usually atrophied. The mechanism of torsion was obscure, each author advancing a theory to fit his own case. All laid great stress on trauma, even though this were of the lightest. Walking, jumping, straining, even the violent contraction of the cremaster had been advanced as the immediate cause. One author believed that the torsion was of slow development and that symptoms only developed following the last partial turn which completed the obstruction. If this were true one would expect to find occasional twists of the cord in the numerous operative exposures for hernia, etc. Adhesions would probably form and the twist would probably remain after the cord was removed, whereas, as a matter of fact, it nearly always disappeared. In some cases the torsion occurred during sleep, this would presumably, but not necessarily, exclude trauma. In a rather noticeably large percentage of cases there was a distinct history of increased intraabdominal pressure immediately preceding the onset of symptoms. The force might act upon the different elements of the cord as they approached the internal ring, but more probably it was exerted through the open funiculus directly through the weak posterior wall of the canal. A coincident contracture of the cremaster very likely pulled one part of the cord more than another, thus starting the twist. It was easy to see how a quarter turn of the testis might be present at any time and the flattened testis would naturally lie on its side in the confined space of the canal. A very slight turn would thus suffice to give another quartet of a turn. With the onset of torsion great congestion ensued, accompanied usually by a serous transudate, more or less sanguinous in character, into the tunica vaginalis. The increasing congestion dilated the veins, changing their lengths, and thus again increasing the tendency to twist around the unchanged arteries and vas. In general, the cord did not untwist spontaneously, perhaps because of the irregular shape of the testes and epididymis allowing rotation in one direction only. In several cases there had been an apparent reason for the maintenance of the twist, which was easily reduced and showed no tendency to recur. In one case, however, a tendency to recur was noted. The number of twists varied from a half turn to four or more complete turns, averaging about two. Curiously, the left testis usually tended to turn clockwise, the right anti-clockwise. This might possibly be due to the above-mentioned pull on the different elements of the cord or to the natural tendency of the heavier and larger body of the testis to fall downward and outward towards Poupart's ligament as it came through the internal ring. He had found no record of supravaginal torsion of the cord in an inguinal testis. In the descended cases it must imply simply a very loose connection between the dartos and the parietal layer of the tunic. It seemed fair then to assume that torsion of the undescended testis was largely due to intraabdominal pressure, acting directly or indirectly upon the cord and testis, an attempt, perhaps, on nature's part at a forced descent, and comparable to the passage of the fetal head through the pelvic outlet. The symptoms of torsion strongly imitated those of strangulated bubonocele, even in some cases to the extent of obstipation. Generally, however, the symptoms were less severe, shock less in evidence, and temperature and pulse only slightly elevated. Vomiting was apt to occur repeatedly, and the pain was exceedingly severe. This with the testicle missing from the scrotum should lead one to suspect the condition, but remembering the frequent coincidence of a hernia with possible incomplete strangulation, one was never quite sure of the diagnosis. Less than 10 per cent. of the cases had been correctly diagnosed, a few more had been guessed at, but the great majority had been treated first for orchitis, epididymis, or strangulated hernia. The treatment in the undescended cases was obvious; immediate operation offered the only hope of saving the testis and relieving the patient of intense suffering. The prognosis for the patient was always good, or the testis nearly always bad except in very early and very mild cases. The testes removed had all shown intense passive congestion, ecchymosis, and subcapsular hemorrhage, degeneration of the testicular substance, and varying degrees of necrosis, and even gangrene. Infection was rarely present.

Dr. MARTIN W. WARE said that infection was a part of the torsion of the cord. He had had six cases of strangulation of undescended testes, but, unlike Dr. Farr's, his cases occurred among the old, one patient being as old as sixty-two years. In some cases the bacteriological examination showed infection, and one in particular was seen and examined by Dr. William W. Keen of Philadelphia. Some years ago Dr. John Van der Poel undid a twist, replacing the testes, and no atrophy followed. Nearly all of these cases occurred in adults about the age of puberty. Dr. Ware passed around some drawings to illustrate the condition.

Two Instruments for the Reduction of Fragments in Fractures (Preliminary to Plating).—Dr. JOHN C. A. GERSTER presented these instruments.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

AT a stated meeting held April 26 Dr. ROBERT N. WILLSON, JR., demonstrated slides illustrating "Lesions of the Spinal Cord from a Case of Pernicious Anemia." The patient was a woman whose blood yielded a Wassermann reaction and who presented, in addition to symptoms and blood changes of pernicious anemia, also symptoms of posterior spinal sclerosis. After death the spinal cord exhibited characteristic degenerative changes of a diffuse character involving especially the ganglion cells and columnar fibers. Other members of the family presented clinical features suggestive of a syphilitic origin. Dr. ALFRED GORDON presented a specimen of "Spina Bifida Complicated by Tuberculous Meningitis." The patient had been a child five weeks old and after death, in addition to other lesions, a tuberculous focus was found at the apex of one lung. Dr. Gordon presented also a specimen of "Extensive Hemorrhage into the Brain." The patient had been a man about thirty-eight years old, who had complained of recurrent headaches, and who while reading in the recumbent posture became comatose, with slight signs of hemiplegia, and soon died. After death a copious extravasation of blood was found in one lateral ventricle. Dr. E. M. WILLIAMS described "A Form of Degeneration of the Brain Known as Etat Vermoulu." The disorder occurs especially in association with arteriosclerosis, and is characterized by superficial and deep-seated losses of tissues in areas of varying, though not great, size. Drs. E. A. SPITZKA and H. E. RADASCH presented a communication entitled "The Brain of the Recently Electrocuted." They described a condition that they had observed constantly in the brain stem of electrocuted individuals and not under other conditions, and consisting of multiple rarified areas surrounding small blood-vessels and which in turn were bounded by dense areas. The changes were believed to be due to electrolytic effects induced by the powerful electric currents employed and conveyed through the blood stream. Dr. WM. G. SPILLER presented a communication entitled "Some Pathological Conditions Complicating Operations for Tumor of the Brain." He pointed out that in some cases in which operation, radical or decompressive, has been performed for the relief of symptoms of brain tumor, and in which there is reason to anticipate a satisfactory result, death at times occurs suddenly. In some of these cases it may be that there had been gradual distortion or displacement of parts of the brain from the presence and extension of the new growth, and with the reestablishment of more nearly normal relations fatal interference with respiration or circulation results. Thus he has observed undue separation of the occipital lobes and displacement or deflection of the pons. In other instances hernia of the brain becomes an unpleasant or even a fatal complication. This is sometimes due to swelling of the brain tissue and in other instances to an actual increase in the tissue of the brain. Dr. W. WAYNE BABCOCK described "A Quick and Accurate Method of Determining the Specific Gravity of Minute Quantities of the Cerebrospinal Fluid." The procedure consists in introducing a drop of the fluid to be examined into a succession of test tubes containing mixtures of glycerin and water and hav-

ing known specific gravities until the drop neither rises nor falls. In this way it was found that the specific gravity of the cerebrospinal fluid varies little from 1.006 under the most varied clinical conditions at all ages. The information gained in this way furnishes a guide as to the specific gravity of the fluid employed by intraspinal injection for the induction of anesthesia, in accordance with the desire of the operator that the fluid should rise to a higher or fall to a lower level.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS

BOARD OF MEDICAL EXAMINERS, SOUTH DAKOTA

Huron, January 10 and 11, 1912

ANATOMY, EMBRYOLOGY, AND HISTOLOGY.

1. What are the distinctive types of embryonal cells? In the formation of what part of the anatomy is each type mainly concerned?
2. Describe briefly the histological structure of the kidney.
3. Name the principal subdivisions of the lymphatic glands of the head and face and give their respective location.
4. Give origin and distribution of the great sciatic nerve.
5. Name the extensor muscles of the foot, give origin and insertion of each.
6. Where is the circle of Willis? Name the component parts.
7. Name the branches of the radial artery in the forearm.
8. What structures would you sever in making an amputation of the arm midway between the shoulder and elbow?
9. Describe a dorsal vertebra.
10. Give the nervous supply of the heart

PHYSIOLOGY.

1. Describe the glands and villi of the intestines.
2. How is heat produced in the body?
3. Describe cholesterin, and state where found, and also its function.
4. Mention some of the ductless glands.
5. What is the function of the retina?
6. How is the sensation of sound conveyed to the brain?
7. What exercises injuriously affect the heart? And why?
8. What is the normal ratio of heart pulsation to respiration?
9. Give some examples of morbid reflex action.
10. Give the reaction of the following fluids, and state the cause of the reaction: (*a*) gastric juice, (*b*) urine, (*c*) pancreatic juice, (*d*) blood.

CHEMISTRY.

1. Give chemical formulæ for common salt, nitrate of silver, sulphuric acid, hydrochloric acid, and nitric acid (*b*) Complete following:

$$HCl + CaCO_3 =$$
$$Zn + H_2SO_4 =$$
$$Ba + 2HCl =$$

2. How would you test for hydrochloric acid in gastric juice? (*b*) Give a test for lactic acid. (*c*) What are the normal limits of total acidity and free hydrochloric acid in gastric juice?
3. Give common names and properties of mercurous chloride, corrosive sublimate. (*b*) Mention two easily applied tests that will distinguish one from the other. (*c*) How would you treat a case of poisoning from the latter?
4. Define specific gravity. (*b*) What are the normal limits of the specific gravity of urine? (*c*) How would you determine the total amount of solids in the urine, knowing the specific gravity?
5. Give the characteristics of the urine in diabetes mellitus, cystitis, and chronic parenchymatous nephritis. (*b*) Give and describe a reliable test in each case.

PATHOLOGY

1. What is the pathology of acute lobar pneumonia? How does it differ from bronchopneumonia?
2. Give the pathology and diagnosis of typhoid fever. (*b*) What connection has typhoid fever with the formation of gallstones?
3. Give the pathology of osteomyelitis.
4. Differentiate pathologically between a typhoid ulcer and a tubercular ulcer of the intestine.
5. What is pathological leucocytosis? (*b*) Name three physiological conditions which produce leucocytosis.
6. What is ascites and state its causes.
7. Differentiate pathologically between osteomyelitis and inflammatory rheumatism.
8. Differentiate between fatty degeneration and fatty infiltration.
9. What is meant by metatastic growth?
10. Give the pathology of parenchymatous nephritis

BACTERIOLOGY

1. Describe the technique of making a microscopic examination of urethral pus for gonococci.
2. What is (*a*) an antitoxin? (*b*) A bacterial vaccine?
3. What do you understand by the term anaphylaxis?
4. How would you make a culture from a throat in a suspected case of diphtheria? Describe the growth as it appears on the culture media. How would you stain the bacteria? What is the appearance of the diphtheria bacillus under the microscope?
5. A dealer in hides has a carbuncle on the back of his hand. Tell how you would make and grow a culture for diagnosis. Describe briefly the organisms you would expect to find

THERAPEUTICS AND PRACTICE

1. What do you understand by cardiac insufficiency? Give some causes and symptoms.
2. How would you treat a case of lobar pneumonia during the first twenty-four hours of the disease?
3. Give causes, symptoms, and treatment of acute anterior poliomyelitis (infantile paralysis). Would you quarantine the patient? If so, for how long?
4. If a patient came to you complaining of "indigestion, distress, and pain in the stomach" how would you proceed to make a diagnosis? What questions would you ask? What physical examination would you make?
5. Give full directions to the patient and family for the care of a case of pulmonary tuberculosis in the home.
6. Give directions for the artificial feeding of an infant.
7. Give diagnosis and treatment of pleural effusion.
8. Name the chronic systemic diseases in which skin lesions are of diagnostic value. Give the characteristic lesion of each disease.
9. Give symptoms and physical findings in a case of exophthalmic goiter.
10. November 1, 1911, A. B., a real estate agent, twenty-six years old, gave the following history: Scarlet fever when two years old. Ten years ago had a mild attack of tonsillitis; at this time his physician told him he had albumin in his urine. Since that time he has had his urine examined frequently, and traces of albumin were always present. September 10, 1911, he was exposed to a cold rain, "caught cold" which was followed by capillary bronchitis. He has coughed ever since, raising small amount of white tenacious mucus streaked with blood. He has felt tired and weak, but ate and slept fairly well until four days ago, when breathing became difficult; could not breathe when lying down. When first seen he was sitting in his chair, leaning forward with his head on the table. Breathing labored; thirty times per minute. Harsh respiration over both lungs. No rales. Pulse 130. Apex beat two inches to left of nipple. Soft systolic blow over base of heart. Arteries of temple prominent and tortuous. Blood pressure 180 mm. Hg. Feet and ankles slightly edematous. Liver one inch below costal arch. Spleen not palpable. Urinary examination showed specific gravity 1008, large amount of albumin, numerous casts, hyaline and granular. What diagnosis would you make in this case? Give treatment you would institute. What prognosis would you make? What other data would you need to complete the history?

OBSTETRICS.

1. Diagnose pregnancy in early months.
2. Give treatment of pernicious vomiting of pregnancy
3. Name stages of normal labor.
4. What would you do for puerperal eclampsia?
5. Give management of adherent placenta.
6. Diagnose placenta prævia and give method of procedure.
7. How would you control postpartum hemorrhage?
8. Give indications for forceps.
9. How would you manage a case of shoulder presentation?
10. Treat a case of inevitable abortion.

GYNECOLOGY.

1. Define endometritis. Give varieties, cause, and treatment.

2. Describe and treat a case of prolapsus uteri.
3. What organs are usually affected in gonorrhea in the female? Describe and treat a case.
4. What conditions do you think of that might cause sterility that are susceptible to treatment?
5. What can you say about the hygiene of puberty?

SURGERY.

1. Give diagnosis and treatment for case of indirect inguinal hernia.
2. Give diagnosis and treatment for acute appendicitis.
3. What is Lane's kink? Give treatment for same.
4. Give etiology, diagnosis, and treatment for empyema.
5. Give treatment for varicose veins of leg.
6. Diagnose and treat fracture of clavicle.
7. Discuss briefly the use of Lane's bone plates, giving indications and contraindications for their use.
8. Give in detail your treatment for incised wound of scalp.
9. Give diagnosis and treatment for downward dislocation of shoulder.
10. Discuss briefly (*a*) ether; (*b*) chloroform; their administration and dangers of each.

EYE, EAR, NOSE, AND THROAT.

1. What do you understand by the following: Hypopyon, Argyll-Robertson pupil, mydriasis, presbyopia, ptosis?
2. (*a*) Treat a case of severe corneal ulcer. (*b*) Treat a case of severe iritis.
3. Give two indications for use of atropine in eye.
4. Give technique for removal of foreign body imbedded in cornea.
5. Diagnose and treat a case of ozena.
6. Give symptoms and treatment for hypertrophied turbinate.
7. What is your treatment for a child of ten years who often has discharge from ears and habitually breathes through the mouth?
8. Patient presents with following history: Age 25, three weeks ago had severe attack of la grippe, since which time there has been a great deal of frontal headache aggravated by stooping forward or blowing nose, discharge from nostrils, temperature 100°, marked tenderness along the supraorbital ridge, eyelids somewhat puffy. What is your diagnosis and treatment?
9. Describe thoroughly your method of examination of patient complaining of loss of hearing.
10. Treat a case of chronic laryngitis.

SKIN AND GENITOURINARY.

1. Give causes for orchitis and treatment for same.
2. Name stages of syphilis.
3. Diagnose and treat acute cystitis.
4. Describe acne.
5. Write a page on eczema.

HYGIENE AND SANITARY SCIENCE.

1. Trace the entrance of (*a*) typhoid; (*b*) tuberculosis into the system.
2. Give in detail an effective method for controlling an epidemic of diphtheria.
3. Describe the method of making examination of school children for infectious diseases and general defects.
4. What is antitetanic serum? and give uses for same.
5. (*a*) Give method for pasteurizing milk. (*b*) Name two diseases commonly carried by means of milk.

MEDICAL JURISPRUDENCE.

1. Describe rigor mortis and tetanus.
2. What is the order of occurrence of rigor mortis in different parts of the body?
3. If summoned to view the dead body of an infant, how would you determine whether it was mature, and whether it had been born alive?
4. How would you determine if a woman had died from the effects of a criminal abortion, at about the third or fourth month of pregnancy?
5. Define (*a*) delusion, (*b*) hallucination, (*c*) illusion.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS, SOUTH DAKOTA.

Huron, January 10 *and* 11, 1912.

ANATOMY, EMBRYOLOGY, AND HISTOLOGY.

1. The distinctive types are the epiblastic, mesoblastic, and hypoblastic cells.

From *the epiblast* are derived: The skin, and its appendages (hair, nails), and glands (including the mammary glands); the nervous system (brain, spinal cord, ganglia, and nerves); the epithelial parts of the organs of special sense.

From *the mesoblast* are derived: The skeleton; connective tissues; muscles and bones; heart, blood-vessels, lymphatics, and spleen; the urinary and generative organs.

From *the hypoblast* are derived: The epithelial lining of the alimentary canal and its glands; the epithelial lining of the respiratory tract, Eustachian tube, thyroid, and thymus.

5. *Extensor muscles of the foot:* Gastrocnemius, soleus, tibialis posticus, peroneus longus, peroneus brevis, flexor longus digitorum, and flexor longus hallucis.

For their *origins and insertions* see Cunningham's "Anatomy" (1909), pages 370, 378, 379, and 375; or Gray's "Anatomy" (1910), pages 530, 534, 535, and 536.

6. The circle of Willis is situated at the base of the brain. The *circle of Willis* is formed: In front by the two anterior cerebral arteries (branches of the internal carotid) which are connected by the anterior communicating artery; behind, by the two posterior cerebrals (branches of the basilar artery), which are connected to the internal carotid on each side by the posterior communicating artery.

7. Branches of the radial artery in the forearm: Radial recurrent, muscular, anterior radial carpal, superficial volar.

8. Structures severed in an amputation of the arm midway between the shoulder and elbow: Skin, fascia, the humerus. *Muscles:* biceps, coraco-brachialis, brachialis anticus, triceps; *arteries:* brachial, superior profunda, inferior profunda; *nerves:* median, ulnar, musculospiral, internal cutaneous, musculocutaneous.

9. See Cunningham's "Anatomy" (1909), page 81; or Gray's "Anatomy" (1910), page 53.

10. *Nerve supply of the heart:* From the superficial and deep cardiac flexures, and through these it is connected with the pneumogastric, spinal accessory, and sympathetic; also the cardiac ganglia.

PHYSIOLOGY.

2. *Heat is produced in the body* by: (1) Muscular action; (2) the action of the glands, chiefly of the liver; (3) the food and drink ingested; (4) the brain; (5) the heart; and (6) the thermogenetic centers in the brain, pons, medulla, and spinal cord.

3. *Cholesterin* is a monoatomic alcohol belonging to the terpene series. It has no odor and no taste; is insoluble in water, but soluble in ether, glycerin, hot alcohol, and solutions of the biliary acids. It is found in almost every animal tissue and fluid, chiefly in the bile, nerve tissues, intestinal contents, sebum, and feces. It is also found in biliary calculi, brain tumors, pus, hydrocele fluid, etc.

It is a waste product of cell life, and at the same time it exerts an important protective influence against toxins.

4. *The ductless glands* are: Thyroid, parathyroids, thymus, spleen, suprarenals, carotid, coccygeal, pineal, and pituitary.

5. *Functions of retina:* Perception of light, of form, and of color.

6. "The waves of sound are gathered together by the pinna and external auditory meatus, and conveyed to the membrana tympani. This membrane, made tense or lax by the action of the tensor tympani and laxator tympani muscles, is enabled to receive sound waves of either high or low pitch. The vibrations are conducted across the middle ear by a chain of bones to the foramen ovale, and by the column of air of the tympanum to the foramen rotundum, which is closed by the second membrana tympani, the pressure of the air in the tympanum being regulated by the Eustachian tube. The internal ear finally receives the vibrations, which excite vibrations successively in the perilymph, the walls of the membranous labyrinth, the endolymph, and, lastly, the terminal filaments of the auditory nerve, by which they are conveyed to the brain."—(Brubaker's *Physiology.*)

7. Any exercise which is severe, prolonged, or indulged in when the person is tired may be injurious. Unusual and violent exercise is particularly apt to be harmful. It is largely a question of what a man is accustomed to. "If the exercise is too severe the heart is overstrained, breathlessness and palpitation are brought on, and the pulse becomes small, very frequent, and irregular. Prolonged exertion of a severe kind thus tends to cause cardiac pain and palpitation, and may give rise to hypertrophy of the left ventricle if the overexertion is habitual. Rupture of blood-vessels from overexertion is uncommon before middle life. The muscles, including the cardiac muscle, require rest to get rid of the accumulated products of their action (possibly lactic acid), and to take

in a fresh store of oxygen. Without definite periods of rest suited to the kind of exercise the muscles become exhausted and their contractions are gradually enfeebled until they cease altogether. The diastole of the heart is quite sufficient for its recuperation when the body is at rest."—(Parke's *Hygiene.*)

8. The normal ratio of the heart pulsation to respiration is about 72:18, or 4:1.

9. *Examples of morbid reflex action.* Increased patellar reflex in neurasthenia, hysteria, tetanus, cortical hemiplegia, and lateral sclerosis.

10.

	REACTION.	CAUSE OF REACTION.
Gastric juice	Acid	Hydrochloric acid
Urine	Acid	Acid sodium phosphate
Pancreatic juice	Alkaline	Sodium carbonate
Blood	Alkaline	Alkaline sodium phosphate

CHEMISTRY.

1. The *chemical formula* of common salt is NaCl; of nitrate of silver, $AgNO_3$; of sulphuric acid, H_2SO_4; of hydrochloric acid, HCl; of nitric acid, HNO_3.

$$2HCl + CaCO_3 = CaCl_2 + CO_2 + H_2O$$
$$Zn + H_2SO_4 = ZnSO_4 + H_2$$
$$Ba + 2HCl = BaCl_2 + H_2$$

2. *Test for free hydrochloric acid in the gastric juice.* The best is probably the Dimethylamido-azobenzol test; the reagent is used in 0.5 per cent. alcoholic solution, of which one or two drops are added to a like amount of the filtered gastric juice. If free HCl is present, the yellow solution turns red.

"*The presence of lactic acid* is detected by *Uffelmann's reagent*, which consists of a solution of Fe_2Cl_6 and phenol, diluted to an amethyst blue color, which is changed to yellow by lactic acid. In order to avoid error by the action of other substances which have a like action upon the reagent, 10 c.c. of the filtered gastric contents are agitated with ether, and the ethereal extract separated and agitated with the reagent; or, it may be evaporated, the residue dissolved in water and the solution added to the reagent."—(Witthaus' *Manual of Chemistry.*)

The *total acidity* is said to be about 50 to 75 *degrees*, the *free hydrochloric acid* is normally about 0.2 to 0.3 per cent.

3. *Mercurous chloride*, calomel, mild chloride of mercury; is a heavy cream colored powder, insoluble in water, alcohol, or ether; it sublimes without fusing when heated to about 800° F.

Corrosive sublimate, mercuric chloride, bichloride of mercury; heavy, colorless crystals; soluble in water, alcohol, and ether.

The two can be distinguished by (1) the solubility; (2) when treated with potash, calomel gives a black precipitate, while corrosive sublimate gives a yellow precipitate.

Corrosive sublimate poisoning is treated by the administration of white of egg, or milk in moderate quantity, and then emptying the stomach by emetic or siphon.

4. *Specific gravity* is the weight of a given volume of a substance as compared with the weight of an equal volume of some substance taken as a standard of comparison, under like conditions of temperature and pressure.

The normal limits of the specific gravity of urine are generally given as 1015 to 1025.

To determine the total amount of solids, multiply the last two figures of the specific gravity by 2.33. The product is then multiplied by the number of cubic centimeters of urine voided in 24 hours, and divided by 1000. The result is the total solids in grams.

5. In *diabetes mellitus:* "The quantity of urine is very large. The color is generally pale, while the specific gravity is nearly always high—1030 to 1050, very rarely below 1020. The presence of glucose is the essential feature of the disease. The amount of glucose is often very great, sometimes exceeding 8 per cent., while the total elimination may exceed 500 grams in twenty-four hours. It may be absent temporarily. Acetone is generally present in advanced cases. Diacetic and oxybutyric acids may be present, and usually warrant an unfavorable prognosis. Accompanying the acidosis there is a corresponding increase in the amount of ammonia."

In *cystitis:* "In *acute* and *subacute* cases the urine is acid and contains a variable amount of pus, with many epithelial cells from the bladder—chiefly large round, pyriform, and round squamous cells. Red-blood corpuscles are often numerous. In *chronic* cases the urine is generally alkaline. It is pale and cloudy from the presence of pus, which is abundant and settles readily into a viscid sediment. The sediment usually contains abundant amorphous phosphates and crystals of triple phosphate and ammonium urate. Vesical epithelium is common. Numerous bacteria are always present."

In *chronic parenchymatous nephritis:* "The quantity is usually diminished; color variable, often pale and hazy; specific gravity 1010 to 1020. Urea and chlorides low. Largest amounts of albumin, up to 3 per cent. Reaction acid. Sediment rather abundant. Many casts of all varieties; fatty casts and casts of degenerated epithelium most characteristic. Blood present in traces; abundant only in acute exacerbations. Numerous fatty degenerated renal epithelial cells, often free globules of fat, and a few leucocytes."—(From Todd's *Clinical Diagnosis.*)

Sugar: Render the urine strongly alkaline by addition of Na_2CO_3. Divide about 6 c.c. of the alkaline liquid in two test tubes. To one test tube add a very minute quantity of powdered subnitrate of bismuth, to the other as much powdered litharge. Boil the contents of both tubes. The presence of glucose is indicated by a dark or black color of the bismuth powder, the litharge retaining its natural color.

Pus in the urine: Acidify the urine with acetic acid, then filter it, and treat the filter with a few drops of freshly prepared tincture of guaiacum; a deep blue color denotes the presence of pus.

Albumin: The urine must be perfectly clear. If not so, it is to be filtered, and if this does not render it transparent it is to be treated with a few drops of magnesia mixture, and again filtered. The reaction is then observed. If it be acid, the urine is simply heated to near the boiling point. If the urine be neutral or alkaline, it is rendered *faintly* acid by the addition of dilute acetic acid, and heated. If albumin be present, a coagulum is formed, varying in quantity from a faint cloudiness to entire solidification, according to the quantity of albumin present. The coagulum is not redissolved upon the addition of HNO_3.

PATHOLOGY.

4. In a *typhoid ulcer of the intestine:* "The edges are undermined, its floor is smooth, its main axis is parallel with that of the intestine, it lies opposite to the mesenteric attachment; on the corresponding serous surface there is no fibrinous deposit; and perforation is common." In a *tubercular ulcer of the intestine:* "The intestine is girdled by the ulcer, its general outline is oval, it lies with its long axis at right angles to the main intestinal axis unless produced in a plaque by junction of several small ones, its edges are thickened and firm because of the fibrous hyperplasia and are not undermined, the base is uneven and covered with pus and necrotic tissue, and on the corresponding serous surface there is an exudation of fibrin together with little lines and series of tubercles in ring form about the intestine. The ulcer may perforate, but the fibrinous process makes adhesions between neighboring coils or other parts and prevents the escape of fecal matter." (Thayer's *Pathology.*)

5. *Pathological leucocytosis* is an increase in the number of colorless blood corpuscles found in certain diseases and pathological conditions.

Physiological leucocytosis may be produced during digestion, during pregnancy, and after exercising.

6. *Ascites* is an abnormal collection of serous fluid in the peritoneal cavity. And see French's "Practice of Medicine" (1910), page 880; or Osler's "Practice of Medicine" (1909), page 580.

8. In *fatty infiltration* the tissues contain fat brought from without; there is no change in the cell protoplasm, and such damage as the tissue undergoes is due to the mechanical pressure caused by the fat.

In *fatty degeneration* the cell protoplasm undergoes change; the fat is in the cells, and not between them.

9. A *metastatic growth* is one that is set up in a part of the body not directly continuous with the original growth.

BACTERIOLOGY.

1. To demonstrate *gonococci.* On a cover-glass make a smear with the discharge as thin as possible, and let it dry in the air; cover it with a freshly made solution of anilin-oil-gentian-violet for one or two minutes; wash it in distilled water; leave it in Gram's solution for two minutes; wash it in 95 per cent. alcohol until decolorized; wash it in distilled water; counterstain with a dilute carbolfuchsin without heat, or with a saturated aqueous solution of Bismark brown; wash in distilled water, dry with filter paper, mount, and examine with an oil-immersion lens. The gonococci will appear as *diplococci within the leucocytes*, which have been *decolorized by Gram's stain*, and have taken the counterstain.

2. An *antitoxin* is a substance formed in the body, of a protective character, and capable of rendering inert the poisonous products of bacteria.

A *vaccine* is an emulsion of dead cultures of specific bacteria.

An *antitoxin* consists of products of bacteria, but not the bacteria themselves; whereas a *bacterial vaccine* is a preparation of killed bacteria.

3. *Anaphylaxis* is a condition of supersensitization induced by the injection of a serum. It is the opposite of prophylaxis, and in place of rendering the person injected immune the serum has made him particularly susceptible. It has been manifested in some instances by alarming symptoms, such as: Heart failure, collapse, convulsions, coma.

4. *To obtain a culture.* A sterile swab is rubbed over any visible membrane on the tonsils or throat, and is then immediately passed over the surface of the serum in a culture tube. The tube of culture, thus inoculated, is placed in an incubator at 37° C. for about twelve hours, when it is ready for examination. A sterile platinum wire is inserted into the culture tube, and a number of colonies of a whitish color are removed by it, and placed on a clean cover slip, and smeared over its surface. The smear is allowed to dry, is passed two or three times through a flame to fix the bacteria, and is then covered for about five or six minutes with a Loeffler's methylene-blue solution. The cover slip is then rinsed in clean water, dried, and mounted. The bacilli are from 2 to 6 mikrons in length and from 0.2 to 1.0 mikron in breadth; are slightly curved, and often have clubbed and rounded ends; occur either singly, or in pairs, or in irregular groups, but do not form chains; they have no flagella, are non-motile, and aerobic; they are noted for their pleomorphism; they do not stain uniformly, but stain well by Gram's method and very beautifully with Loeffler's alkaline-methylene blue.

The *bacillus of anthrax* is a large, rod-shaped microorganism; with slightly thickened ends; it has a tendency to form long threads; it is non-motile and non-flagellated; it is aerobic.

For treatment of the endocarditis and nephritis, see French's "Practice of Medicine" (1910), pages 582 and 615; or Osler's "Practice of Medicine" (1909), pages 701 and 690.

THERAPEUTICS AND PRACTICE.

8. By *chronic systemic diseases* is probably to be understood "constitutional diseases." See French's "Practice of Medicine" (1910), pages 943, etc.; or Osler's "Practice of Medicine" (1909), pages 389, etc.

10. From the case as reported one might diagnose acute nephritis and endocarditis. The patient may also have cardiac asthma. No final diagnosis or prognosis can be made from the history alone; the patient must be seen and examined more than once; the physical signs may change.

OBSTETRICS.

3. *Labor* is divided into three stages: The *first stage* begins with the commencement of labor, and ends with the complete dilatation of the os uteri. The *second stage* begins with a complete dilatation of the os uteri, and ends with the birth of the child. The *third stage* immediately follows the second, and ends with the expulsion of the placenta and the beginning contraction of the uterus.

10. *Management of inevitable abortion:* "Two methods of treatment have been advised for these cases. The first is *the expectant plan:* Place the patient in bed, and if the bleeding is profuse insert a tampon of iodoform gauze (one yard) well up against the cervix. If this fails to control the hemorrhage, reinforce it by another yard or two of gauze and a perineal pad and binder. Small doses (3ij) of the fluid extract of ergot should now be given every two or three hours. At the end of from eight to twelve hours remove the tampon, when the ovum may be found extruded from the cervix; if not, a vaginal douche of mercuric chloride (1:4000) must be given, and another tampon introduced. If, upon the removal of this second tampon at the end of ten or twelve hours, the ovum is not discharged, then more vigorous methods to secure its expulsion must be adopted. *Active plan:* The physician's hands and instruments are sterilized; the patient is etherized and placed on an appropriate table; the genitalia are thoroughly cleansed and a vaginal douche of mercuric chloride (1:4000) is given; the anterior lip of the cervix is brought down to the vulvar orifice; the cervix is dilated if necessary; the placental forceps is introduced into the uterus, and as much as possible of the ovum is removed; the uterus is thoroughly curetted, and an intrauterine douche of sterile water is given. A light tampon of iodoform gauze is placed in the vagina; the patient is then returned to bed. A strip of gauze may be placed in the uterus in cases of sharp retroflexion, to secure free drainage, and occasionally an intrauterine tampon will be necessary, when the uterus refuses to contract and hemorrhage persists after the use of the curette."—(Gould & Pyle's *Pocket Cyclopedia.*)

GYNECOLOGY.

1. *Endometritis* is inflammation of the mucous membrane lining the uterus. The acute form is due to the introduction of septic bacteria, and is manifested by pain, constipation, irritability of bladder, rapid pulse, rise of temperature, and a profuse discharge. *Treatment* following miscarriage or labor consists in curettage, intrauterine hot sterile douche, free purgation, heat over the lower abdomen, milk diet, and stimulants. Chronic endometritis may accompany numerous pathological uterine conditions, but is generally due to gonorrhea. The symptoms are backache, headache, leucorrhea, profuse menstruation, and impairment of the general health. *Treatment* consists in removing the cause when possible, and when due to gonorrhea curettage and irrigation of the uterus, with the application of an antiseptic.

2. PROLAPSUS UTERI. *Definition:* "A condition in which the uterus sinks below its normal level, but does not protrude through the vagina. *Pathology:* "Decrease in the power of uterine support. Distention and eversion of the vagina with decrease in the power of its sphincter and thickening of its epithelium. The uterus is enlarged from impairment of its circulation, its cavity is increased in size, and hyperplasia of its areolar tissue may result. The endometrium becomes thickened, congested, and inflamed. Ectropion may occur. Varicose degeneration of the vessels of the cervix may take place with consequent absorption of its proper tissue; ulceration may also occur. Pelvic congestion from compression of the hypogastric veins. Tension on the broad ligaments may produce obstruction of ureters and hydronephrosis. Occasionally, epithelioma from continued irritation of the cervix. Varicocele of the pampiniform plexus from torsion of the broad ligaments. When cystocele is present, complete evacuation of the bladder cannot be obtained, and the result is dysuria, ardor urinæ, and cystitis or retention of urine."

Etiology. Injury at childbirth, lacerated perineum, relaxation and elongation of the ligaments of the uterus, loss of rigidity of the abdominal walls, increase in the weight of the uterus, subinvolution, increased intraabdominal pressure. *Treatment:* "Operative, unless some contraindication to operation exists. In such a case some *mechanic device* should be tried for the support of the uterus. Pessaries are not to be recommended, as their constant use leads to irritation and excoriation of the vaginal walls. Probably the best means for supporting the uterus is by Braun's colpeurynter. This is worn only during the day, and can be introduced by the patient herself every morning. The uterus is replaced and the colpeurynter well anointed with carbolized vaseline and containing about an ounce of water, is introduced into the vagina. It is then distended with air, thus making an even pressure on the vaginal walls and not causing ulcerations. *Operative treatment* gives the most satisfactory results in prolapse. In slight cases of prolapse repair of the perineum will effect a cure. The severer grades will require, in addition, some operation on the anterior vagina. The best of these is Martin's operation for cystocele. If the cervix is hypertrophied it should be amputated. Three operations—on the perineum, for cystocele, and amputation of the cervix—are required in the usual case of prolapse. In addition, hysterorrhaphy may be advisable, since there can be no prolapse so long as the uterus maintains its normal position of anteflexion. These operations failing, hysterectomy may be performed."

3. GONORRHEA. *Symptoms:* Pain and burning in the vulva; pain and burning on micturition; dyspareunia; yellowish or greenish discharge, in which the gonococcus can be found; the vagina is hot, red, swollen, and tender. *Possible results:* Cystitis, urethritis, vulvitis, endometritis, salpingitis, septic peritonitis, sterility, condylomata of vulva, abscess of Bartholin's glands.

Treatment: Rest, if possible in bed; freedom from alcoholic or sexual excitement; a mild and unirritating diet; salines and diuretics; plenty of water to drink; a warm sitz bath; douching of vagina with about a gallon of a 1:5000 bichloride solution, or of borax (1 dram to the quart); the douche is to be taken in the recumbent position.

4. Conditions that might cause sterility, and that are susceptible to treatment: Atresia of cervix, malposition of the uterus, membranous dysmenorrhea, lacerations, and anemia.

5. *Hygiene of Puberty:* Constipation must be remedied; diet must be nutritious but simple; frequent rest, moderate amusements, and adequate exercise are necessary; the girl should be instructed with regard to menstruation and the menstrual periods; overwork at school, and nervous excitability, late hours, and much company should be avoided; books, amusements, and associates should be carefully selected.

SURGERY.

3. *Lane's kink* is a condition in which there is a bending or twisting of the ileum near its junction with the cecum; there are also adhesions, generally in the ileocecal region. The condition is caused by descent of the cecum. *Treatment:* Laparotomy and division of the adhesions; Lane recommends ileocolostomy, ileosigmoidostomy, or excision of the colon.

7. *Lane's bone plates* are used in the treatment of fractures. Opinion as to their use is divided. They are probably *indicated* when reduction is difficult and apposition hard to maintain, when tissues or structures are interposed between the fragments, when there is considerable displacement, when the fracture is spiral or multiple. They are *contraindicated* when the fracture is simple, the bones easily reduced and easily maintained in position.

EYE, EAR, NOSE, AND THROAT.

1. *Hypopyon* is a collection of pus in the bottom of the anterior chamber of the eye. *Argyll-Robertson pupil* is a condition in which the pupil accommodates for distance but not for light. *Mydriasis* is dilatation of the pupil. *Presbyopia* is loss of accommodative power of the eye, occurring normally in advanced life. *Ptosis* is drooping of the upper eyelid.

2. *Management of corneal ulcer:* The treatment consists in putting the eye at rest, instilling atropine, and the application of a bandage. Leeches to the temple will relieve the pain. Hot compresses have the same effect. The eye should be douched with sublimate solution, 1:5000, and iodoform dusted upon the cornea. Stronger sublimate solution, boroglycerid 50 per cent., and formalin 10 per cent. are sometimes necessary. Cauterization is occasionally indicated. If perforation seems probable, it should be hastened by a puncture.—(Gould and Pyle's *Cyclopedia.*)

Treatment of iritis: Atropine, dionine, the application of leeches to the temples, hot fomentations, absolute rest in bed, protection from the light, light diet, purgatives, abstinence from alcohol, avoidance of all use of the eyes for near work, constitutional treatment varying according to the etiology, paracentesis, and iridectomy.

3. Atropine may be used: (1) To dilate the pupils. (2) to paralyze the accommodation.

4. "The eye is cocainized; the patient is seated facing a good light, with the surgeon standing behind and supporting the head; the lids are separated and the eyeball is steadied by the fingers of the left hand, the index finger is applied to the margin of the upper lid, and the middle finger to the lower lid, and the two fingers are separated, at the same time gently pressing backward. The instruments used are either the blunt spud, the gouge, or the foreign-body needle. When the foreign body is superficial, the blunt spud will answer. When it has penetrated into the corneal substance, it must be picked or dug out with the gouge, or the needle; in such cases, the instrument is passed behind the foreign body. The wound which results must be kept clean by frequent irrigation with solution of boric acid; frequently a protective bandage is indicated. If a ring of rust is present this also should be removed. Care must be taken to inflict as little injury as possible, and when the foreign body is deep, not to perforate the cornea."—(From May's *Diseases of the Eye.*)

7. Examine the child for adenoids, and if present, remove them.

8. The case is probably one of inflammation or suppuration of the frontal sinus. See Rose and Carless' "Surgery" (1911), page 755; or Da Costa's "Surgery" (1911), page 882.

9. *To examine for deafness:* "If the ticking of a watch or the vibrations of a tuning fork are heard faintly or not at all when held at varying distances from the ear (aërial conduction), but become distinctly audible when the watch or the handle of the fork is placed in contact with the skull or mastoid process (bone conduction), the deafness is of the ordinary variety and due to aural disease. If, on the other hand, watch and fork are heard indistinctly or not at all, both in contact and at a distance, the deafness is due to some lesion of the nerve or its connections. In the first case the nerve is normal and can appreciate vibrations brought by the bone, while, through some fault in the mechanism, aërial vibrations are not transmitted to the nerve endings. In the second case the nerve is at fault and cannot appreciate vibrations, no matter how well they may be conducted." (Butler's *Diagnostics of Internal Medicine.*)

SKIN AND GENITOURINARY.

4. "*Acne* is an inflammatory disease of the skin occurring in and around the sebaceous glands, characterized by papules, pustules, or tubercles, affecting chiefly the face, and running a more or less chronic course. Puberty, gastrointestinal disorders, menstrual disorders, uterine disease, anemia, and general debility are etiological factors. Bromides and iodides internally and tar externally may produce acne." (Gould and Pyle's *Pocket Cyclopedia.*)

5. ECZEMA. "An acuate, subacute, or chronic, noncontagious inflammatory disease of the skin, characterized primarily by erythema, vesicles, papules, or pustules, and, secondarily, by scales and crusts, and accompanied by itching and burning. The various forms of eczema constitute about 30 per cent. of all skin diseases. There are several varieties corresponding to the most predominant lesion. These may continue as such or terminate in eczema rubrum or eczema squamosum.

"*Etiology:* The causes of eczema are both *internal* and *external*. *Internal* causes include in their category disorders of the alimentary canal (dyspepsia, constipation, intestinal autoinfection, etc.), functional and organic nerve affections, general debility, rheumatism, uric acid diathesis, Bright's disease, diabetes, affections of the uterus and appendages, dentition, and scrofula. These may at times act as predisposing causes, at other times as exciting causes. The number of *external* causes is legion. They may be classified under the heads of chemic, thermal, and mechanic irritants.

"*Diagnosis:* The diagnosis of eczema is, as a rule, easy. The most distinctive features are: (1) Serous exudation; (2) the gradual merging of the patches into the surrounding healthy skin; (3) polymorphism of the lesions; (4) the symmetry of the eruption; (5) the marked itching and burning.

"The diseases for which eczema may be mistaken are scabies, herpes, zoster, impetigo, sycosis, erysipelas, psoriasis, and ringworm.

"*Prognosis:* Nearly all cases will yield to judicious and persevering treatment. Factors influencing the prognosis are: (1) Type of the disease; (2) duration and extent of the eruption; (3) history of previous attacks; (4) removability of the cause or causes; (5) ability of the patient to care for himself properly.

"*Treatment:* A careful study of the hygiene, digestion, occupation, etc., should be made, and, if necessary, treatment instituted. The gastrointestinal tract most frequently needs attention. The diet must be carefully regulated. Tea, coffee, and alcohol should be reduced to a minimum. Laxatives, salines, and diuretics are often indicated, and alteratives and tonics are of great value." Gould and Pyle's *Pocket Cyclopedia.*)

HYGIENE AND SANITARY SCIENCE.

3. For details of the method of examining school children, see a good text-book on *Diagnosis* or *Pediatrics.*

4. *Antitetanic serum* is a serum prepared on the same general plan as the diphtheria antitoxin, and after injection into a person it supplies sufficient antitoxin to prevent the development of tetanus after infection. It is used as a prophylactic and also as a curative agent in all cases liable to be infected by the bacillus of tetanus. Besides being used in all suspicious punctured wounds it should be used in "fourth of July wounds."

5. Milk may be *pasteurized* by being heated for about thirty minutes to 150° F.

Two diseases commonly carried by means of milk: Typhoid and tuberculosis.

MEDICAL JURISPRUDENCE.

1 and 2. *Rigor mortis* is the condition of rigidity or contraction into which the muscles of the body pass after death. It begins at a period varying from about fifteen minutes to about six hours. It usually begins in the muscles of the eye, neck, and jaw; then the muscles of the chest and upper extremity, and last of all those of the abdomen and lower extremity are affected. It passes off in the same order, in about twenty-four hours. It is said to be due to the coagulation of the muscle plasma.

If respiration has taken place, the lungs will float on being put into water; if respiration has not taken place, the lungs will sink. Further, the lungs before respiration are situated at the back of the thorax and do not fill the cavity; whereas, after respiration, they fill the whole cavity.

4. It may be impossible to determine whether the woman had died from the effects of a criminal abortion. The vagina and uterus should be examined for marks of injury by the use of instruments. Wounds on the walls of the vagina would indicate the use of instruments, most probably by an inexperienced hand; while perforations of the neck of the womb, and sometimes of its fundus, indicate the use of pointed instruments, very possibly in

the hands of a professed abortionist. In some instances a blunt instrument, such as a catheter, is employed; and the instrument may pass up between the membranes and the uterine walls, and tear the placenta, producing internal hemorrhage, and ending fatally. In cases of instrumental violence there will frequently be discovered marks of metritis and peritonitis. The stomach and bowels should likewise be carefully inspected for signs of irritant poisons (abortives), such as redness and the remains of the various reputed abortives, as powdered cantharides, savin, ergot, etc.; also for the oils of savin, tansy, pennyroyal, etc.; the latter may sometimes be recognized by the odor, or they may be separated by distillation or by ether.—(From Reese's *Medical Jurisprudence.*)

5. A *delusion* is a belief in something which has no real existence, but is purely imaginary, and out of which the person cannot be reasoned. An *illusion* is a false or perverted impression received through one of the senses. An *hallucination* is the same as an illusion but without any material basis.

If an individual believes himself to be made of glass, and is afraid of being touched lest he be broken, he is suffering from a *delusion*. If the whistling of the wind is mistaken for a voice telling a person to do a certain thing—that would be an *illusion*. If a person fancied he heard a voice when there was nothing at all to be heard that would be an *hallucination*.

Medicolegal Notes.

Non-expert Opinion as to Condition of Injured Person.—The opinion of a non-expert witness as to the apparent condition of an injured person is not, it is held, admissible unless the injury is such that its nature, extent, and effect would be obvious to the common mind—such injuries, for instance, as the loss of a limb. The apparent condition of an injured person might not be the real condition and testimony thereof by one not an expert on the essential effect of appearances would have very little, if any, tendency to disclose that the injured party "was not injured as badly as he claimed to have been."—Carr v. Stern, (Cal.), 120 Pac. 35.

Admissibility of Physician's Expert Evidence.—In a murder case where the theory of the State was that the deceased was asleep when he was shot and never moved after the fatal injury was inflicted it was held proper to allow practising physicians to testify that a man shot in that part of the head where the deceased was shot, the bullet ranging as they judged this one did, "no voluntary movement would occur, as there would be no volition and would produce instant paralysis of the entire physical system."—Streight v. State, Texas Court of Criminal Appeals, 138 S. W. 742.

Limitation of Actions for Malpractice.—In an action of damages for injuries caused by unskillful treatment the defense was not guilty and also that the cause of action did not accrue within three years before the action was commenced. The declaration alleged that the defendant did "undertake the treatment of" the plaintiff, and that "it was the duty of the defendant as physician to properly and skillfully treat the plaintiff; but the defendant did so carelessly, negligently, and unskillfully treat the plaintiff that he was thereby injured." These allegations, it was held, are applicable to a tort growing out of a contract, and they do not exclude the existence of an express or implied verbal contract relation between the parties which is usual in such cases. Thus considered, the action was upon an "obligation or liability not founded upon an instrument of writing," and was barred in three years under the Florida Statute (1906), Section 1725, Subd. 5.—Palmer v. Jackson, Florida Supreme Court, 57 So. 240.

Necessity for Medical Expert Evidence.—A railroad passenger's breast was pierced by an umbrella rib while he was alighting from a train. The physician who attended him testified that he took the plaintiff's statement to that effect for granted, and that he saw that the wound had a scab on it which he did not pull off. Whether the wound was a mere surface wound or whether the instrument which made it went through the chest the evidence failed to describe. The physician's evidence showed nothing as to an injury to the plaintiff's lungs or speaking organs. It was held to be error to permit the plaintiff to testify that the injury to his chest had affected his lungs or speaking organs. That was a matter for an expert diagnostician, whose opinion, when rendered upon a given state of facts, would, without being held infallible, go to the jury as evidence to be weighed by them, along with the other evidence, in passing on the question of the true cause of the disease.—Central of Georgia Ry. Co. v. Clements, Alabama Appellate Court, 57 So. 52.

Medical Items.

Value of the Wassermann Reaction in a General Medical Service.—O. Weill tested all the patients who entered his medical service during six months with the Wassermann reaction. None of these patients came in on account of florid syphilis, and all syphilitic cases were supposed to have been sent to another clinic. The patients tested were 225 in number; of these 64 reacted positively to the Wassermann test, that is, 28.44 per cent. After the positive test they were carefully questioned as to their previous illnesses and in all cases they admitted having had syphilis. There were among these patients cases of visceral sclerosis, diabetes, bronchial dilatation, aortic dilatation, neoplasms, icterus, cerebral hemorrhage and softening, tabes, general paresis, amyotrophic lateral sclerosis, Jacksonian epilepsy, meningomyelitis, and other nervous phenomena. The author's results give a valuable demonstration of the value of the Wassermann reaction in general medicine. This reaction allows one to recognize many cases of syphilis that would not be otherwise detected, and to treat them properly. It shows the terribly disastrous effects of the disease and the profound mental and moral decay that it causes. Nearly all the nervous maladies of organic form seem to be due to syphilis.—*Journal Médical de Bruxelles.*

Chronic Prolonged Angina Due to a Staphylobacillus.—J. Perquis and F. Cheverel present the history of a case of prolonged sore throat lasting for some nine months, in which there was every local appearance on the tonsils of a diphtheritic membrane, but without general symptoms. Applications of antiseptics caused the membrane to be absorbed, but it soon reformed. Antitoxin given repeatedly did not produce any curative effect, although symptoms of anaphylaxis developed. The bacteriological examination showed no Klebs-Loffler bacilli, but revealed an organism that was Gram positive, slightly virulent to the guinea-pig, and that was a white staphylobacillus. This same organ has been reported by several other authors as causing angina. It was found in the throats in two cases of meningitis, one tuberculous, and the other caused by the meningococcus; in the intestinal mucus of a case of enteritis, and in the blood of one case of septicemia. It probably resides generally in the intestine. Systematic examination of all cases of pharyngitis might show this germ frequently present in chronic sore throats.—*Gazette des Hôpitaux.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended May 11, 1912.

Places	Date	Cases	Deaths
CHOLERA			
India: Bassein	Mar. 10–16	3	2

THE LUETIN TEST FOR SYPHILIS.

A PRELIMINARY REPORT OF FORTY-FOUR CASES.

BY R. B. H. GRADWOHL, M.D.,

ST. LOUIS.

IN the *Journal of Experimental Medicine*, Vol. XIV, No. 6, 1911, Noguchi gave a brief report of his work with the use of dead cultures of the *Treponema pallidum* in the diagnosis of syphilis, using them by the "cutaneous test" method. This work follows up the idea of von Pirquet with respect to the diagnosis of tuberculosis by a skin test, in other words, an effort was made by Noguchi to elicit from syphilitic tissue by means of stimulation with dead cultures of the specific organisms a reaction dependent upon "anaphylaxis," or active or passive immunity, or "allergy," as it has been variously called. It is undeniable that tissues thoroughly infected by a specific organism take on characteristics of such a nature that when these selfsame tissues are irritated so to speak, by rubbing or injection with killed specific organisms of that disease, typical and classical phenomena occur, to wit, redness, swelling, the formation of papules, pustules, etc. In the von Pirquet test for tuberculosis we know that the reaction is a reddening of the skin following the scarification and rubbing in of dead cultures of the tubercle bacillus. Up to the time of Noguchi's discovery that he could artificially cultivate the *Treponema pallidum* by means of a culture medium composed of ascites fluid and agar, with a piece of kidney of a rabbit, all contained in a long tube covered with paraffin oil, to promote anaërobiosis and at the same time prevent the evaporation and drying out of the medium, no one had succeeded in definitely producing a skin test for syphilis. Meirowsky, Wolff-Eisner, Tedeschi, Nobl, Ciuffo, Nicolas, Favre and Gauthier, Neisser and Bruck, and Jadassohn had all attempted to induce this reaction by using extracts of syphilitic tissue. These attempts were not uniformly successful.

Noguchi succeeded in obtaining uniformly a characteristic reaction upon the skin of syphilitics by putting into the superficial layers of the skin a dead culture of *Treponema pallidum*. He made the cultures for the cutaneous test, as described in his original paper, in the following manner: "Two strains of the pallidum were used. Pure cultures were allowed to grow for periods of six, twelve, twenty-four, and fifty days at 37° C., under anaërobic conditions. One was cultivated in ascitic fluid containing a piece of sterile placenta, and the other in ascitic fluid agar also containing placenta. The lower portion of each solid culture in which a dense growth had occurred was cut out and the tissue removed. The agar columns which contained innumerable spirochætæ were then carefully ground in a sterile mortar. The resulting thick paste was gradually diluted by adding, little by little, the fluid culture which also contained an enormous mass of the pure organisms. The dilution was continued until the emulsion became perfectly liquid. The preparation was next heated to 60° C. for sixty minutes in a water bath, and then 0.5 per cent. carbolic acid was added. When examined under the dark-field microscope, 40 to 100 dead pallida per field could be seen. Cultures made from this suspension remained sterile, and with them no infection could be produced in the testicles of rabbits. The suspension was kept in a refrigerator when not in use. I propose to speak of this preparation ununder the name of "luetin." In order to ascertain whether the reaction produced with this suspension might not be due to the introduction of the carbolized culture medium alone, it was necessary to prepare a similar emulsion with uninoculated media for control purposes."

I wish to briefly catalogue a series of cases in which I attempted to determine the value of the test in the diagnosis of syphilitic infection, in conjunction with the Wassermann complement fixation test. Dr. Noguchi was good enough some time ago to supply me with a quantity of luetin for this purpose. Some of the cases in my series were injected by Dr. Noguchi himself, upon the occasion of a recent visit made by him to this city. I can do no better than by submitting the cases at once, with a very brief clinical history of each. I wish to express my sense of obligation to the following gentlemen for the privilege of using their cases for this work: Drs. H. J. Scherck, W. M. Robertson, W. W. Graves, L. Sale, G. Cale, L. Schuchat, O. L. Suggett and W. B. Dorsett.

It can readily be seen from scanning this list that the luetin test is negative in primary syphilis, negative at times in secondary untreated syphilis, negative in some latent and parasyphilitic diseases. Also, it is to be noted that it is positive in treated secondary cases, particularly after an injection of salvarsan; positive in tertiary cases as a rule. Its relationship to the presence and absence of the Wasserman reaction can also be seen from the above; namely, the Wassermann is often positive when the luetin is negative, and vice versa. We know that the Wassermann test is dependent upon the infectivity of the invading microorganism, while the luetin test is dependent entirely upon the anaphylactic reaction of long-infected syphilitic tissue. Naturally, we cannot expect the luetin test to be positive until the individual has been infected long enough for his tissue to become sensitized. Once this sensitization of tissue has taken place, a positive luetin reaction will be observed as long as the patient is infected. Noguchi advances the hypothesis that the disappearance of the luetin reaction may mean that the patient is "cured" of the disease. We know that the disappearance of the Wassermann has no rela-

4[illegible]	[illegible] (Dr. [illegible]), supposed syph. stricture rectum, no history		Negative
4[illegible]	A. F., optic nerve atrophy, luetic case 1½ yrs. old. Salvarsan [illegible] 1 yr. ago into hip, lot of pain, swelling, no other treatment until 1 week ago, another Salvarsan intravenous, with Hg. injection now being taken, more tests to follow	[illegible] a "torpid" reaction. Negative	Positive + +

tionship at all to a definite stamping out of the disease. Sometimes it becomes negative without any treatment. Sometimes after becoming negative the Wassermann becomes strongly positive under full treatment, not on account of such treatment, but in spite of it. Sometimes there is a fluctuation in the complement fixation test, now positive, now negative, and again positive. In other words, the Wassermann to my mind has no prognostic or therapeutic importance. It is present in my personal series of reactions in about 40 per cent. of tertiary cases, whereas the luetin test I believe will show up in a much greater percentage of cases.

I should like to say a word or two regarding the technique of administration of the luetin test. Dr. Noguchi keeps it in cork-stoppered bottles. It should be kept on ice when not in use. It is used by mixing one part of the luetin to two parts of sterile salt solution. Two syringes are to be used, one for the luetin, the other for the "control" fluid, which is simply a suspension of the culture medium without any spirochetes. The luetin is injected into the left arm, the "control" fluid into the right arm. About 0.05 c.c. of the solution is to be injected. The skin is prepared by rubbing briskly with sublimate-alcohol solution, then allowing it to dry. The luetin is injected intradermically, that is to say, as superficially as possible into the layers of the skin, not subcutaneously. To do this properly one should use a very fine needle with a short sharp point. The needles that ordinarily come with the regulation tuberculin syringe I find quite ideal for this purpose. Syringes and needles should be thoroughly boiled before use. Where one has a large number of cases to test, the two needles attached to the syringes loaded with many doses of the luetin and control fluid respectively, can be "flamed" between each injection, thus saving a good deal of time and also preventing infection. No dressing is applied to the inoculated places. The injection is made into the outer aspect of the arm just above the elbow joint. If the injection is made properly, a small white wheal is raised by the fluid. Extreme caution is to be used to make the injection as superficial as possible. This can be done by sliding, as it were, the needle into the skin so that the eye of the needle just passes beyond the observer's vision into the skin. Every step of the process must be carried out with a full "bacteriological conscience," from the time of opening the bottle containing the luetin or control fluid until the needle is withdrawn from the skin of the patient. The stopper of the bottle should not be touched by the fingers except where it does not come in contact with the neck of the bottle.

The stopper can be "flamed" before it is put back into the neck of the container. The luetin and control fluid should be sucked up into the syringe from a sterile glass container so that any chance of contamination of the bulk of the fluid may be properly avoided. Before using either the luetin or the control fluid, it should be inoculated upon culture tubes to determine whether there is any bacterial contamination. These culture tubes should have been placed in the incubator twenty-four hours before they are inoculated, to determine their own sterility. If found sterile, then they may be inoculated, and, if the test fluids show no growth after twenty-four hours incubation, one may safely proceed with the test. From time to time, reinoculations from the bottles should be made on culture tubes in order constantly to control their sterility. It is manifest that if these fluids become contaminated with gas-producing organisms such as the staphylococcus, one will obtain pustules in all cases in the left or right arms, or both, dependent upon whether one or both bottles are contaminated. This of course vitiates the findings. Too much care cannot be taken in preserving inviolate the sterility of these two fluids.

The reaction which takes place should be looked for after the seventy-second hour or later. One should not look at the subjects until the third day, so as to give the traumatic effect time to subside. One will observe a positive reaction in the three following forms (quoting from Noguchi):

"(A) Papular form: A large, raised, reddish, indurated papule, usually five to ten millimeters in diameter, making its appearance in forty-eight hours, surrounded by a diffuse zone of redness and marked telangiectasis. The dimensions of this lesion increase slowly for three or four days, after which the inflammatory signs begin to disappear. The induration lasts about a week, except in certain instances where the reaction persists; this is seen in secondary syphilis under full mercurial treatment where there are no manifest signs at the time of the making of the test. Congenital syphilis shows this also.

"(B) Pustular form: This resembles the papular form until the fourth or fifth day, when the inflammation increases, the surface of the papule becomes edematous and multiple vesicles form, with central softening of the papule. In twenty-four hours the papule changes into a vesicle filled with semi-opaque fluid that becomes purulent. This pustule soon breaks, with a definite defect in the skin. I have seen this become quite severe, almost resembling a very large pustular infection of the skin (Case 38). This had to be treated surgically, bichloride packs, etc. This is seen in tertiary cases.

"(C) Torpid form: In rare instances, the injection sites fade in three or four days and then suddenly flare up." This was true in Case 43, where I made the mistake of calling the reaction "negative" after the fourth day. Three days later it suddenly flared up, with pustular formation.

I have seen all grades of these three forms in the cases cited above. I must say in regard to the normal or control cases that all traces of the injection in both arms disappeared in three days, the only visible indication that anything had been done to the skin being a faint bluish discoloration. In other words, there seems no possibility of mistaking a negative for a positive reaction, provided one has made the injection properly, and also provided the fluids are sterile.

Noguchi describes a peculiar phenomenon of the skin of syphilities seen in the right or "control" arms of the patients upon whom this test is performed, namely, what he calls, after Neisser's celebrated designation of the peculiarity of syphilitic tissue, "Umstimmung." Neisser first called attention to the pathological condition of the skin of syphilities whereby a slight traumatism will produce much more severe reaction than would be the case with the skin of normal individuals. Finger called this "superinfection," presupposing that a trauma applied to syphilitic skin created a spot of weakened resistance and wandering of the spirochetes thither from some hidden focus. Neisser's view seems to be more correct inasmuch as no one has ever found spirochetes in such traumatic spots. I have seen this "umstimmung" reaction in the control arm in five of the forty-four cases just cited. The reaction in this "umstimmung" arm was not nearly as severe as in the luetin-injected arm. Noguchi does not believe that the luetin reaction is altogether "umstimmung" in nature; rather does he incline—and I believe rightly—to the original idea of its being an allergic phenomenon. Of course, some "umstimmung" might be mixed up with the allergic reaction.

I wish to state that the Wassermann reaction worked out in conjunction with these cases was made according to the so-called "straight" Wassermann technique, using the anti-sheep system, with careful controls, with two kinds of antigen, etc. Definite quantities of the patient's serum were used in falling doses, beginning with 0.2 c.c. and dropping to 0.1, 0.05 and 0.025 c.c.

From these considerations one might conclude that the luetin test of Noguchi will become quite useful in assisting in the diagnosis of lues and, possibly, may help us in estimating a "cure" of the disease, if one can conjure up his imagination sufficiently to believe that this disease can be cured. We cannot expect any help from the test in the primary and secondary stages. When active treatment has been given in the secondary stage, particularly salvarsan, one can expect a positive luetin reaction. It will be of greatest service, I believe, in those obscure tertiary manifestations where the Wassermann reaction so often fails. As to its presence in so-called parasyphilis, I have not as yet had sufficient opportunity to draw deductions in this group of cases. We expect to try it out thoroughly in the service of Dr. W. W. Graves in the Neurological Department of the Alexian Brothers Hospital, due report of which results will soon be published. Noguchi has certainly given us a test which will rank up close to the Wassermann reaction in certain cases. Nevertheless, like the Wassermann, it is a symptom and only a symptom, and until further light can be thrown upon it, it should be regarded only as such.

GONORRHEAL ARTHRITIS: METHODS OF DIAGNOSIS AND TREATMENT.*

By G. K. SWINBURNE, M.D.,

NEW YORK.

For the intelligent treatment of all cases of arthritis an accurate diagnosis is essential. The following case will illustrate the importance of this point:

Case I.—In November, 1911, a physician, age 33 years, married about four or five years, and

*Read before the Boston Orthopedic Club, February 12, 1912.

having one child, came under my care with a chronic arthritis of the left knee-joint. The leg was fixed in extension, the knee swollen and painful and surrounded by a good deal of old inflammatory exudate. At the age of 13 he acquired a gonorrhea which lasted about two months. Two years later, when 15 years old, his left knee-joint became severely inflamed and he was taken to an orthopedic surgeon, who pronounced it tuberculous. He had been under this surgeon's care for a period of 18 years, during which time the knee had never been completely well, though the condition varied from better to worse. At times it was so nearly well that he was able to dance, and then the condition would relapse. At the age of 23 he acquired a second gonorrhea, for which he was treated about seven weeks, but no further trouble from this infection was noted. For the last few years his knee gave him a good deal of trouble. It was almost always painful, and slight trauma would lay him up in bed for several days. Finally, in the early fall of 1911, he had an *x*-ray plate made. The physician who took this stated that it did not appear to indicate a tuberculous joint, so he took the plate to another orthopedic surgeon, who stated that the plate suggested a gonorrheal joint. The patient came to me and asked if I would give him injections of gonococcic bacterins. An examination of the prostate and vesicles showed that he had chronic prostatitis and vesiculitis. Examination of the expressed material did not reveal any gonococci, nor could I find any microorganisms in it. I did not have a culture made. I advised that before anything was done that the complement-fixation test for gonorrhea should be made from a specimen of his blood. This specimen was examined by Dr. H. J. Schwartz, who reported that the blood reaction was positive for gonorrhea. I then started in with gonococcic bacterins, beginning with twenty millions and running up at each successive injection, every other day, until five hundred millions were reached for the dose. The prostate and vesicles were also treated. At the end of two weeks the pain had practically ceased, the patient was able to walk without a cane, and to stand all day without fatigue. At the end of six weeks the bacterin treatment was ended. At this time there was absolutely no pain in the knee and it was reduced three-quarters of an inch in circumference. The prostate and vesicles were treated during the remainder of the winter. The patient from that time to this has remained in the same condition. As regards pain there is none. The knee is still stiff, but there is no pain and the slight movement would seem to indicate that there is no bony ankylosis.

The second case, which would show the importance of diagnosis, was a case appearing in the practice of Dr. George W. Warren, who gave me the man's history.

Case II.—H., age 42, married, manufacturer. Had many previous attacks of gonorrhea. Last attack occurred four years ago. He had then empyema of the seminal vesicles, acute prostatitis, double epididymitis, a general systemic infection which manifested itself in a rise of temperature varying from 101° to 104° for four weeks. During this time the knee was swollen and contained fluid. A finger and one sternoclavicular articulation were also involved. At this time, four years ago, he left town with pus in the prostate, but no gonococci were found at that time. He remained in fairly good condition for a year and a half. During the past two years he has been losing weight, his general condition going down hill; both knees alternately swelling, with great pain in the muscles of the back, and great difficulty of motion after rest for a short time. During the time that he was out of New York he spent most of the time in business in Ohio, and he sought relief by going to various springs and places where he received the bath treatment for rheumatism, not only without relief but getting worse all the time. Present history: He returned to New York early in December with a loss of weight of twenty pounds since the last visit; inability to walk in an upright position; his right knee markedly swollen, and with inability to bend it; his urine clear and containing a few shreds, with an indurated seminal vesicle felt on left side; his prostate hard and nodular and yielding a secretion showing pus and cultures of which were found to contain pure *Staphylococcus aureus*. Nevertheless, on December 28, 29 and 30, he was given 2 c.c. of antigonococcic serum without improvement. His bladder was washed daily and massage of the prostate was performed at regular intervals. In view of the fact that there was no improvement from the serum and that the *Staphylococcus aureus* and no gonococci were found, on January 1 treatment with the combined bacterins (Van Cott) was begun. These were administered twice a week, while on the other days of the week he was given the new Schäfer products with which we are experimenting. The one used was the "mixed infections vaccine." I will give a description later of the different varieties of the Schäfer so-called vaccines. Under this treatment, which continued from January 1 to January 25, there was steady improvement in the patient's condition, rapid at first, slower afterwards. The injections were oftentimes followed by considerable reaction. Sometimes there was a sleepless night, with chill, fever, and sweating. There was steady diminution of the swelling of the knee. On January 23 the patient was able to enter a bowling match, to spend an entire afternoon at the Automobile Show, where he was exhibiting, and to run up and down stairs. At this period he left town without further treatment. In reviewing the history of this case it is to be noted that the greatest improvement followed each of the injections of the "combined bacterins" (Van Cott).

The importance not only of making an accurate diagnosis of joint lesions, but in gonorrheal arthritis of accurately determining what lesions exist in the urinary and genital tract, is exemplified in the following case:

Case III.—The first year that I began experimenting with Rogers-Torrey antigonococcic serum, I had a Swedish patient, about 35 years of age and weighing about 200 pounds, who visited the dispensary. At the time of admission he had an acute gonorrhea, which rapidly became posterior. In about three weeks he developed acute gonorrheal rheumatism in both knees and feet and the right shoulder. The urethral discharge was profuse; the urine in both glasses was very cloudy. I thought this a good case for treatment with the serum, which was administered for a period of nearly six weeks, during which time the patient lost fifty pounds in weight. There was not the slightest indication of improvement in his condition; the only change seemed to be loss of appetite and weight. It was with great difficulty that he could get to the dispensary, although he lived only a few doors away. This patient gave a history of gonor-

rhea fifteen years before, and despite the fact that he now had a profuse purulent discharge, well loaded with gonococci, I made an examination of the urethral canal for the first time and found a narrow stricture situated about three inches from the meatus through which I could barely pass a flexible bougie No. 12 F. This stricture yielded readily to dilatation, so that in ten days I had the urethra up to its full capacity, and without further medication the patient's condition began to improve. The pain left his joints, the discharge ceased, the urine became clear, and from then on for a period of six weeks he had entirely regained his weight. The only lesion remaining was a stiffness of the right shoulder joint. In raising the arm the scapula would move with it, showing marked adhesions about that joint without ankylosis. I then again injected antigonococcic serum with the result that in about two months he was completely restored to health.

CASE IV.—This is another example illustrating the importance of accurate diagnosis. A. J., 35 years, single, had been irregularly treated at the dispensary three years previously for gonorrhea. One year later he appeared with marked stiffness and swelling of the fingers of both hands so that he was unable to work. He got at that time a few injections of the antigonococcic serum and then disappeared. A year later he returned to the dispensary with his hands in the same condition and asked me if something could not be done, that he had been unable to work for the last year or more, and was down and out. I took it for granted at that time that his trouble was gonorrheal rheumatism, and I made a complete examination of the urinary tract. Everything, however, appeared practically normal. I began to treat him with the gonococcic bacterins with negative results. I decided on a complete change of treatment and employed electrical treatment with the D'Arsonval current, the static current, the different forms of sparking and brush discharge, and the Morton wave current. Some slight improvement was noted which allowed him to go back to work for a few days, at the expiration of which time he returned to the dispensary as bad as ever. In July, 1911, I obtained some of his blood for the complement-fixation test for gonorrhea. The test gave a negative reaction. At this time I was carrying on a series of experiments with the gonorrheal vaccines (Schäfer) and the fixed infection vaccine (Schäfer), giving on alternate days 5 c.c. subcutaneously beneath the scapula. Ten injections were administered and steady improvement was noted in the fingers of both hands. He left the dispensary, went back to work, and has not been in since. What his present condition is I cannot say nor have I been able to trace him; but from the fact that he was so much improved, and was so enthusiastic regarding the treatment, I believe that if the results were not permanent he would, at least, have come to see whether anything more could be done.

The complement-fixation test for gonorrhea, in my opinion, has added a valuable means for making a differential diagnosis in cases of arthritis, and it is my habit to use it almost constantly. It is, of course, more important in chronic cases than in acute. An acute arthritis following closely upon a recent gonorrhea, with a history of repeated attacks of gonorrheal rheumatism occurring during the attack, as quite frequently we see them, renders it quite probable that such cases are pure gonorrheal arthritis. The tendency of the patients to conceal their urethral condition from the physician, unless he is the one who has been treating it, makes it important in cases of joint disease to bear in mind the possibility of gonorrheal infection.

Treatment: Since 1900 I have been working on such cases of gonorrheal arthritis as come to me in the course of my clinical work with serums and bacterins. The manner in which they have been employed has been somewhat outlined in the histories already related. On several former occasions I have given my views as to the value of the antigonococcic serum and stock gonococcic bacterins. During the past year, through the courtesy of the Department of Experimental Medicine of Parke, Davis & Company, I have been enabled to employ two experimental products prepared according to the suggestions of A. F. Schäfer, of Bakersfield, Cal. These are known as mixed infection vaccine (Schäfer) and gonorrheal vaccine (Schäfer). The application of the term vaccine to these products seems to me to be a greater misnomer than its application to suspensions of dead bacteria, commonly called bacterial vaccines, as no bacteria are in the solution, which consists merely of the filtrate of cultures grown on a fluid medium. According to Schäfer's description in the *Therapeutic Gazette*, April 15, 1911, the mixed infection vaccine is made from a large variety of pathogenic bacteria, grown in suitable culture media, and after the addition of pure carbolic acid the product is then filtered through porcelain, and the filtrate is the material employed. The filtrate, therefore, contains the metabolic substances which have developed from the growth of many bacteria on the culture media. The finished product contains about 0.5 per cent. phenol as a preservative. The mixed infection vaccine is the basis for the production of all vaccines, but for the treatment of specific conditions an excess of a similar filtrate is added, that is, in the preparation of gonorrheal vaccine (Schäfer) 50 per cent. of the product is mixed infection vaccine and the remainder is a similarly grown product in which the gonococci alone are employed.

In the use of these experimental products I have not found it necessary to change my views which I have previously stated on several occasions relative to the fact that gonorrheal arthritis, occurring in the course of a primary gonorrhea, is almost invariably amenable to treatment by antigonococcic serum, and in my opinion it may be considered an absolute specific for such cases. In chronic gonorrheal arthritis my results with gonococcus bacterins have been more efficient than with the antigonococcic serum. All my clinical experience has been limited to the use of stock bacterins, as at no time have I used the autogenous products, but so far my results from these stock vaccines have proved very beneficial in cases in which, in addition, careful attention has been given to the proper diagnosis and the proper treatment of the chronic lesions in the urinary and genital tracts. In the majority of cases of chronic arthritis occurring in the male (and my experience is chiefly limited to infections of the gonococcus in the male) the prostate, vesicles, and verumontanum are the usual seat of the lesions in the urinary and genital tract. As it may prove of some interest I am submitting some cases in which I have successfully employed the Schäfer vaccines. One of the earliest gave a history as follows:

CASE V.—A. G., age 21, single, Russian, applied to the dispensary for treatment July 29, 1911. The

primary attack of gonorrhea began four weeks before admission. Two weeks later marked swelling with acute pain, redness, and tenderness occurred in the left elbow joint, with flexion limited to 95° and extension to 130°. One week later hematuria from the posterior urethra made its appearance. Previous to his coming to the dispensary he had received six injections of antigonococcic serum. These at first produced some slight improvement, but later the condition remained stationary. At the time of admission the urine was clear, the prostate appeared normal, and the elbow was swollen and painful. On his first visit he received 5 c.c. gonorrheal vaccine (Schäfer) subcutaneously, and with the exception of a slight headache occurring a few hours after, no other reaction was noted. On his next visit to the dispensary the patient felt very much improved and the pain in the elbow was markedly diminished. Both flexion and extension were increased, the former to 85°, the latter to 145°. Similar injections were administered, usually on alternate days, until August 26. During this time a total of eleven injections were given without any reaction, but with steady and rapid improvement in the condition, so much so that by August 10 flexion and extension were practically complete. It will be noted in this history that it was an arthritis occurring during a primary attack of gonorrhea and that the administration of antigonococcic serum did not produce marked benefits. The injections of gonorrheal vaccine (Schäfer) produced immediate improvement and ultimately effected a cure.

Case VI.—This case was referred to me by Dr. Louis E. Schmidt, of Chicago. In October, 1911, the patient contracted gonorrhea, which was followed by a prostatitis, and at this time a carbuncle made its appearance on his neck which made him very ill. This was followed by swelling, pain, and redness of the metacarpophalangeal joint of the middle finger. The corresponding joint of the right foot was similarly affected and he also complained of marked pain in the region of the lumbar vertebræ. Before coming to New York the patient had received two injections of 2 c.c. each of gonorrheal vaccine (Schäfer), administered subcutaneously by Dr. Schmidt. At the time of his first visit to me the patient was still in distress, the swelling of the feet being so great that he was obliged to wear a much larger shoe than usual, and he had to use a cane and walked with a decided limp. The discomfort forced him to remain indoors, thereby delaying his visit to me for a few days. Following the local treatment of his prostate and urethra for the prostatitis, I administered a single injection of antigonococcic serum without any effect. This injection was followed two days later by an injection of 2 c.c. mixed infection vaccine (Schäfer) subcutaneously which produced a decided reaction, necessitating his going to bed. For the chilly sensation hot-water bottles were applied. The following morning he was able to walk with much greater ease and the swelling of the feet and hand were markedly diminished. Unfortunately, he was obliged to leave the city and on this account I refrained from giving him a second injection.

Case VII.—T. K., age 31, a Chinaman, born in the United States, came to the dispensary October 4, 1911, with a history of an attack of gonorrhea six months previously. On examination it was found that the prostate and vesicles were affected and the left knee was flexed with but slight motion and considerable pain, which was increased by motion. The patient walked on the ball of his foot. This condition had existed for five months. Frequent injections of 5 c.c. gonorrheal vaccine (Schäfer) subcutaneously were administered from this time until December 19, with the result that shortly after the institution of this treatment the pain had entirely disappeared. At the present time the knee is still stiff and slightly flexed and the patient still walks on the ball of the foot, but there is no evidence of pain. I have recited the history of this case for comparison with that of the first case reported, that is, the physician with a stiff knee, who had been treated for eighteen years, and I would like to ask the orthopedic surgeons if from their point of view, anything can be done to relieve the stiffness of the joints in these two cases. In one case the gonorrheal rheumatism, as far as I can see, has remained cured for more than a year, and in the other case there has been no sign of the disease for at least three months.

So far my observations have been limited to the clinical results following these vaccines. At the present time I am not in a position to formulate or fully discuss any theories as to how the Schäfer products act. Dr. Schäfer explains these results on the basis of multiple infections and quantitative reactions. The action of these products is certainly peculiar and not thoroughly understood, but some interesting facts have been noted. Dr. Schäfer has stated that the pain in an inflamed joint, whether due to trauma, as a sprained ankle or bacterial infection, as a gonorrheal joint, is relieved by the administration of these vaccines. This is probably due to relief of the tension in the joint. The phenomena that occur following the administration of these vaccines are usually quite pronounced, but vary to a marked extent. The most common are as follows: Two to four hours after the injection the patient complains of a chilly sensation which may vary from a slight sensation to a distinct chill. This is followed by headache, malaise, fever, pain over the stomach, nausea, vomiting, diarrhea, increased perspiration and urination, with usually the relief of pain and swelling in the affected area. Occasionally herpes around the mouth appears. This occurred in only one case of the series I have treated. When the reaction is complete the patient feels much improved. The majority of the cases treated by me have been ambulatory and have been controlled with difficulty. At no time have I administered the material by the intravenous method, by means of which it is claimed the reactions are more rapid and pronounced. G. F. Seaborn in a personal communication has offered a theory relative to the action of these products which may possibly explain their effect in part. He suggests that the Schäfer vaccines may cause pronounced movements of tissue lymph, thereby rapidly calling forth normal antibodies from remote areas into the blood stream, and then supplying them to the infected area. This may also explain the rapid improvement in the case of A. G., in whom the administration of antigonococcic serum did not produce beneficial effects, but in whom the ultimate use of gonorrheal vaccine (Schäfer) caused rapid improvement. The latter product may have caused the rapid movement of the antibodies administered to the infected area, thus effecting the cure. In the case referred to me by Dr. Schmidt, of Chicago, the same result may have occurred or the carbuncle may have produced a mixed infection in the joints which were benefited by the administration of the

mixed infection vaccine (Schäfer). We propose to attempt some experiments along this line in the hope that we may determine the action of this product. I have had in the past two years the following two cases of arthritis occurring with a gonorrhea:

CASE VIII.—A physician came to me with an acute primary attack of gonorrhea. The disease was confined to the anterior urethra. He had been under treatment for several days when an injection which I gave him distended the urethra rather rapidly to such an extent as to cause some pain. I immediately released it and made a slower second injection which the patient held for the usual length of time. There was some slight bleeding from the urethral canal, showing that a trauma had taken place. In the evening the patient was seized with chills, fever, and severe pains and swelling in the left knee-joint. He suffered all that night with the pain and the next day was unable to perform his work. He remained in bed that day and in the evening I was telephoned for and told that his knee had swollen and that he would like to see me. I went, thinking I had to deal with a gonorrheal rheumatism, and was prepared to give him an injection of serum. I saw him about nine o'clock that evening, but before I had arrived the pain had ceased. He was feeling much more comfortable. There was still some swelling, but I decided to do nothing until the following morning, by which time the knee had considerably improved. After remaining in bed all day the following morning he was able to go about, and experienced no more trouble. No treatment other than the local application of heat and cold and no medication other than a brisk cathartic were used in this case. He rapidly recovered from the gonorrhea and had no further trouble nor symptoms. The inflammation of the urethra did not extend beyond the cut-off muscle. He never had a posterior urethritis. It is my belief that in this case the trauma to the urethra enabled some toxins, bacteria, or what not to enter the general circulation. This arthritis was quickly overcome by the patient's own organism without further interference, and my belief is that it was a true gonorrheal rheumatism.

CASE IX.—This was a young man who was treated by me for his first attack of gonorrhea. It was a rather severe anterior urethritis, but never became posterior. One day he appeared with some slight discomfort in the wrist that increased during the day, and the following day when he came the wrist was swollen, red, and painful. I gave him at once an injection of antigonococcic serum. The following day when he appeared the signs of the trouble had markedly diminished. I then gave him a second injection with the result that on the following day there was hardly a trace of the trouble. At the end of three days the wrist had entirely recovered, and no further treatment of the rheumatism was required.

A year ago I became acquainted with the different forms of static electricity, more especially the Morton wave current, the D'Arsonval current, and also the Oudin current as employed by W. B. Snow, of New York. I have found great assistance in the treatment of chronic prostatitis and vesiculitis occurring as a causative factor of gonorrheal arthritis, by the application of the Morton wave through the prostatic electrode over the prostate and vesicles, and I have obtained more rapid and better results than heretofore.

64 EAST FIFTY-SIXTH STREET.

A CASE OF TYPHOID FEVER WITH AN UNUSUALLY LONG DURATION OF 78 DAYS OF THE PRIMARY ATTACK. TWO TRANSFUSIONS. RECOVERY.

BY MORRIS MANGES, M.D.,

NEW YORK.

PROFESSOR OF CLINICAL MEDICINE, UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE; VISITING PHYSICIAN, MOUNT SINAI HOSPITAL.

THE present case is remarkable from two standpoints: first, from the very long duration of a primary attack of typhoid fever without any relapse; and second, from the fact that two transfusions were performed, one to save life after severe hemorrhages; the other, to terminate the disease. To enter into many details of a case of such long duration would involve needless expenditure of time; hence the reader is referred to the chart from which a general conception of the course of the disease may be gained. Only the more interesting features will be especially referred to.

W. M., 30 years of age, came under my care on December 2, 1911, with a characteristic early typhoid fever history of 10 days' duration. The Widal reaction was reported positive on the first examination, which was made on the eleventh day of the disease. The leucocyte count was 6000 with 83 per cent. polynuclears. The urine showed a mild nephritis. The roseola was very scanty, and, indeed, throughout the course of the disease few rose spots were present, the crops being widely scattered. The most profuse crop consisted only of about 15 to 20 spots and accompanied the colon infection (53d to 62d day). The course from the 10th to 17th day was that of an ordinary typhoid fever of moderate severity. On the evening of the 17th day the temperature rose to 105.4°, falling abruptly to 100° early the next morning. A very large intestinal hemorrhage was the cause of this drop in temperature. It is interesting to note that instead of the pulse and respiration rising after this large hemorrhage they actually fell, the pulse from 104 to 96, and the respiration from 32 to 30. Within a few hours after the abrupt drop, the temperature rapidly rose to 105°. After the hemorrhage the hemoglobin was 65 per cent., and the leucocyte count was 10,400, with 85 per cent. polynuclears. Twenty cubic centimeters of human serum were injected to control the bleeding. At midnight there was another drop of temperature from 104.8° to 101°, followed by a chill, and a rapid rise to 105.4°. This drop was not due to the hemorrhage or to the serum, as such oscillations of temperature never occur after injections of human serum.

The whole picture of the disease was entirely changed by the hemorrhage, from that of an average case of typhoid fever to one of a severe type; the most striking feature was the marked distention of the abdomen with pronounced rigidity and partial obliteration of the liver dullness. Flatus was expelled only in very small quantities, and with great difficulty. So extreme was this distention that for the following week a perforation seemed imminent, and all preparations were made for that eventuality, which, fortunately, however, did not occur. The white blood cells kept around 10,000, but the percentage of the polynuclears rapidly sank to 50 per cent. The hemoglobin fell to 60 per cent. About this time a diastolic murmur appeared over the pul-

monary area and persisted throughout the entire disease. Two chills, probably antipyretic, occurred on the 22d day. Clots were passed on the 24th and 25th days. Twenty cubic centimeters of human serum were injected on the 24th day. High temperatures with a clear sensorium persisted without any interruption save for occasional chills. The 33d and 34th days were marked with wide oscillations of temperature which were probably associated with a large hemorrhage which became evident on the 34th day, on which day 20 centimeters of human serum were again injected. The hemoglobin had fallen to 45 per cent. The leucocyte count was 6000 with 72 per cent. polynuclears. The evidence of the anemia had now become very pronounced; the temperature ranged between 105° and 106°, the pulse was 128, respiration was 34, and the general condition was so grave that more radical measures had to be considered to improve the situation. Accordingly, on the 37th day after consultation with Drs. Janeway and Libman, it was decided to transfuse. This was done none too soon, for on the morning of this day there was another chill and a drop of temperature from 106° to 102.4°, and 20 centimeters of human serum were again injected. Again the temperature abruptly rose to 105.4° after a chill and at once fell to 101.6°. While the patient was on the operating table, being prepared for the transfusion, there was another very large hemorrhage of fully a quart. The hemoglobin fell to 30 per cent. An arm-to-arm transfusion was rapidly performed by Dr. Buerger; the flow of blood was stopped when the hemoglobin had risen to 49 per cent.

The good effects of the transfusion on the patient's condition were very striking; the temperature fell to 100° within six hours, the pulse improved in quality and dropped to 100, and the respiration fell to 20. This improvement continued in spite of a very severe chill 10 hours after the transfusion, and a rise to 106.4°, followed by a fall to 101.8° twelve hours later. On the following day (the 39th) there were also several wide oscillations from 104.5 to 99.2°. For these wide ranges of temperature no explanation could be found. The following week was most satisfactory; the range of temperature was moderate, and the general condition was excellent. The hemoglobin kept between 47 and 52 per cent.; the leucocyte count hovered around 4,000, with 75 per cent. of polynuclears. There were no further hemorrhages at this time nor throughout the remainder of the disease.

On the 46th day the temperature again rose to 104.4°, the white blood cells also rose to 6,000, with 84 per cent. polynuclears, the cause being a bronchopneumonia in both lungs. This was not of a severe type, and lasted for five days, camphor in capsules, guaiacol carbonate, and Priessnitz compresses giving excellent results. Fresh trouble now appeared on the 53d day, when a very severe colon infection developed and lasted for nine days, the stools being numerous, profuse, and exhausting. The hemoglobin which had remained steady at about 46 per cent. now began to fall, being only 43 per cent. on the 61st day (white blood cells 6,000, 67 per cent. polynuclears); a high range of temperature persisted. There were occasional involuntary urinations, and the delirious typhoid state, which had been so conspicuously absent all along, finally appeared on the 61st day. On the 63d day the pulse became irregular and intermittent, ranging above 130. The respiration was rapid and shallow and varied between 30 and 50. Hypodermic stimulation with camphor and digalen was now begun; up to this time the requisite stimulation had been obtained with large doses of alcohol and camphor capsules. The hydriatic treatment by means of packs and sponges of various kinds was carried out with great difficulty and the vasomotor tone was lost. Excellent results, however, in improving the latter were obtained by squirting four cold siphons of aerated water, and then giving a short, vigorous sponge. Very little effect was produced upon the temperature, but a rosy glow of the skin was obtained, and the character of the pulse improved.

The condition was now very desperate. The patient lay in a typhoid state with very marked subsultus; feeding was very difficult; the temperature persisted high, between 102 and 105°; the pulse was irregular and above 130. The heart was widely dilated and displaced upward. The diastolic murmur was loud and the sounds were feeble, and an occasional pericardial rub could also be heard at the apex. The abdomen was distended. Both lungs were engorged and full of hypostatic râles with scattered areas of bronchovesicular breathing. Subicterus of the conjunctiva and a very large liver had been present since the 60th day. Two crops of petechiæ had appeared upon the chest and abdomen on the 62d and 66th day. The hemoglobin was falling steadily day by day, so that it was only 39 per cent. on the 67th day, 37 per cent. on the 68th day, and 35 per cent. on the 69th day. The blood culture which was made on the 66th day by Dr. Libman showed that the typhoid bacilli were still present in the blood. The stools were still frequent and exhausting, being nine in number on the 68th day. Evidently the intestinal ulcers were not healing, no immunity was being developed by the patient, and the persistence of the typhoid bacilli in the blood, as late as the 66th day, made it all too evident that the patient was apparently unable to fight his infection, which was still severe enough to cause temperatures of 105° on the 68th day. On the 69th day the only glimmer of hope that there might be a change for the better lay in the fact that there were no stools on that day, and for the first time there had been a profuse sweat. On this day, at a consultation with Drs. Carel, Libman, and Janeway, another transfusion was decided upon, in the hope that the addition of fresh blood might enable the patient to cope with his infection. Unless something radical were done the patient would surely succumb, as he was now almost moribund, and the circulation was rapidly falling in spite of powerful stimulation. Any additional complication of the slightest kind would surely have had the gravest consequences.

Donors having already been selected by Dr. Ottenberg no time was lost in performing the transfusion, which was done a few hours later by Dr. Buerger. In anticipation of this transfusion the fluids had been reduced to half during the preceding 24 hours, and ¼ grain of morphine was injected just before the operation. So extreme was the subsultus that an arm to arm transfusion was impossible, and the arm to leg route was chosen, so that the transfused blood would be introduced more slowly, and would thus embarrass the weak heart much less than an arm to arm transfusion might. The flow of blood was stopped when the hemoglobin had been raised from 35 to 52 per cent. The results of the transfusion were again most gratifying, the temperature fell from 103.2° to 101.2°; the pulse from being 130

and irregular fell to 110 and became regular; and the respiration fell from 34 to 24. There were drenching perspirations during the night. On the following day the temperature rose to 103.6°, but the general improvement in the patient continued. The hemoglobin kept at 52 per cent., and the white blood cells fell to 3,400, with 70 per cent polynuclears. The temperature fell by lysis, and touched 98.8° on the 75th day, five days after transfusion, being accompanied by a profuse sweat each day. On the 78th day the temperature finally touched 98.4°, and remained normal thereafter. The convalescence was rapid and uninterrupted.

The very long duration of 78 days of a primary attack of typhoid fever without relapse is especially noteworthy, as being longer than any other case which a search of the literature has disclosed. Flint's* longest case lasted 58 days. T. C. Janeway has informed me that the longest case which he could recall in the large experience represented in his father's and his own practice was 63 days. Musser† reports a case in which the temperature lasted for 73 days without any known complications. Up to the present year the longest duration of a primary attack which I had observed had been 45 days. During the past winter I had a patient in my service at the Mount Sinai Hospital, in whom the fever lasted 66 days without any complication; yet this case must be excluded, as the temperature touched normal on the 42d day, and immediately rose again; this being a recrudescence, it could therefore not be considered a prolonged primary attack. The long duration due to relapse is well known. All those who have had a large experience with typhoid fever can recall cases which lasted a very long time. Thus, I would mention a case which I saw with Dr. Post which lasted six months, the long duration being due to three relapses. I would also cite the case of a woman whose disease lasted 102 days, on account of a complicating empyema. P. Claisses's‡ case is probably the longest on record, as it lasted 200 days, the initial attack having been followed by five relapses.

That the present case lasted so long was due to a persistent typhoid bacteriemia, as typhoid bacilli were found in the blood culture taken on the 66th day. It is true that there was a distinct downward tendency after the first transfusion, and it looked as if the disease would soon end around the 46th day when the complicating pneumonia occurred. Clinically, however, the disease was still active at this time, even though the temperatures were on the low grade, as the characteristic stools, etc., were still present. After the pneumonia had subsided the severe colonic infection began, and lasted about ten days. Thus the present case presents involvement of both small and large intestines. The two transfusions which were performed are also of interest, since I can find no record of any case in which two transfusions were done successively, each having been performed for a different indication. The first which was done to relieve profound anemia was eminently successful, even though the preliminary drop of temperature that is seen after transfusions in any febrile condition was followed by a secondary rise. The latter is also often seen after transfusions. In this case, however, it rose to the unusual height of 106.4°. The subsequent course for the following week (40th to 45th days) showed a most decided improvement in every respect until the complicating pneumonia occurred on the 46th day. This first transfusion also emphasizes the importance of being prepared for emergencies in typhoid fever. For several days the possibility that a transfusion might be necessary was apparent, and donors were carefully selected by Dr. Ottenberg. Hence it was possible to perform the transfusion within three hours after a decision to do so had been made. In the meantime, the fourth and most alarming hemorrhage of all occurred, just as the transfusion was about to be begun. Had the usual delays which are so disagreeable a feature in all operations in private houses occurred, the loss of time might have been very disastrous to the already enfeebled patient. The second transfusion was performed for an entirely different reason. It is true that the hemoglobin was rapidly growing less and had fallen to 35 per cent. on the 69th day. The purpose of the transfusion, however, was not alone to raise the hemoglobin, but also for the distinct purpose of trying to combat typhoid bacteriemia, by the introduction of fresh blood which might possibly assist in the formation of the antibodies which the patient seemed so unable to produce. The possible danger that this procedure might be a two-edged sword was not lost sight of; hence in choosing a donor, one who had had typhoid fever was sought, as this would have enabled the patient to escape the possible danger that the fresh blood might have to be immunized against the typhoid infection. However, as no such donor could be obtained, and as the need was so urgent, this possible risk was run. The fears of possible harm from the transfusion proved to be groundless, nothing untoward occurring except the usual slight hemolysis, as shown in a moderate number of red blood cells in the urine. It is impossible to assert positively that this second transfusion arrested the disease, yet it is very probable that it did, because of the very marked improvement in the patient's general condition, and the marked betterment of the pulse and respiration and the rapid lysis after it. The only argument which might be advanced against this view is the fact that on the day preceding the transfusion the diarrhea had ceased, and for the first time in the course of the disease a profuse sweat had occurred without any chill; but inasmuch as the temperature was still as high as 105° during the night preceding the transfusion, and as typhoid bacilli were still present in the blood, as shown by the culture taken three days before the transfusion, both these facts would indicate that the rapid lysis which occurred would not have taken place without the transfusion. Such a marvelous change from a moribund patient to that of a rapidly convalescing patient, with a vigorous circulation, is never seen at the end of a severe typhoid fever when nature is left to its own devices.

My belief in the possibility that transfusion may have arrested the disease is strengthened by an experience which I had a year ago in the case of a young woman who was admitted to my service at the Mount Sinai Hospital. For two weeks before admission on November 15, 1910, she had had very severe metrorrhagia and fever from no apparent cause. She was markedly anemic; the red blood cells were 2,000,000. The hemoglobin was 21 per cent.; the colon index 0.5; the white blood cells were 15,000, and there was 73 per cent. of polynuclears. The red cells showed marked poikilocytosis

*"Practice of Medicine," 5th Edition, 1884, page 950.
†*University Medical Magazine*, Philadelphia, 1895.
‡Hare & Beardsley: "Typhoid Fever and Exanthemata," 2nd Edition, 1900, page 277.

and anisocytosis. A few normoblasts were found. The coagulation time was seven minutes. There was no family history of hemophilia. The physical examination was practically negative in every respect. The stools were also negative. The temperature was 102°. The patient stated that she had been feverish for some time. In spite of all treatment, the bleeding and a moderate fever persisted. The patient became so exsanguinated that ten days after admission the red cells had fallen to 1,400,000, and the hemoglobin to 16 per cent. The qualitative changes in the red cells became more pronounced. Several blood cultures were sterile; the Widal and Wassermann tests were negative. On November 27 Dr. A. A. Berg transfused the patient and raised the hemoglobin to 48 per cent. On the following day the red cell count was 3,000,000; the hemoglobin was 56 per cent., the white blood cells were 7,800; the polynuclears were 79 per cent., and the colon index was .9. Microscopically the red cells were almost normal. On December 1 the red blood cell count was 4,200,000, and the hemoglobin was 60 per cent; on December 27 the red blood cell count was 5,200,000 and the hemoglobin was 67 per cent. The bleeding from the uterus ceased after the transfusion and has never returned. During the year following the transfusion the menstruation has always been normal, and the patient has otherwise remained healthy. The temperature was 103.4° before the transfusion; 103 , eight hours after it, and there was a rise to 104.8° 24 hours after the transfusion. On the following morning it had fallen to 100°, but it rose to 104.4 in the afternoon. From this time on there was a gradual lysis to normal within four days. Thus within a week after the transfusion the temperature had become normal, the bleeding had been arrested, and besides a very marked improvement had been obtained in the condition of the blood. In this case the addition of the fresh blood not alone stopped the hemorrhages, but also arrested a fever which had persisted in spite of all treatment for over a month. The nature of this fever must remain unknown, since the blood cultures remained sterile. It was not due to the anemia, but was the result of the same unknown cause which produced the metrorrhagia.

A number of other features deserve mention. Thus the pronounced change in the type of the infection after the first hemorrhage. From running an ordinary course of a moderate infection the patient at once became very ill and the abdominal distention and rigidity became extreme, so much so that perforation seemed imminent. Indeed, those who lay much stress upon performing laparotomy in the pre-perforative stage would more than once have found all their indications for operative interference. A curious feature in the abdominal rigidity was due to the state of distention of the bladder. Polyuria was pronounced throughout the disease; on many days 120 to 130 ounces were passed in 24 hours; on one day the total amount of urine reached 159 ounces. The amount of urine at one time was frequently 26 to 30 ounces; and as soon as the bladder was emptied the rigidity of the recti muscles became very much less marked. Often dullness in both flanks was present; whether, however, free fluid was present or not I do not know. At all events I wish to emphasize the fact that free fluid in the peritoneal cavity without perforation is by no means an infrequent occurrence in typhoid fever. I have seen a number of such cases both in private and hospital practice. Dr. Albert Kohn has also seen a number of these cases in my service at Mount Sinai Hospital.

As I was enabled unfortunately to prove the presence of free fluid in the peritoneal cavity by operation even early in the course of the disease, I will cite a few details of the case. The onset of this attack of typhoid fever was very abrupt, and the symptoms were apparently due to the taking of some tainted food. On the third day the pain in the right iliac fossa was very marked, the fever had rapidly risen to 104 , there was an increasing rigidity of the right rectus muscle and a vaguely defined mass could be felt about the caput coli. The leucocytosis was 15,000 with 85 per cent. polynuclears. The Widal reaction was negative, and the suspicion that a typhoid fever might be present, possibly with a typhoid appendicitis, was ruled out. This possibility has been considered because of the slowness of the pulse, and because there was something about the patient which suggested that one was not dealing with an ordinary appendicitis. On the fourth day free fluid could easily be demonstrated in the peritoneal cavity, and as the pain and fever persisted an operation was insisted upon. On opening the abdomen a large amount of fluid escaped. The appendix and gall bladder were normal; nothing could be detected except injected and infiltrated areas in the ascending colon with enlarged glands in the mesentery. The operation was well borne. But the fever and the leucocytosis persisted; there were neither roseola, enlarged spleen, or any other symptoms of typhoid fever, except diarrhea. Repeated Widals all remained negative, and it was not until the fourth week that the blood cultures revealed a few typhoid bacilli, and thus enabled the making of the diagnosis of typhoid fever, from which the patient eventually recovered.

Human serum was injected on four different occasions after each hemorrhage. It is very difficult to say whether the serum had any effect or not. It certainly did no harm, which is more than can be said of rabbit serum, which so often is followed by a chill and high fever and other anaphylactic phenomena. The coagulative power of the blood was very high, the time of coagulation being less than four minutes. Hence the cause of the bleeding was the erosion of blood vessels in the ulcers, rather than any deficiency in the coagulating power of the blood. It is also of interest to note that in spite of this high coagulating power of the blood no venous thrombosis occurred.

The development of the basal diastolic murmur in the third week is also difficult of explanation; it was persistent throughout the course of the disease. During convalescence it was still present, but was gradually becoming less marked. In spite of this murmur the heart and the peripheral circulation remained excellent until the beginning of the tenth week, when dilatation of the heart became extreme, the arrhythmia pronounced, and the peripheral circulation in the skin so poor that no tâche could be obtained. It was at this time when the peripheral circulation was so poor that the squirting of the cold siphons of aerated water gave so much aid in producing such good reactions of the skin. This procedure of Dr. Baruch's can certainly be recommended as an easy and efficient way in restoring tone to the paralyzed vasomotor system, and

thus affording great relief to an embarrassed circulation. The subicterus and the enlargement of the liver which were constant features after the 60th day, and the appearance of two crops of petechiæ on the 62d and 66th day should also be mentioned. The petechiæ appeared after the last crop of rose spots had disappeared. That these petechiæ were not due to the typhoid bacteriemia alone is probable; otherwise they would be of frequent occurrence. I myself have never seen them in typhoid fever, except in the rare forms of the fulminating hemorrhagic cases.

In conclusion I would say that the experience of this case would indicate that the possible benefits of transfusion should be considered in the treatment of desperate cases of typhoid fever, and that its sphere of usefulness may be a wider one than the relief of acute anemias after profuse hemorrhages.

72 East Seventy-ninth Street

AUTOINTOXICATION THE DIRECT RESULT OF MECHANICAL DEFECTS WHICH PRODUCE STASIS IN THE COLON.

By CLARENCE E. COON, M. D.,

SYRACUSE, N. Y.

ASSOCIATE PROFESSOR OF CLINICAL SURGERY AND RONTGENOLOGY, COLLEGE OF MEDICINE, SYRACUSE UNIVERSITY; ORTHOPEDIC SURGEON, ST. JOSEPH'S HOSPITAL; ORTHOPEDIC SURGEON AND RADIOLOGIST, WOMEN'S AND CHILDREN'S HOSPITAL AND FREE DISPENSARY.

Metchnikoff announced about four years ago that after a careful study of the causes which tend to shorten life, he was of the opinion that chief among the general causes was autointoxication or self-poisoning, and that the chief source of this self-poisoning was the large intestine. "The human organism is by no means perfect; we have within us many defective parts; it is being clearly shown that one of the chief of these is the large intestine. There can be no doubt as to the damage which it inflicts." To overcome some of the evils of autointoxication and thereby prolong life, he advocated the introduction into the colon of bacteria which tend to prevent fermentation, putrefaction, etc. As a result of his studies, we have the sour-milk treatment.

During the past four years, this neglected part of our anatomy has been the subject of considerable study and attention. Sufficient facts have been proven to surely warrant further study, to the end that another subject will be added to those included in preventive medicine, that many lives will be prolonged, and that a majority of our chronic sufferers will be made more comfortable.

The following is compiled from the histories of fifty-five cases, examined and treated between February 1, 1911, and February 1, 1912. I have excluded those examined previous to the former date because of lack of completeness of the clinical examination. A comparative study of these fifty-five cases was undertaken with the idea of possibly finding some symptoms common to all and to make it possible to diagnose most cases without the *x*-ray. In a majority of the cases, the *x*-ray was used and the relation between the clinical symptoms presented by the patient, and the information furnished by the *x*-ray plate, was so constant, that there can be little doubt as to the correctness of the reasoning. It is a well known fact that the patients with obscure troubles which reach the *x*-ray man for study, do so after having consulted from five to twenty-five or more doctors. They belong to the large class of chronic sufferers always seeking relief.

When presenting himself for examination, the patient frequently gives a history of more or less constant abdominal pain more often in either the left or right hypochondriac region and I am requested to make an *x*-ray examination for renal calculi. When I obtain the clinical history, I am apt to find that the patient is always nervous and irritable, and is liable to be restless at night, even when free from pain. He sometimes sleeps very sound and wakes in the morning feeling very tired. He complains of lack of ambition; he is very liable to feel dull or dizzy; he has always had symptoms of indigestion; and he is quite often subject to bilious attacks and sick headache. A majority of the cases have always been constipated and have required very frequent cathartics ever since they can remember. Most of them complain of constant coldness of hands and feet and if the case is at all extreme they present a symptom which I have come to believe to be almost pathognomonic of self-poisoning, namely, a peculiar numbness of the ends of one or more fingers, more often found in the index and middle fingers. The finger presents a blanched, bloodless appearance, a changed sense of feeling, and no interference with motion. This condition is most pronounced on the palmar surface and may persist for an hour or more in spite of the application of heat, friction, motion, etc. When it begins to assume normal tone, there is considerable prickling and a sense of swelling and the part becomes very hyperemic. Since October 1, 1911, I have made this symptom a point of routine examination and out of a total of twenty cases, it was positively present in twelve, doubtful or not given in seven, and surely absent in one. It has been observed that these patients, as a rule, have a subnormal temperature and do not perspire easily.

Many of these patients complain of floating specks before the eyes. Tinnitis aurium is frequent. So-called rheumatic attacks either of muscles or joints are very common. It is rare to find one of these patients that eats meat freely and in general they are underfed and improperly nourished. They have gradually discontinued different articles of diet because of some symptoms which appeared; not necessarily from the food last eaten, which may have been easily digestible. The actual cause of the symptoms having been other food taken some hours previously and which had had time to reach the colon. The distress, of course, was charged up to the last food, and thereafter this was eliminated from the diet and so gradually they get to a starvation diet. Comparatively few have distress soon after eating. Occasionally the active symptoms are referred to the stomach and there may be frequent nausea and quite constant pain. Fermentation and gas formation are usual. In women painful menses are the rule.

The posture of these patients is almost invariably bad. In the relaxed standing position, the lower abdomen is prominent and pendulous, the upper abdomen is constricted and depressed between the level of the umbilicus and the free border of the ribs; the hips are thrown forward and the trunk backward and the lumbar lordosis is less than normal or entirely absent. The shoulders may be thrust forward with the production of the round-shouldered slumped posture. It is often very easy to outline the

stomach and frequently the colon by light percussion, because of the gas present. Quite often, the right kidney is freely movable and it is not at all uncommon to find both kidneys well down. The following is a fairly typical case of visceroptosis:

Miss C. K., age 27, referred by Dr. Larkin. Complains of distress after eating, with gas formation and pain in the right side of the abdomen. She has had this right sided abdominal pain more or less since the age of 14; she has always been subject to bilious attacks, headaches, vomiting, etc. Says she has never been constipated and that several years ago the bowels moved two or three times daily. The menses have always been painful. One year previous to her visit to me she was operated upon for appendicitis and a ventral fixation was done at the same time; two weeks later there was a second operation in which the right kidney was anchored. Pain in her right side is still present and is only relieved by lying down; she is sure the pain is much worse when the bowels do not move regularly. She describes the pain as the dull pulling kind. She is very nervous, and at times very depressed; liable to be restless at night without apparent cause; feels very tired in the morning; she has lost about ten pounds in weight in the last few months. Her diet is very limited, eats very little meat; she finds it necessary to lie down each day for an hour following the midday meal, otherwise she is completely exhausted during the latter part of the afternoon. Examination: patient rather above medium height, inclined to be slim, very little subcutaneous fat, abdomen pendulous below and constricted above, lumbar lordosis nearly normal. Posture erect. This patient was treated by means of an abdominal support. Ten days later she volunteered the information that she did not think it possible to ever feel as well again as she had felt most of the time for the past few days.

In order to make the *x*-ray examination of value, it was first necessary to know the normal size, shape, and position of the stomach and colon. It was very early discovered that the position of the stomach in life is quite different from that found post-mortem, and so with the colon. In the normal, the ascending and descending portions of the colon are located in the position described by all anatomics. The transverse colon is seldom, if ever, above the umbilicus when the patient is in the upright position, so that instead of crossing the abdomen with an easy curve, convex upwards, there is somewhat of an angle at both the hepatic and splenic flexures and the curve of the transverse colon is convex downwards; in other words, the transverse part of the colon in the normal does not remain in one location, and varies from two inches above to some point well below the umbilicus, depending upon the position of the individual, so that if we find the flexures at the normal level and the lowest point in the curve of the transverse colon, not more than one and one-half inches below the level of the umbilicus, and the patient is in the upright position, I would consider the condition as normal and would not expect to find evidence of autointoxication. All *x*-ray examinations are made with the patient standing. The first plate is made immediately after administering an ounce or two of bismuth; this plate gives the size, shape, and position of the stomach; another plate is made at an interval a little longer than the average normal time in which the stomach empties itself, three and one-half to four hours. It was a matter of great surprise to find that many markedly ptosed and dilated stomachs, even when the lowest point of the greater curvature is down nearly to the level of the symphisis pubis, are capable of emptying themselves in normal time. This would seem to indicate that the mere fact of having a dilated stomach is not necessarily of serious consequence. If there is moderate activity of the stomach some of the bismuth will be shown in the colon at this time. Eight or nine hours after the bismuth meal all bismuth is found in the ascending colon and the first part of the transverse colon. The bismuth is widely diffused while passing through the small intestines; only in rare instances is it possible to get a shadow of anything like a mass after the bismuth leaves the stomach until it reaches the colon. The normal time for the journey from pylorus to cecum is much shorter than we have believed to be possible, and probably in less than two hours after leaving the stomach the bismuth has arrived in the colon. It was suggested to me some time ago by an internist that because of the slow action of the colon, some of the symptoms were due to the backing up and retention in the ileum of the products of digestion. I have made several examinations to determine whether there was stasis in the ileum in the region of the ileocecal valve; in no single instance have I been able to show any such condition. The material is very promptly delivered to the cecum and ascending colon. The average normal individual requires about twenty-four hours for the complete process of digestion, from the time food is taken until it is evacuated. From sixteen to eighteen hours of this time it is contained in the colon; it enters this part of the intestine as a fluid and during its progress a large part of its moisture is absorbed. I think physiologists are agreed that the absorptive function of the small intestine is selective in character and that only the products of the digestive action are abstracted here and that the large intestine removes the water and what it contains in solution. The gradual change from fluid consistency with its smooth outlines in the cecum and ascending colon to the lumpy condition and irregular outline in the transverse and descending portions is clearly shown on the *x*-ray plate. Now, if for some reason this material is delayed in its passage through the colon, and this delay may be a day or a week or a month, what is to prevent the growth of bacteria, the fermentation, putrefaction, etc.? And, also, what is to prevent the absorption of the soluble toxins elaborated by the changes which must take place in a medium well suited for the growth of bacteria?

There is a wide variation of positions in which the colon is found in these cases of chronic autointoxication. It is seldom that any part of it is found in the normal position. In all cases examined the degree of displacement of the colon corresponded quite closely to the severity of symptoms as given by the patient. The splenic flexure, or in these cases the splenic angle, is more often located nearer the normal level than any other part of the colon. In cases of obstinate constipation I expect to find the cecum and ascending and transverse colon well down in the pelvis, while the splenic flexure is held high. On the other hand, if the hepatic flexure retains the nearly normal position and the splenic flexure has slumped, there may be no constipation. This is accounted for by the fact that the contents of the bowel are fluid until the hepatic angle is passed, and solid when the splenic angle is reached. In other

cases, the entire colon may be full of kinks and massed in the pelvis, and the surprising thing is not that these people suffer from constipation and its attendant evils, but that an evacuation of the large intestine is possible even when forced by a drastic purge, and it seems logical to believe that in a majority of these cases, the colon is seldom if ever completely emptied. It has been found that constipation is not an absolute essential to the development of self-poisoning. With an abnormal position of the gut, and some kinking, local stasis may result. Fecal masses may be firmly attached to the walls of the colon and remain there long enough to produce ulceration. Frequent attacks of diarrhea may occur and yet the colon may retain material for a long time. One may emphasize the following facts: first, that in the ordinary case of autointoxication food is not unduly delayed either in the stomach or small intestine; and second, at least two-thirds of the first twenty-four hours after food is taken it will be found in the colon in the normal case, and in the abnormal case it may remain many days. It is, at first thought, very surprising that in the past more attention has not been given to this part of the digestive tract. I believe the explanation of this fact is or was the lack of any means of making a satisfactory examination. The former methods of inflating with gas, with the patient in the horizontal position are absolutely without value unless the colon is held by adhesions. The *x*-ray examination with patient horizontal is of some value but does not give the true picture. Examination should always be made with the patient in the upright position.

Not all of these ptoses are acquired either as a fault of diet or dress; the condition is found about as often in men as in women; many are born with the mesocolon of the quadruped. It is estimated that one out of every five individuals has a congenital visceroptosis. I have examined one case of a frail sickly boy with obstinate constipation who had a very marked congenital visceroptosis. It seems hardly probable that the ptosis, of itself, can account for many of the constitutional disturbances; the symptoms are too farreaching to be accounted for on the theory of a pressure or a pulling, or other similar local influence on the nervous system. The symptoms are, with some exceptions, essentially chronic; the patient's versions of his troubles will often seem not to indicate the actual cause. He is cognizant only of results. He has had so many digestive disturbances all his life that they have become second nature to him. Many will tell you that they are not constipated and yet under careful questioning you may find that frequent laxatives are taken. I have found that the patient's idea in regard to his present trouble is not of great value.

It would be of the greatest interest to know what proportion of those who acquire tuberculosis in some form are habitually self-poisoned as a result of stasis in the defective colon and because of the lowered general resistance become an easy prey for the bacillus of tuberculosis. It would also be of the greatest value to know the possible relation between the obstinate constipation of insanity and a ptosed colon. It is very easy to explain why most cases of appendicitis are the direct result of a fault of the colon. As has been shown, the ileum very promptly delivers the material into the cecum and ascending colon; if there is obstruction by an angle at the hepatic flexure or an impacted colon beyond, it is quite certain that the ascending colon, the cecum, and even the appendix itself, are going to be distended. I have a number of plates which show the appendix distended with bismuth. Unless this pressure is relieved by onward movement of the contents of the colon, it will be seen at once what will happen to a rudimentary organ like the appendix as a result of stretching. Later in life, there are many toxic symptoms that are as bewildering to the doctor as they are disagreeable to the patient; symptoms referred to any part of the body—arteriosclerosis, arthritis, neuritis, tonsilitis, catarrhal deafness, chronic blepharitis, acne, urticaria, etc.; in fact, most any chronic condition which is clearly the result of an irritant and which cannot be explained by the presence of some well defined exciting cause. The study of these chronics will be much simplified if we keep in mind the probable toxic cause.

The fairly constant symptom previously mentioned, of numbness of fingers, I believe to be very important and having some manifestations similar to those of erythromelalgia and Raynaud's disease suggests a possible cause for the latter. The fact that a patient has been under medical treatment for a long time, perhaps many years, and has not obtained relief, ought to stimulate us to try to find the reason for the failure on the part of the medical man, before we class our patient as a neurotic and prescribe a placebo and allow him to migrate to the next doctor. Is it not worth while to investigate all possible causes? The chronics are always with us, and by chronics I mean those who have been examined many times and have been assured each time that there was no organic trouble. Yet it is evident that they are miserable. How much are we able to accomplish for their relief? The diagnosis of stasis in the colon is not difficult, but there is much work to be done before an entirely satisfactory line of treatment can be outlined. It ought to be comparatively easy for the chemist to study the results of changes which take place in the retained contents of the colon. The physiologist and pathologist should be able to study the effect of the toxins upon living animals; the surgeon should seek to aid nature in the disposal of waste products by relieving some of the kinks and angles; the orthopedist is called upon to afford some temporary relief in the way of artificial support, and when there is a more general recognition of the actual cause of autointoxication—the ptosed colon—treatment will be devised which will do a lot to relieve these cases. The only satisfactory treatment depends upon the recognition of visceroptosis in the young child; then by careful attention given to the posture and habits, associated with special exercises and perhaps a little medicine, it will be possible to prevent a great deal of suffering later in life. Much can be done to relieve those who have reached the class known as chronics. If the condition is extreme, a surgical operation may be performed to relieve some of the kinks in the colon, the entire sagging transverse colon may be removed, an anastomosis may be made between the ileum and the sigmoid flexure, etc. Excellent results from these procedures have been reported. In less severe cases it is sometimes necessary to put the patients in bed, and keep them in the dorsal horizontal position with no pillow under the head and to elevate the hips in order to facilitate gravitation of the colon to the normal location; many mild cases do very well with a simple abdominal support. In

a great majority of cases, the improvement begins very soon after the recognition of the cause of the trouble and the beginning of treatment, and whatever the treatment, surgical, mechanical, hygienic, or physical, if we keep the idea in mind that we are striving to correct an abnormal position of the abdominal viscera and by so doing enable nature to better eliminate waste products, the real proof of the correctness of the reasoning will be the marked improvement of the general condition of the patient.

The subject is entirely too large to consider in detail in a brief paper. The reasoning from cause to effect, oftentimes a very remote effect, is so complete, the demonstration of abnormalities by means of the *x*-ray and of the results obtained by treatment is so positive, that there will be danger of overdoing this subject in the near future. Let us not forget that there are other organs in the abdomen.

SITOPHOBIA: A DIGESTIVE PHANTASM.

By GEORGE M. NILES, M.D.,

ATLANTA, GA.

PROFESSOR OF GASTROENTEROLOGY AND THERAPEUTICS, ATLANTA SCHOOL OF MEDICINE.

This term, signifying a morbid fear of, or aversion to food, merits the consideration of every thoughtful student of dietetics. Though the term itself is of somewhat recent use, the condition is an ancient one, being one of the manifestations of those peculiar "distempers" in which certain foods were repugnant or even dangerous, and in which the horror of some highly esteemed viands was ascribed to demoniac possession. When, as happened over 200 years ago, the last witch was hung in Salem, the doctrine of personal devils, with all the accompanying devilish attributes, entered into a swift decline, and at present we hear but little of such cant outside of the ignorant and superstitious, with the exception of an occasional echo voiced by some attenuated disciple of the late Mother Eddy.

From the days of "nervous prostration" we arrived by easy stages to the period of "neurasthenia," and then, with a closer insight into various nervous and psychic states, came the present-day psychasthenias and obsessions and phobias. In the same class of phobias as comes the fear of high places, or of open places, or of closed rooms, may be placed sitophobia, with its fixed and often apparently causeless antipathy to some articles of food. Frequently this phobia is confined to a single viand. Probably every physician who reads this study will call to mind a patient, who fancies that some ordinarily harmless article contains for her or him a dreadful potentiality for evil. The patient will explain that since a child this article has been tabooed, and that to eat it would invite direful consequences. Close inquiry may elicit the admission that the aforesaid article has never been eaten, but perhaps it disagreed with some other member of the family and the inference has been drawn that it would necessarily act as a poison to this particular individual.

I have in mind a neurotic traveling salesman, who is morbidly afraid of butter or any dish prepared from it. The sight of butter on the table before him fills his mind with fearful forebodings, while much of his pocket money is spent in tips to waiters and cooks that nothing may be served him containing this evil agent. An eminent neurologist of New Orleans, some months ago, related to me the experience of a citizen of Louisiana, who developed a phobia for garlic, a flavoring agent of high repute in some sections of that State. As nearly all of the savory French and Spanish dishes there contain a "touch" of this somewhat pungent condiment, the patient, who lived in a hotel, found his protein diet extremely restricted. One day, however, in desperation, and at the earnest solicitation of his physician, he partook of a dish containing a little garlic, but he required his medical attendant to stay by his side for six hours to save him from the disastrous consequences anticipated by his abnormal imagination. Finding that he was not injured nor even distressed his phobia fortunately disappeared, and he has since relished the toothsome flavor imparted by this bulb of ancient use, the same that comforted the laborers as they built the pyramids for Cheops, and for which the Children of Israel yearned on their dreary journey in quest of the Promised Land.

As the years go by, and the physiologists delve more deeply into the underlying factors controlling various digestive phenomena, we are disposed to accord to these factors more respectful consideration. Since the epoch-making experiments of Beaumont upon the Canadian voyageur, St. Martin, the chemical functions of the stomach have been fairly well understood. The mechanics of the stomach and intestines when disposing of a meal have also been graphically depicted by Cannon and made clear by many demonstrations with the Röntgen ray. Up to quite a recent date, however, insufficient weight was allowed the psychic factors responsible for the excitation or inhibition of these juices, or for the orderly movements accompanying physiological stomach and intestinal digestion. Briefly stated, when food is taken the secretion first inaugurated is due to the sensations of eating and of taste, that is, it is purely a psychic secretion. The afferent stimuli, whose duty it is to transmit messages of gastronomic interest, originate in the mouth and nostrils, and these stimuli, in their intelligent manner, send the necessary tidings through the afferent path containing the secretory fibers, which path is embraced in the vagus nerve. This psychic message insures the beginning at least of gastric digestion, though its effort is supplemented by further action arising in the stomach itself.

Certain foods contain substances called secretagogues, which are capable of causing a flow of gastric juice when taken into the stomach, for instance, meat extractives, meat juices, soups, etc. Other foods bland in quality such as bread and white of eggs, are lacking in these ready-formed secretagogues, and have to depend practically on the psychic secretions for their digestion. In addition, there are substances generated in the intestinal and pancreatic secretions, designated by Starling hormones, from a Greek word meaning to arouse or excite. These hormones are influenced by the food ingested, varying from a slight to a potent effect, and to a marked extent regulating the various digestive juices, so that both the amount and specific quality are supplied according to the mechanical and chemical needs. These needs are previously interpreted by the psychic sensations evolved, so that it can readily be seen how the mental impress of food as it is eaten may regulate the supply and character of the necessary juices for its digestion; how a placid and cheerful frame of mind may aid the organs concerned in the bodily upkeep, or how a distaste or antipathy may, as it were, "dry up the

fountains" for certain articles, converting them to all intents and purposes into foreign bodies. Thus, it is apparent that a violent dislike or fear amounting to a phobia for any particular foods, will, through the influence of these hormones, exert a real and tangible inhibitory effect on the special agencies required for their digestion, and that to force a fearful patient to eat them might result in serious damage.

The borderline between nervous anorexia and sitophobia is but dimly drawn. The former may deepen into the latter, or the sitophobia may dwindle down to a simple, unreasoning dislike, unexplainable to the patient himself. Such a dislike may be ascribed to temperamental peculiarities, to education, or to environment, and to trace back some of these antipathies or phobias to their starting point is often interesting indeed. Several instances will be mentioned that have come under my personal observation.

A gentleman of intelligence relates to me that when a lad on his father's farm there grew an apple tree right at the stable. This tree which was of the "June apple" variety exhibited a most luxuriant foliage and bore immense quantities of luscious red apples; but, knowing the immediate cause of this bountiful fruitage, he could never eat any of the apples from that tree nor has he to this day been able to eat any June apples. The sight or thought of them sets up a train of disgusting associations which would disturb his whole digestive apparatus were he to attempt to partake of them.

Some years ago a disciple of Izaak Walton betook himself to the Flint River, a Georgia stream, at a time when it was high from a recent freshet. Finding a promising eddy, where the swirling waters circled under an overhaging willow, he began fishing, and, to his gratification, soon caught an amazingly large number of fine catfish. Two days later he decided to again seek that spot, but when he arrived, the fallen river disclosed the putrid carcass of a cow, entangled in the dèbris collected by the eddy, and he quickly understood his phenomenal "catch." From that day to this he has never been able to eat catfish, nor can he enjoy a meal when any of this fish is on the table.

Another etiological factor in producing a sitophobia is a disagreeable or painful personal experience with some food or food product, as the following shows: A lady of mature years informed me that, when a little girl, she was inordinately fond of apple dumplings, thinking she could never get enough. On one occasion, however, the cook made a special baking of the coveted delicacy, so as to permit this youthful epicurean to have her fill. The result was a severe attack of indigestion, leaving in its wake a phobia for apple dumpling that time has not erased.

One of the most fruitful causes of the various sitophobias lies in the "half-baked" writings of self-appointed health teachers, who with lurid philippics hurled at some of our most wholesome articles of food, couched as they are in attractive language, and bolstered up by specious arguments, create injurious dietetic fads. I have in mind one religious sect who constantly inveigh against meat, so that some of its members possess a real sitophobia for this most econominal protein. Thus we find the cults and isms, the schools of "new thought," the vegetarians and fruitarians, and others, who with a cheerful ignorance, flavored with more zeal than discretion, are constantly sowing the seeds of fear for the very classes of food most necessary for the well-being of the bodily economy.

Man is essentially an omnivorous animal. Our food customs are not of recent date but are evolved from the earliest antiquity; they are built upon the inherent needs of the human body, as interpreted by countless millions, and to lightly cast aside the rational dietaries fixed by the natural craving not of individuals but of nations and peoples would invite nutritional disaster.

The chronic dyspeptic especially of the nervous type furnishes the most comprehensive sitophobia. Ascribing, sometimes correctly, sometimes not, his ills to certain articles, he proceeds to omit one after another, eschewing the ones he most loves, and, as it were "crucifying the flesh" at the fancied behest of a finical stomach. These are the melancholy examples of an unreasoning phobia for the very viands for which a starving body is crying night and day, and whose inarticulate wails react on the entire personality, souring the disposition, depressing the spirit, and clouding the mental horizon.

The question now arises, how to manage this phobia; how shall we induce a distorted digestive viewpoint and a recalcitrant stomach to "get in line?" Suggestions must, of necessity, be general, embracing more of the psychic than medicinal, more of the educational than coercive. Children should be informed that a varied diet is the heritage of civilization and that a restricted one is a step backward toward savagery. The domestic sciences, including cookery, should be more universally taught, for often a sitophobia is first started by badly cooked or illy served food, which may cause either bodily distress or mental disgust; it little matters, the results being the same. Actual idiosyncrasies should be respected, but they are not as frequent as one would suppose. A mere dislike does not constitute an idiosyncrasy, nor does a phobia necessarily render an article indigestible, though, as previously mentioned, an inhibitory psychic influence may be exerted, militating against its easy digestion.

In order to act with intelligence and confidence, the physician should investigate both the secretory and motor functions of the stomach, and if they are found in fair condition he should set about gaining the patient's confidence, thereby paving the way for a systematic onslaught on the sitophobia. With a courage born of confidence, he must urge these timid and rebellious alimentary tracts to do their duty, and every available aid, medicinal, psychic, and otherwise, must be brought to bear. I have many times assured such patients that if they would eat certain articles I would help them with their digestion, and if I could once get them to take the supposed risk and no harm arose, the victory was won. In exceptional instances strategy is justified in getting some feared article ingested, and afterward pointing out that it had been eaten without discomfort. The physician should be quite sure of his ground, however, before risking this procedure, for breaking the news might result in both indignation and retroactive disgust, defeating the desired end. Some sitophobias, limited to unimportant articles, are best ignored. If the patient is well enough nourished, if other foods in the same class are taken in sufficient quantities to furnish ample calories, and if no special inconvenience is given other members of the family, strenuous efforts to abate such harmless phobias are not justified.

Change of environment, of food, of habits, and of occupation, all exert a helpful influence on fearful

and unreasoning appetites. Muscular exercise to the point of fatigue is perhaps the best of all remedial measures in overcoming a sitophobia. Manual labor in the open air, if pushed to the physiological limit, seldom fails to produce a keen hunger. Those who in years gone by earned their bread by physical toil will remember the joy accompanying the arrival of meal time, and will also remember that sharp and comprehensive appetite, relishing everything in sight, and that zest which small deficiencies in food or preparation could not dull. Thus, if we can induce our ill-nourished and timorous patients to enter into a complete change of habits and diet, so that as far as practicable muscular effort may take the place of sorrowful meditation; that live, outward interests may banish morbid introspection; that real, bodily fatigue may replace microscopic self-analysis, then may we confidently anticipate a healthy desire for those articles of food demanded by a normal body, a desire whose cheerful and harmless indulgence will effectually dispel the doubts and apprehensions of that digestive imp, sitophobia.

SURGICAL TREATMENT OF EXOPHTHALMIC GOITER.

SOME INTERNISTS' VIEWS AND SURGICAL EXPERIENCE.

By MARTIN B. TINKER, B.S., M.D.,

ITHACA, N. Y.

Over fifteen years ago a medical man, and not a surgeon, R. J. Möbius of Leipzig, presented some of the strongest arguments yet advanced for the surgical treatment of goiter. Writing in 1896 he presented evidence to show that exophthalmic goiter produces a general systemic poisoning, which would explain all the manifestations of the disease; that cure under the usual medical measures is extremely doubtful; in nearly all cases improvement is only temporary, and that recurrence with advance of the disease is the rule; that partial excision of the thyroid removes the source of the poisoning and reduces secretion to a relatively harmless amount, and that there can be no question of the completeness and permanency of surgical cure.

Osler, writing in the same year, prefaced his recommendations as to treatment by the statement that "medical methods are extremely uncertain," and gave the results of operative treatment as known at that time. Although surgical treatment was suggested by these distinguished internists as long as fifteen years ago, very little had been done with the operative treatment of exophthalmic goiter in this country until five years ago. The first considerable series of operations undertaken in this country were then being performed. In the 1906 edition of Osler we find the following: "After three months' careful treatment, if the patient is not better, the question should be considered of surgical treatment. Removal of part of the thyroid gland offers the best hope of permanent cure. It is remarkable with what rapidity all the symptoms may disappear after partial thyroidectomy. . . . The operation under cocaine may be done with safety when the condition of the heart and the extreme tachycardia do not contraindicate an operation." It is interesting to note how positively the distinguished internist speaks with regard to the advisability of surgical treatment. At that time, and even now, many surgeons have done little with thyroid surgery. Indeed, with the single exception of Kocher, a few progressive internists have been the prophets in advocating the surgical measures which have proved so successful in the treatment of goiter in recent years. This is not an unusual condition as concerns progress in cases on the borderline between medicine and surgery. The internists have frequently been well in the van, urging operative measures at a time when the surgeons were still in doubt. As an example of this attitude one may note the recommendation of von Leyden, who advised surgery in the treatment of gastric ulcer and other diseases leading to perforative peritonitis several years before Mikulicz performed the first operation; and also the paper of Reginald Fitz, advocating the surgical treatment of appendicitis. The advocacy of the surgical treatment of goiter by Möbius and others was based on sound logical reasoning.

Why is operative treatment the only logical treatment in all well-developed cases of goiter? The symptoms of goiter are the symptoms of poisoning, similar to those produced by narcotic poisons. The excessive secretion, acting as a poison, is produced by the thyroid. In removing a portion of the thyroid gland we remove the cause of the trouble. The overuse of tobacco causes tachycardia and weakness of the heart's action, not at all unlike the condition seen in hyperthyroidism. Excessive use of tobacco also causes nervousness, general unrest, tremor, sleeplessness; sometimes nausea, vomiting, and diarrhea. The presence of excessive thyroid secretion in the circulation has a very similar effect. No sensible man would consider it logical to treat tobacco heart or tobacco amblyopia and allow the patient to continue the excessive use of tobacco. It is just as logical to treat exophthalmic goiter with drugs without removing the source of the excessive thyroid secretion. That the symptoms are produced by excess of thyroid secretion is further shown by the fact that they may be produced by feeding large quantities of thyroid extract to healthy persons, and by the fact that removal of a good-sized portion of the overactive gland cures the symptoms in the average patient. Ligation of one or more arteries of the thyroid gland, perfect rest in bed, the application of cold, and all other measures which reduce the activity of the overactive gland improve the patient's condition. Study of the evidence supporting these statements will convince almost anyone who doubts the efficacy of surgical treatment.

When is operation advisable? If we are convinced that surgical treatment is the logical treatment in exophthalmic goiter, when should such treatment be advised? No one, whether internist or surgeon, is so radical as to suggest operation in all cases. Mayo has well stated that some patients get well without any treatment whatever, some with appropriate treatment, and some in spite of treatment. As with most chronic diseases, there are periods of improvement; the acute symptoms are relieved, the patient feels relatively well, although there is never complete relief. Then after a varying time the acute symptoms return, worse than ever, and so the disease goes on from year to year until death results, quite as often from some intercurrent disease or secondary condition as by the goiter itself. Osler's advice that surgical treatment should be recommended if the patient is not better after three months' careful medical treatment, if it were generally followed, would save many lives and restore to efficiency many others who do not die. All who have seen the condition of many of these neglected cases will agree with Osler's

further statement that "much valuable time is lost in trying various remedies." Sometimes this is the fault of the patient who refuses to accept the advice of a competent physician. Quite as frequently the physician is at fault. Remedy after remedy is tried for a period of months or years. Usually the patient gets discouraged from failure to get adequate relief and changes doctors many times, but each new physician as he sees the case for the first time has some new medical fad to try and so the case goes on for years until the favorable time for operative treatment has passed. Operation should certainly be advised before irreparable damage has resulted to important vital organs. The greatest strain comes on the organs of circulation and the nervous system, but almost every important vital organ suffers in the advanced cases. The arteriosclerosis which results probably from the increased blood pressure, from the pounding, over-active heart, and damage to the intima of the blood vessels by thyroid poisoning, also has its effect on the condition of the kidneys and liver, the same as arteriosclerosis from other causes. Albumin and casts are practically always found in the urine in acute cases of exophthalmic goiter. Cirrhosis of the liver is apt to result in the cases which have been allowed to drag on under various medical measures for years. Operation should certainly be advised before too great damage has been done to the kidneys and liver. The terrific strain which is put on the heart in many of these cases is often overlooked. The amount of energy required to pump the blood is not less than that required forcibly to open and close one's fist. It is not at all an extreme case of goiter in which the heart is beating 120 to 130 per minute; 140 to 160 is by no means unusual. Suppose we represent the amount of energy expended by the amount required to open and close the hand forcibly. A pulse of 130 represents 50 beats per minute above normal for the average person. Try opening and closing your hand 50 times a minute for an hour if you can, and see what an amount of energy is wasted and what strain is put on the heart. In many cases which have come under my care the heart has been considerably dilated. In cases of long standing the heart muscle and endocardium always suffer. The way to avoid a permanently weakened, crippled heart, is to relieve the strain before irreparable damage has been done.

The need for operation before the nervous system has suffered too greatly is equally urgent. Quite a large proportion of these patients come to our sanatoria for treatment with a diagnosis of neurasthenia, psychasthenia, or hysteria. In a previous paper I have pointed out that there may be discovered by examination a real lump in the throat instead of the supposed globus hystericus. The strain in the toxic cases with long continued sleeplessness and general unrest, which do not permit quiet for repair of exhausted energy night or day, must have a profound influence on the nervous system and produce permanent damage unless the strain is removed early.

A distinguished internist in talking with me recently, said that all of these goiter patients are mentally somewhat unbalanced and very close to the borderline of insanity. The superintendent of one of our large state hospitals for the insane tells me that there are always a considerable number of goiter cases in the hospitals for the insane. He believes that thyroid poisoning is the cause of insanity in these cases; in the same way that general poisoning by syphilis and alcohol is attributed as the cause of insanity in at least 25 per cent. of the cases in our state hospitals. It is extremely doubtful whether many of these cases of well developed insanity can be benefited by partial thyroidectomy. The damage to the nervous system is done. Surgery at that stage is like locking the stable door after the horse is stolen. Some cases of dementia præcox have apparently been benefited as reported by Winslow (*Journal of the American Medical Association*, 1910, Vol. 55, page 1155), but there are probably a large number in which no benefit can be hoped for. The most logical course would be to operate early, removing the cause of the nervous and mental strain before the damage is too great.

Results of Surgical Treatment of Exophthalmic Goiter.—In 1907 Kocher made the statement that all cases of goiter are curable by surgery if taken in time. My own experience in these cases is in accordance with Kocher's statement. An important point mentioned by Kocher and emphasized by Crile in this country is the need for prolonged and judicious after treatment. The worn out, damaged nervous system requires prolonged rest as the most efficient means of restoration to normal. Rest is as important in the nervous breakdown resulting from hyperthyroidism as rest in the treatment of nervous breakdown from overwork or any other cause. The dilated heart is also best restored to normal by prolonged rest in bed. Every medical man is familiar with the fact that the heart does many times less work when the person is lying down than when he is up and about. Many fail to take the load off the heart and give it this much needed opportunity for repair by perfect and long continued rest. For five years I have been an advocate of open-air treatment of these cases preparatory to and following operation. Not only do the patients get the splendid tonic effect but the higher percentage of oxygen helps them to eliminate their thyroid poisons. Flushing the kidneys by the use of large quantities of good water also helps to eliminate the toxins. Many times patients will more readily take some bottled spring water for which they pay a good price than equally pure water which they can get free of cost. Careful attention to diet is always desirable. In a recent paper Reid Hunt (*Journal of the American Medical Association* 1910, Vol. 55, page 1555), has called attention to those foods which stimulate thyroid activity and which obviously should be avoided in the treatment of goiter cases. For several years overfeeding with plenty of raw eggs which do not stimulate the thyroid has been a part of my routine treatment of these cases before and after operation. I have emphasized the importance of operating in stages in the toxic cases. These patients will not stand very much in the way of surgical interference. Experience and judgment as to what it is best to do and what to leave undone are often of more importance than even operative skill. With careful preliminary study of the patients to determine how much can be done with safety; by dividing the operation into several short stages, a few days or even weeks apart; with the operation performed under local anesthesia or in some cases nitrous oxide anesthesia, the operative risk can be reduced to a minimum. An occasional bad risk goes wrong but at one time this year my series numbered over 180 consecutive operations before a fatality occurred.

In conclusion I would advise anyone who is in

doubt about the advisability of operation for exophthalmic goiter to look up the opinions of the great medical authorities, in case they distrust the advice of the surgeon. If anyone believes that he is obtaining great success with internal remedies, I would ask him to carefully follow his cases. He will find that many fail to get the expected permanent relief, go from one internist to another, and that a large percentage are finally operated upon. Most important of all, one should not wait too long before resorting to surgical treatment.

TRUE DIVERTICULUM OF THE CECUM — A UNIQUE CASE.

By J. F. BALDWIN, A.M., M.D.,

Columbus, Ohio,

Surgeon to Grant Hospital, etc.

The patient, C. C., aged 60 years, and residing in Piqua, Ohio, where he had been under the care of Dr. J. H. Baker, was seen by me for the first time December 15, 1911, at the Piqua Hospital where he had been taken for operation. Twelve years before he had had an attack of what had been supposed to be appendicitis, which lasted three or four weeks. He seemed to get over it all right, but occasionally had trouble in the appendicular region. Seven years ago he had a second attack somewhat like the first. He continued to have some disturbance in the same region after the last attack, but nothing that was serious. December 4, 1911, he was taken with a slight chilly sensation and pain in the region of the appendix. On examining himself he found that there was a distinct lump in that region. Dr. Baker saw him soon afterward and also noticed the lump. The course of the disease had been practically afebrile, the temperature having never been more than a half degree above normal. There was no vomiting whatever. The bowels readily responded to laxatives. Dr. Baker thought that the lump increased in size for a while, but that it seemed to flatten out somewhat. His presumptive diagnosis was appendicitis with abscess formation. In discussing the matter with Dr. Baker on the way to the hospital, I demurred to the diagnosis because of the age of the patient, the absence of vomiting and of fever, and particularly because of the presence of the tumor at the onset of the symptoms; objections which he had himself noted. I suggested malignancy, owing to the age of the patient, or massive tuberculosis of the cecum. A little later, when told that the patient had a right inguinal hernia, I suggested the possibility of torsion of the omentum. On personally examining the patient and getting more of the details of the history, I felt that tuberculosis could be excluded but could not exclude either malignancy or torsion of the omentum. The tumor was very distinct but a little irregular in outline, the tenderness was not extreme, nor was the muscular rigidity as pronounced as in cases of appendicular abscess. I concurred in the advisability of immediate operation.

The operation was performed under ether. In order to be sure of ample room I made the incision through the rectus. On examining the tumor from the inside I was quite inclined to think that I was dealing with cancer of the cecum. I separated the adhesions on the outer side of the tumor, and then rolled it over so as to bring it well up into the incision. It was then found that the tumor was covered by several loops of adherent small intestine, a mass of omentum, and the appendix, the last being curled up around the lower and outer border of the tumor. With gauze the adhesions, which were clearly recent, were readily pushed back so that the tumor itself was distinctly outlined. It was globular in shape, hard, and about 2 inches in diameter. It was found to spring from the cecum at a point directly opposite the attachment of the ileum. There was no pedicle but the growth could be pulled away so that a clamp was applied next the cecum and the tumor was cut away. While manipulating the tumor a few drops of very offensive mucopus escaped through a minute opening in its upper surface where the wall was becoming gangrenous. The opening in the cecum was closed in the usual way, and then the appendix was cut off, its stump being ligated and cauterized with carbolic acid. A stab incision was made to the outer side for a drainage tube, and the incision was closed in the usual way. On examining the specimen the tumor was found to be a diverticulum filled with a most solid fecal mass, which was in concentric layers. The opening connecting with the cecum would just admit a small finger. The appendix was congested and swollen but had not been the seat of any special trouble. Subsequent microscopic examination of the sac showed that its wall contained all the coats of normal intestine, so that it constituted a true diverticulum. The patient recovered.

After determining the character of the mass I told the physicians present that I could not recall ever having heard of such a diverticulum of the cecum, and had, therefore, not considered its possibility in the diagnosis. On returning home I looked the matter up in my own library but could find nothing. I then placed the further investigation in the hands of Dr. Lochboehler, of Washington, D. C., who is an expert in looking up matters in the library of the surgeon-general's office. He replied a few days later that he had gone through the entire list of references, and had looked through a large number of authorities from the earliest period up to the most recent date, but was unable to find "a single case of cecal diverticulum, or any condition which approaches the one you so carefully detail in your letter." In addition to his own researches he took the matter up with Dr. Harrison, who compiles the index catalogue and is co-editor of the *Index Medicus*, and he also was unable to throw any light upon the case. Their joint inference was that the case "must be unique."

SEASICKNESS AND THE PNEUMOGASTRIC.

By AUGUSTUS MAVERICK, M.D.,

San Antonio, Texas.

Whatever may be the exact cause of that disagreeable condition known as seasickness, a comparison of its symptoms with those of irritation of the pneumogastric nerves, as determined experimentally, makes it evident that the two conditions are closely related.

What are the symptoms of pneumogastric irritation? Here is a list of the most important; nausea and vomiting; peristalsis of the gullet; peristalsis of the stomach; dilatation of the cardiac orifice of the stomach; peristaltic action of the small intestine, causing diarrhea or spastic constipation; increased secretion of the gastric juice—hyperacidity; increase in the biliary secretion; increase in the salivary secretion (through the glossopharyngeal nerve);

spasm of the glottis; dilatation of the peripheral blood vessels and flushing of the face; sweating (nervous hyperidrosis); bradycardia; low blood pressure; contraction of the vessels of the heart; contraction of the pupil; sinking back of the eyeball (the reverse of exophthalmus); cramp of the bronchial muscles (asthma), and general irritability.

Of all symptoms, nausea and vomiting predominate in seasickness. That increased peristalsis of the stomach and probably that of the gullet are associated is evident; and that the cardiac orifice is not contracted is certain. Diarrhea is occasionally present in seasickness; constipation, however, is far more common, and that this is of the spastic type is shown by the relief atropine will give. The frequent eructations of sour material are very suggestive of hyperacidity, while the large amounts of bile often expelled after vomiting has continued for some time, point to an exaggerated activity of the liver. Increased salivary secretion is associated with nausea from any cause. Very characteristic of *mal de mer* is spasm of the glottis; so characteristic, indeed, that Stocter's article in Allbutt's "System" mentions this as the underlying cause of the whole symptom complex. The next two symptoms above listed, flushing of the face and nervous hyperidrosis, may appear in nausea and vomiting from any cause and are not particularly noticeable in seasickness. A slow pulse, I believe, is quite common, except, of course, when the victim is retching or is exhausted from a severe attack. I have no data relating to the blood pressure, the cardiac vessels, or the condition of the eyes. It would also be interesting to know whether asthmatic subjects are more susceptible to attacks during a rocky sea voyage. The last symptom named, general irritability, would certainly be acknowledged by all unfortunate enough to have experienced a touch of this distressing malady.

If overstimulation of the vagi is accepted as of chief importance in the pathogenesis of seasickness, we still have to explain what produces this overstimulation. The theories of concussion of the brain, cerebral anemia, congestion of the central nervous system, functional impairment of innervation, visual disturbances, labyrinthine disturbance, molecular concussion of the viscera, concussion of the sympathetic ganglia of the plexuses, disturbance of equilibrium, regurgitation of bile into the stomach, disagreeable odor from the bilges, spasm of the glottis, and succussion of the stomach contents, are all insufficient or altogether unsatisfactory explanations. Instead of trying to explain a simple group of symptoms with a very complex explanation it might be easier to find a simple explanation which will do just as well. A continued rocking to and fro of the stomach, loaded or empty, from any cause, would certainly be enough to excite nausea and vomiting through irritation of its motor nerves, the pneumogastrics, and would suffice to explain the symptoms of seasickness. Certain it is that a tight binder or the pressing of the stomach against some hard object often gives relief; the reason it does not always do so may be because the gradual collection of bile and gastric juice in the oversensitive stomach, splashing about with the motion of the vessel, is sufficient to excite a return of the symptoms. The imagination, aided by the special senses—the sight of the rising and falling vessel, the odor of heated oil and bilge-water, the noise of the engines—certainly plays a part in encouraging an attack, as it is apt to do in any functional trouble.

If pneumogastric irritation alone is insufficient to explain the cause of seasickness, it does help to place the treatment on a more rational basis. Given an irritation of the vagi from any cause, what would be the treatment? The answer is, artificial stimulation of the sympathetic nervous system, that great antagonist of the vagi. Atropine stimulates the sympathetic and antagonizes the pneumogastric; atropine has been used empirically in seasickness with a certain amount of success. Better than atropine is adrenalin, which is probably the purest and most powerful sympathetic stimulant which we now possess.

Crossing the Atlantic more than a year ago I had occasion to try adrenalin on a fellow passenger, a middle-aged woman, who was suffering from retching and vomiting of the most distressing type. I gave her a hypodermic injection of atropine and strychnine, but these gave little or no relief. An hour later, instead of repeating these drugs, I obtained the patient's consent to inject intramuscularly fifteen minims of adrenalin solution (1:1000). During the next thirty minutes the symptoms cleared up in a remarkable manner, and another fifteen minims some time later put the patient on her feet. Atropine, 1/150 grain three times a day, kept her well until the sea cleared a day or two later. I have since advised those about to take a sea voyage to use the ordinary stock tablets of adrenalin, dissolved on the tongue and taken every hour or two until relieved. From the small number heard from the results have been encouraging. Adrenalin is said not to be effective when given by the stomach or hypodermically, but to be readily absorbed from the mouth, nose, and rectum, and from intramuscular injections. The transitory action of this substance also demands frequent repetitions of doses or its alternating use with atropine. The above recorded instances, of course, have no practical worth in determining the value of adrenalin in seasickness, but from theoretical reasons alone the drug is well worth a trial.

507 Bedell Building.

Arthritic Diseases on the French Mediterranean Littoral.—G. Sardou gives the reasons for the value of a sojourn on the seacoast of the Mediterranean in the south of France, which region has an effect quite similar to that of American southern climates in the treatment of arthritic diseases. This climate is at once stimulant, eliminant, and protective. The warmth of the weather even in winter is such as to induce the patient to spend a great part of his time out of doors, at a season when he would be obliged in a Northern climate to stay in the house to protect his joints from the assaults of cold. Exercise in the open air induces increased elimination by means of the skin, and the action of the kidneys is increased, while the bowels act better. The bright sunshine induces a better mental and psychical state at the same time. The increased elimination enables the patient to get rid of the poisonous compounds which are causing the joint symptoms. In this the increased circulation is a great factor, while all the internal organs are stimulated to action by it. Appetite is better; the liver, stomach, and intestines all functionate better; the nervous system becomes more normal; and the glands of internal secretion increase their secretions. The dryness and purity of the atmosphere and its luminosity, the combined influences of sea and mountains, the brilliant sun and the vegetation, together with the change of surroundings and of scene all act favorably upon the nervous system of these semi-invalids.—*Bulletin Général de Therapeutique.*

New York, May 25, 1912.

THE MILITARY TRAINING OF A PHYSICIAN.

WAR has its uses in the world other than the making of history, the settling of international disputes, the glorification of nations. It is terrible in its devastation, its ruin of hopes, its fearful sacrifice of useful lives, but there is a compensation in its moulding of character, its perfecting of the survivors of its perils. A wise writer has said (was it George Eliot?) "We find ourselves constantly in the anomalous position of loathing war and loving its discipline." And certainly there is no discipline to be compared with it. The true man who has passed through its ordeals, who has braved the horrors of battle, of disease in camp, of the hurried retreat, even of victory, has gained in a few months or years the experience of a lifetime; he has learned to be patient under trials, to be courageous in the face of death, to be hopeful in defeat and not too confident in victory, to be prompt in decision and instant in the correction of mistakes; his heart has been attuned to sympathy with the suffering, and in him has been strengthened the instinct to relieve distress and to sink self in the service of mankind. These are preeminently the qualities demanded of the physician in his mission of humanity, and little wonder is it that following the Civil War the last quarter of the nineteenth century in this country saw a race of medical men that has never been excelled in all the virtues that make for the perfect physician.

These thoughts have been prompted by the war letters of the late Dr. William T. Lusk, recently collected and published by his children.[1] When the war broke out young Lusk was studying medicine in Germany, but promptly returned to America to offer his services to his country. He enlisted in 1861 as a private in a New York regiment of volunteers, but was soon commissioned lieutenant and the following year became a captain. During the war he took part in the battles of Blackburn's Ford, Bull Run, Port Royal, Chantilly, South Mountain, Antietam, Fredericksburg, and many other engagements, and these letters from the front, the product of a young, alert, highly educated and gifted, as well as modest man, form an invaluable contribution to the history of the period. Written without a trace of personal egotism they yet betray in every page the man who afterwards became a shining ornament of the medical profession, and the same qualities of fearless courage, noble energy, and self-forgetfulness form the basis of this splendid record, as they did of the later life of the physician. In his youth he offered his life for his country on the field of battle, and in his maturity he dedicated it to the cause of humanity in a strenuous and heroic warfare against disease and death.

[1] War letters of William Thompson Lusk, Captain, Assistant Adjutant-General, United States Volunteers, 1861-1863, afterward M.D., LL.D. New York: Privately Printed, 1891.

BIOCHEMICAL STUDIES ON CELLULAR ACTIVITY.

THE recent work of Ehrlich and Wassermann upon the selective affinity between compounds of tellurium and eosin and the cells of mouse sarcoma draws attention to the other important investigations that are being undertaken with the aid of the new methods of intravital staining. E. E. Goldmann reports in the *Lancet*, May 4, 1912, the interesting results that he obtained with these methods in the study of various forms of cellular activity in health and disease. Of the different aniline colors placed at his disposal by Ehrlich he has obtained the best results with isamine blue, which when injected into rats is distributed throughout the body and is deposited in the granules of specific cells, as in the free round cells of the subcutaneous tissues. When pregnancy occurs in the vitally stained animal the blue color disappears from the skin and is concentrated in the uterus, where it appears chiefly in the free cells of the decidua serotina. But the embryo remains perfectly colorless, the placenta and the appendages forming a protective barrier against the passage of the stain from the maternal into the fetal organs. During embryonic development there occurs a functional hyperactivity in the production of glycogen, chiefly in the maternal liver. Special "glycogen carrier cells" are developed from the endothelial cells of the uterine vessels and carry the glycogen from the decidual layer of the placenta to the fetal cells. This and other facts apparently show that the placenta is not an organ which produces the material needed for the nutrition of the embryo, but that this material is attracted by the placenta from the maternal organism. The fertilized ovum moreover exercises a distinct functional effect upon the entire maternal organism, as is manifested in the resulting hyperactivity of the liver as well as of the other organs which produce material for the nourishment of the growing embryo.

Goldmann draws a striking analogy between the fertilized egg and the cancer cell. The liver and spleen evince signs of increased hemopoiesis under the influence of malignant growths, while at the same time large quantities of glycogen are hoarded up in the liver cells. It is suggested that a great step forward would be achieved if it were possible to determine which bodies are needed for the growth and which for the nutrition only of the tumor cells. In fact, in pregnant cancerous animals a race for these bodies takes place between the embryo and the tumor cell and in most cases the

embryo is victorious, and the tumor either atrophies or remains stationary in size. The thought suggested itself to Goldmann that it would be of the greatest practical value to inquire as to whether the body of the tumor-bearing animal possessed any organ analogous in function to the placenta of the pregnant animal, and to determine whether it were possible to inhibit the transmission of the substances needed for the growth of the tumor cell. Taking a cue from Claude Bernard's conception of the functional analogy existing between the placenta and the liver, the author started an experimental inquiry into the possibility of arresting the growth of cancer by producing lesions in the liver of such a nature as temporarily to impair though not entirely or permanently to suspend the normal functions of this organ.

In the production of experimental necrosis of the liver the author employed a substance first prepared by Ehrlich, and belonging to the "606" series. This substance, which is called "icterogen," when injected into the mouse produces in the latter severe jaundice and miliary necrosis of the liver cells. If the injection of icterogen was followed by an inoculation of a tumor graft, although there was no inhibition of the primary stage of the tumor growth, there was eventually a retardation in this growth. In comparing the size of the tumors in normal and icterogen mice two or three weeks after inoculation it was noted that whereas in the former the growth was the size of a walnut, in the latter it was hardly as big as a pea. The icterogen apparently brought about a more rapid degeneration of the tumor cells than usual, ulceration, and frequently a complete disappearance of the neoplasm. As the result of these observations Goldmann concludes that possibly the traditional good effects of arsenic in cancer are to be attributed to the specific effects of this drug upon the liver cells, and not, as is supposed by those who favor the parasitic theory of the disease, to its germicidal action upon the pathogenic protozoan.

SHOCK VALUES AND SHOCK INDEX.

The ability to gauge the degree of surgical shock that may be expected in any definite operative procedure is one of the signal advances in the recent application of physiological methods in the study of surgical problems. In their investigations on the mechanism of shock, H. Tyrrell Gray and L. Parsons, as reported in Medical Record, May 18, 1912, page 956, have shown that surgical shock may be divided into three stages: (1) the stage of stimulation, or the pressor stage, during which there occurs reflex vasoconstriction; (2) the stage of depression, or the depressor stage, during which there is induced reflex vasodilatation; and (3) the stage of equilibrium, during which abnormal afferent impulses are in abeyance. By means of blood pressure observations taken frequently during the course of an operation it is noted that with each step in the operation there is a definite rise of blood pressure, but as soon as the vasomotor center is fatigued each manipulation causes a fall of blood pressure instead of the previous rise. Gray and Parsons (*British Medical Journal*, May 4, 1912) point out that clinical experience has taught that the shock value associated with the operation for hernia is infinitely less than that associated with operations on bone. One of the most important factors in the production of shock is the region of the body which is attacked. A definite shock value may be attached to each organ, structure, tissue, or operation. The physiological needs of different organs require varying dispositions of pressor and depressor fibers in their nerve supply, to provide for local vasoconstriction or vasodilatation under different conditions. In comparing the tibia and femur it is noted that the former in being more exposed to injury than the latter is accordingly more amply supplied with pressor fibers, which are effective in stopping hemorrhage by causing vasoconstriction. On the other hand, the femur, which is more richly provided with depressor fibers, is thereby more able to withstand infection, by virtue of the vasodilatation brought about by the depressor fibers and the resulting greater blood supply. These theoretical considerations are borne out by clinical experience: osteomyelitis of the femur is a rarer occurrence than osteomyelitis of the tibia. On the basis of their researches, the authors formulate the following law, which they term the "law of inverse immunity," namely, "those parts which are physiologically the most active contain the largest proportion of depressor fibers in their nerve supply, are most immune to bacterial infection, and show the highest shock value; such structures are deep seated and anatomically protected against injury. The converse is equally true."

By means of graphic methods one may determine roughly the minimal shock index of any surgical operation. The total rise of blood pressure gives some idea of the resistance of a structure to pressor fatigue and the number of "spikes" observed in the graphic record gives some idea of the likelihood of depressor stimulation. The individuality of the surgeon, so far as it adds to or subtracts from the stimulus of an operation, is an unmeasurable quantity and is represented by x. "Thus x multiplied by the number of depressor spikes, multiplied by the duration, go on the multiplying line, while the total rise in blood pressure multiplied by 100 go on the dividing line. Thus, the operation for radical cure of hernia gave an average index of 0.003 x in three cases; while the operation for excision of the hip-joint gave an index of 0.09 x, or nearly thirty times as great as the preceding one." In an operation for amputation of the leg under deep chloroform anesthesia the authors recorded the relative shock values of the different structures in the lower limb. The shock value of bone excels that of the other tissues; then follow in diminishing order the great vessels, the fasciæ, and the muscular tissues, and lastly the skin.

In this manner the authors work out the shock index for the various regions of the body and for different surgical operations. The practical utility of these investigations cannot be overestimated. The introduction of mathematical methods into the study of surgical problems imparts an element of precision which may assist in bridging the chasm between the art and the science.

CHEMOTHERAPY IN TUBERCULOSIS.

RAPIDLY effective and specific treatment for syphilis having been found in salvarsan, an artificial product of laboratory synthesis, it is not surprising that similar remedies should be sought for other diseases. Cancer and tuberculosis remain the two great scourges of mankind, and already the work of various experimenters with selenium seems to show that substances exist which are limited in their chemical affinities to cancer cells and which may be adapted for therapeutic purposes. In the problem of tuberculosis the enthusiasm over simple hygienic measures has seen its zenith and the return to tuberculin during the last few years is a good indication of the fact that something else than fresh air and good food is necessary in the everyday fight with the disease. At the present time whatever is put forth as a product of Ehrlich's knowledge and ingenuity in chemotherapy should be given a fair trial, and one such product—tryparosan—is reported upon by Levasheff in *Russkii Vrach*, No. 7, Vol. XI, 1912. This preparation was tried by the Russian doctor in the apparently hopeless cases of tuberculosis which are met with in every hospital devoted to this disease, cases which are the joy of the medical student because of the numerous "physical signs" they exemplify and the despair of the therapeutist because of their regular and inexorable progress to the grave in spite of all medical and hygienic measures.

In one such patient, a young man of twenty-eight years, having a hectic fever and showing the presence of tubercular infiltration of the lungs with cavity formation, with a great many tubercle bacilli in the sputum, tryparosan was given for ten days. During that period, the subjective state of the patient was much improved; the temperature became normal and later somewhat subnormal; the drenching night sweats ceased; the quantity of urine was increased; the nutrition was bettered, as shown by increase in appetite and gain in weight; the physical signs showed corresponding changes for the better, and the number of respirations dropped from thirty to an average of twenty-four per minute.

To escape the fallacy of *post hoc, ergo propter hoc*, Levasheff discontinued tryparosan, and during the following eight days the bad subjective and objective symptoms gradually returned. The patient now himself demanded that the experimental use of the remedy should be resumed, and such resumption was again followed by progressive amelioration of all symptoms. This experiment was again duplicated and the change for the worse with the omission of tryparosan and for the better with its resumption were so regular, that the remedy could logically be looked upon as the cause of the improvement. Indeed, the patient, after thirty-eight days of treatment, felt well enough to leave the hospital, of course against the advice of his physicians. Similar observations, though perhaps less striking, were obtained in several other cases.

Levasheff shows that the drop in temperature in his cases could not be attributed to mere antipyretic properties of the drug. The usual antipyretics keep the temperature down in such continued fevers as tuberculosis or typhoid, for a certain number of days, but finally the fever "breaks through" and the temperature chart shows numerous rises in the curve in spite of the constant use of such remedies. With tryparosan, the fever disappeared, just as the fever of malaria disappears under quinine. Moreover, such special signs of tuberculosis as the sputum showed corresponding changes: it rapidly decreased in quantity and the number of tubercle bacilli in it became likewise much diminished. Levasheff thinks tryparosan may be an "advance agent" of a chemical specific for tuberculosis, just as atoxyl, arsacetin, etc., were advance agents for salvarsan. More efficacious apparently than this complex chemical product is mercury succinimide as employed by Surgeon Wright of the Navy. The drug is believed by him, as a result of numerous experiences to be antagonistic to all the vegetable microparasites as arsenic is to the protozoans.

TRICHINOSIS.

THOSE of the medical profession who obtained their education a score or more of years ago, if asked to-day as an examination question to state the salient points about trichinosis would perhaps reply that the immediate effect is violent gastroenteric inflammation, and the more remote effects the wandering of the parasites into the voluntary muscles, with the production of a severe rheumatism syndrome having little or no tendency to recovery, death resulting from exhaustion. This picture no doubt was partially correct, but applied only to severe cases, and took no account of certain accessory phenomena which were amply sufficient to contribute to death by interference with vital functions. At a recent meeting of the Verein Posener Aerzte (*Deutsche medizinische Wochenschrift*, Feb. 15) Heubner describes an epidemic of 23 cases which occurred in the town of Pinne. He performed two autopsies. Myocarditis was a very common affection, the microscope being necessary for the autopsy diagnosis. In one of the two cadavers nephritis was present. In fatal cases proof of death from trichinosis may not be made from the presence of parasites, for these may no longer be in evidence. The diagnosis is sometimes made wholly from the histological finds, especially from the behavior of the so-called trichinized muscular fibers toward hematoxylin. In the heart, intraacinous tissue of the liver, and elsewhere, clusters of eosinophile cells are visible. In life there is no proportionalism between eosinophilia and clinical severity, for a dispensary patient showed 76.2 per cent. of the former. The diazo reaction is likewise of no prognostic value. Worthy of note is the not infrequent occurrence of subconjunctival hemorrhages. The patellar reflex is often retained even in the most severe cases. Even in the graver forms no embryos were found in the blood after the third week.

THE TUBERCLE BACILLUS AND THE INITIAL HEMORRHAGES OF PULMONARY TUBERCULOSIS.

THERE is no universal or perhaps even wide agreement between medical authorities as to whether the initial hemoptysis of those suffering from pulmonary tuberculosis is accompanied by the expulsion of tubercle baccili or not. Some hold that tubercle bacilli are expelled in the initial bleeding, while others are of the opinion that the absence of bacilli in the blood expectorated is, from the bac-

teriological standpoint, the special feature of this variety of hemoptysis. Fernand Bezançon and Mathieu Pierre Weil of Paris review the matter in a paper published in the *Medical Press and Circular* of April 24, 1912. Hiller, See and Cochez found that in the initial hemoptyses bacilli were present, although in small number, while more recently Mandoul and Ortal have asserted that bacilli are never present in the blood coughed up in the early hemoptyses of tuberculosis. The tuberculosis is still closed so that the bacilli cannot find their way out and be discovered in the blood. Bezançon and Weil think this divergence of views is due to the fact that a distinction is not made between the different forms of hemoptysis. The onset of pulmonary tuberculosis characterized by hemoptysis is distinguished by preceding constitutional and functional symptoms of tuberculous infection, such as fever, loss of flesh, and so on. Attacks of hemoptysis not associated with tuberculosis, on the contrary, occur suddenly without any prodromes. In the hemoptysis of tuberculosis the specific bacilli will almost invariably be found in the blood, and the occurrence of this accident need cause no apprehension, say the writers quoted, if a careful search by microscopical and cultural methods fails to reveal the presence of tubercle bacilli in the expectorated blood.

Antis Still Discovering Mares' Nests.

The Vivisection Investigation League recently emitted one of its characteristic misstatements to the effect that Dr. Noguchi of the Rockefeller Institute had inoculated upward of 150 innocent persons with syphilis. They got the notion, possibly honestly, through a misreading and misunderstanding of an article in the *Journal of Experimental Medicine* describing Noguchi's luetin test. The charge was brought to the notice of District Attorney Whitman, who, together with Mr. Lindsay of the Society for the Prevention of Cruelty to Children, made a thorough examination, and, of course, discovered that there was absolutely no foundation for it. We have not heard that any of the lady directors of the League who signed the circular containing this false charge, or even the men, including Poultney Bigelow and Ernest Seton Thompson, have as yet apologized to Dr. Noguchi for their slander. We hope the report is true that he intends to force them to retract through an appeal to the courts. Laboratory investigators, to whom thousands owe their lives to-day, have been too patient under the malicious attacks of slanderers and it is time they brought these evil speakers to a sense of responsibility for their words.

News of the Week.

Montefiore Home.—The new buildings of the Home now in course of construction on Gun Hill Road, near 210th street, New York, are to be on the pavilion plan, nine in number, all connected by covered corridors. A special pavilion will be devoted to treatment of the diseases of the lungs, and there will be ample laboratory equipment. The plans include a small general hospital, with operating rooms and wards, for the acutely ill, and a gymnasium for those able to take properly regulated exercise, while there will also be equipment for baths, electrical treatment, and massage. The buildings will be of reinforced concrete with brick facing and terra-cotta ornamentation, and will be strictly fireproof. The two city blocks which the Home has acquired will allow ample room for walks and recreation grounds for the patients.

New Jersey Tuberculosis Law.—Governor Wilson of New Jersey has recently signed the bill passed by the Legislature which is designated the most advanced legislation so far enacted for the control of tuberculosis. It provides that tuberculous patients who refuse to obey the regulations of the State Board of Health as to prevention, and thus become a menace to the health of their associates, shall be compulsorily segregated by order of the courts, in institutions provided for this purpose. If any such patient refuses to obey the rules and regulations of the institution in which he is placed he may be isolated or separated from other persons and restrained from leaving the institution. The law further provides that all counties in New Jersey shall, within six months from April 1, 1912, make provision in special institutions for the care of all persons suffering from tuberculosis within the county limits. Maryland is the only other State which has enacted legislation providing for the compulsory segregation of dangerous cases of tuberculosis, although in a few of the larger cities this power is exercised under the provisions of the sanitary code.

Commencement Exercises.—Thirty-six graduates in medicine received their degrees from the Cooper Medical College, San Francisco, on May 9. The Medical Department of the University of Alabama bestowed the degree of Doctor of Medicine on thirty-five students at the annual exercises on May 6, held in Mobile. Governor O'Neal of Alabama addressed the class. Fifty-three students of the Medical Department of the University of Arkansas received their diplomas at the thirty-third annual exercises held in Little Rock on May 10. Dr. J. L. Greene of the Arkansas Hospital for Nervous Diseases delivered the annual address.

Nurses Graduate.—At the graduating exercises of the Training School for Nurses of the Jewish Hospital, Brooklyn, New York, on May 14, fourteen nurses received diplomas.

Oppose New Hospital.—The application made to the State Board of Charities by the Fordham University Medical College for permission to erect and operate a hospital in connection with the institution has met with some opposition, because of the proximity of the proposed hospital to the present Fordham Hospital which is a city institution. The university had proposed to maintain a hospital to be known as the Fordham University Hospital for the purpose of providing facilities for the instruction of students in the medical department. The commissioners took the matter under advisement.

Hospital Fires.—The excellent construction of the Lying-In Hospital, New York, was shown in a fire which occurred in the servants' quarters on the second floor of the building on May 14. Although the fire burned for half an hour, the patients were not alarmed as no odor of smoke reached the wards. The damage amounted to only about $300.

A fire in the basement of a dormitory adjoining the Metropolitan Hospital, Blackwell's Island, New York, on May 16, caused some alarm but was extinguished with only trifling damage.

Public Baths.—The question of municipal public baths was discussed at a conference held in the City Hall, New York, on May 14, delegates being present from many states. Dr. Simon Baruch was

elected chairman of the conference, and told of his efforts to obtain free baths under several city administrations. The delegates also paid a visit to Coney Island to inspect the new municipal bath there.

Medical Building Opened.—Caldwell Hall, the new medical building of the University of North Carolina, was formally opened on May 8.

Charitable Gifts.—By the will of the late Thomas E. Crimmins of New York, the following bequests are made: St. Joseph's Hospital, $500; Seton Hospital, $2,000; St. Vincent's Hospital, $2,000, and St. John's Day Nursery, $500.

Adenoids and Cleft Palate.—Dr. Douglas H. Stewart of 128 West Eighty-sixth Street, New York, writes he has never found adenoid hypertrophy in any patient with cleft palate, and he would be glad to learn of any facts in the experience of others in confirmation or disproof of this observation.

A New Charity.—The International Electric Light Association, which includes a large number of electric light companies in and about New York, has announced its intention of doing all in its power to aid the sick poor in the city this summer by furnishing and running electric fans for their use without cost. The charity is a new one in New York, although it was tried two years ago in Rochester with great success.

Lebanon Hospital.—At the annual meeting of the Lebanon Hospital Association held last week Mr. Jonas Weil was elected *President;* Paul Hirsch and Julius Heinman, *Vice-Presidents;* Samuel L. Hyman, *Treasurer,* and Lewis Coon, *Secretary.* The annual report of the president detailed the successful year which had just passed and called attention to the addition of a hospital building erected to increase the facilities for the outdoor patients.

Red Cross Prizes.—The first prize for the best invention for lessening suffering of sick and wounded soldiers, from the fund established by the Empress of Russia, was awarded by the International Red Cross Conference at Washington to Dr. Louis Lesage of the Necker Hospital, Paris, for a portable *x*-ray laboratory automobile for carrying the wounded from battlefields. The prize amounts to $3,000. Two second prizes of $1,500 each were awarded to Major Riggenbach of Switzerland for a wheeled and folding stretcher, and to Dr. G. Steindorf of Germany for a bicycle stretcher. Third prizes of $500 each went to Captain Henry L. Broawn, U. S. A.; Colonel Pick of Austria, Dr. Glinsky of Russia, Major Halloran, U. S. A.; Dr. L. Linxweiler of Germany, and Captain Roselli, Colonel Taschetti, and Colonel Abbamondi of the Medical Corps of Rome, Italy.

New York City Children's Hospitals and Schools, Randall's Island.—The attending staff of the Children's Hospitals and Schools on Randall's Island held a clinical conference on Monday afternoon, May 20, to which practitioners were invited. The superintendent, the force of nurses, and the house staff cooperated to make the occasion a success. Several cases of idiocy were shown, including microcephalics, hydrocephalics, mongols, and cretins, and a demonstration was made of the ocular findings in amaurotic family idiocy and in cretinism. An imbecile was shown with paralysis caused by an attack of poliomyelitis, and several cases of cerebral diplegia which had been improved by dorsal root sections. Some of the fallacies of the high enema were exposed, and a paper on the morbidity and mortality of the feeble-minded was read. A case of empyema of the accessory nasal sinus in a child with operation and recovery was shown. Several cases of Potts disease of the spine were presented with braces and plaster jackets and on Bradford frames. Many showed most satisfactory results. A case of onychogryphosis in a child was shown, and an extensive tuberculosis of the skin. The conference lasted two hours and afterward a collation was served.

Against Preventorium.—The New Jersey State Board of Health on May 18 held a public hearing to consider the opposition being raised against the establishment by the Montclair Tuberculosis Preventive and Relief Association of a sanatorium in that town. It was argued that the establishment of such an institution would cause a depreciation of 50 per cent. in the value of the surrounding property, a statement which in turn was stoutly denied by those supporting the movement. The decision of the board was reserved.

Dr. Abraham Jacobi of New York, president of the American Medical Association, celebrated his eighty-second birthday on May 6.

Dr. William F. Mathews of Brooklyn, N. Y., has been appointed Fourth Deputy Health Officer of the Port of New York, thus completing the Health Officer's staff.

Dr. Ernst J. Lederle of New York has been appointed by Mayor Gaynor as one of the delegates to the Fifteenth International Congress on Hygiene and Demography, which will be held in Washington next September. Mayor Gaynor has also appointed Superintendent of Schools William H. Maxwell and Nelson P. Lewis, chief engineer of the Board of Estimate, as delegates.

Dr. Albert C. Thomas, formerly on the staff of the Connecticut State Insane Asylum, has been appointed superintendent of the New Haven Hospital, New Haven, Conn., to succeed Dr. H. T. Summersgill, resigned.

Dr. John B. Deaver of Philadelphia was the guest of honor at a dinner given by the Washington Medical and Surgical Society at the New Willard Hotel, Washington, D. C., on May 7. Preceding the dinner Dr. Deaver gave a demonstration of methods of surgery of the stomach at a clinic at Freedmen's Hospital.

Dr. Charles W. Stiles of Washington recently received the honorary degree of Doctor of Laws from the University of North Carolina.

Civil Service Examination.—The United States Civil Service Commission announces an examination for the purpose of filling the position of assistant pharmacologist in the Bureau of Chemistry, Department of Agriculture, Washington, D. C., at $1,800 to $2,000 a year with chance for reasonable promotion. The position affords an excellent opportunity for study and research in pharmacology and physiology in the broadest sense, the laboratory equipment being of the best, and should prove attractive to men of a high degree of scientific training and experience. An educational training equivalent to that required for the degrees of B.S. and M.D., or that required for the degree of Ph.D. from an institution of recognized standing is a prerequisite for consideration for this position. Competitors must be able to show at least two years' work in chemistry. The examination allows 40 weights for general experience and scientific training, 40 for professional experience and fitness, and 20 for publications or a thesis covering the results of

original experimental work. Further details may be obtained from the United States Civil Service Commission, Washington, D. C., on application for Form 304.

The American Society for the Study of Alcohol and Other Narcotics will hold its forty-second annual meeting in the parlors of the Marlborough-Blenheim, Atlantic City, on June 5, 1912. This is the oldest medical society in the world for the study of alcohol and the degenerations following from it. All persons interested in the subject are invited to be present. Full details may be obtained from Dr. T. D. Crothers, secretary, Hartford, Conn.

Obituary Notes.—Dr. Jacob Fats of Shawneetown, Ill., a graduate of the Medical College of Evansville in 1878, died at a hospital in Louisville, Ky., on April 25, aged 74 years.

Dr. Daniel A. O'Hearn of Lowell, Mass., a graduate of the Harvard University Medical School in 1902, and a member of the American Medical Association, and the Massachusetts State and Middlesex County Medical Societies, died at his home of pneumonia, on May 3, aged 33 years.

Dr. Gardner Cox of Holyoke, Mass., a graduate of the University of Michigan, Department of Medicine and Surgery, in 1868, died at his home of heart disease, on May 2, aged 68 years.

Dr. Daniel W. Carroll of Ingersoll, Ont., a graduate of the Medical Department of Victoria College, Ontario, died suddenly while making a professional call on April 25, aged 75 years.

Dr. J. L. Finley of Collison, Ky., a graduate of the University of Louisville, Medical Department, in 1896, and a member of the Kentucky State and Vermillon County Medical Societies, died at his home after a short illness of typhoid fever on April 28.

Dr. Robert Latshaw Walker of Carnegie, Pa., a graduate of the Western Pennsylvania Medical College, Pittsburgh, in 1892, and a member of the American Medical Association and the Pennsylvania State and Allegheny County Medical Societies, died at his home on April 30, aged 41 years.

Dr. Hector Canfield, formerly of Providence, R. I., died at Philadelphia on May 8 at the age of 78 years.

Dr. Edwin Clarence Howard died of diabetes mellitus at Philadelphia on May 10 at the age of 66 years. He was graduated from the Harvard Medical School in the class of 1869. He was a member of the Philadelphia County Medical Society, of the Medical Society of the State of Pennsylvania, and of the American Medical Association. He was one of the original members of the staff of Douglass Hospital and one of the founders of Mercy Hospital. He was at one time surgeon to the Twelfth Regiment, N. G. P., and also a member of the Twelfth Sectional School Board.

Dr. William E. Menahan of Fond du Lac, Wis., a graduate of the Rush Medical College of Chicago in 1901, and a member of the Wisconsin State and Fond du Lac County Medical Societies, was among the passengers of the steamship *Titanic* who lost their lives in the sinking of the ship on April 15.

Dr. Edmund A. Donelan of St. Joseph, Mo., a graduate of the Medical College of Ohio, medical department of the University of Cincinnati, a member of the St. Joseph Medical Society, of which he was at various times president and secretary, a member and former treasurer of the Missouri State Medical Association, and an honorary member of the St. Joseph-Buchanan County Medical Society, for seven terms a member of the Missouri State Legislature, and formerly State fish commissioner, president of the St. Joseph school board, and county and city physician, and one of the founders of the College of Physicians and Surgeons, St. Joseph, later merged with Ensworth Medical College, in which he filled the chairs of materia medica, gynecology, and pediatrics, retiring some years ago with the title of emeritus professor of pediatrics, died at his home on May 10, aged 88 years.

Dr. Hubert Townsend Foote, a graduate of the Eclectic Medical College of New York in 1881, died at his home on May 17, after a long illness, aged 52 years.

Correspondence.

ARREST OF DEVELOPMENT.

To the Editor of the Medical Record:

Sir:—Your editorial in the issue of May 4 entitled "Recent Investigations on the Disorders of Growth" calls attention to a problem which is not only interesting, but also when considered broadly one of fundamental importance to medicine. You state: "In the undersized body heredity plays an important rôle. One need only mention the instances of stunted growth occurring in the offspring of the insane, the syphilitic, the tuberculous, the alcoholic, and the underfed. An undersized body is frequently the unmistakable index of a vitiated ancestral stock," etc. Also: "The tendency of modern writers is to broaden the conception of the term infantilism. It is no longer regarded as signifying a mere persistence of the infantile characteristics, but is defined as a retardation of development," etc.

My interest in the problems involved, especially in that of arrest of development, I trust, will be a sufficient excuse for this communication. This subject has occupied my attention, more especially in its relation to gynecology and obstetrics, since 1886, when in conjunction with the late Dr. Harrison Allen, a series of cases of delayed puberty in girls was studied with the conclusion that in them the arrest of development was not particular as to the sexual organs, but was general and affected their entire morphology, involving all the systems of organs and tissues. We concluded that the term hypoplasia best expressed the condition of their structures, and that the hypoplasia was due to arrest of development.

The exigencies of an active practice and the pressing nature of the surgical problems arising in the growing science of gynecology so engaged my attention that while I continued to observe the facts and study the problem in gynecology I did not write upon it until 1908, when I published a hastily written article entitled "Hereditary Hypoplasia in Man, Due to Degeneracy," etc. (*Jour. Am. Med. Ass'n.*, February 13, 1909). In this paper the hereditary factor alone was emphasized, the influence of environment being reserved for a separate presentation. In 1909 in a paper of a very general or philosophic type entitled "The Law of Degeneracy in Its Relation to Medicine" read before the College of Physicians of Philadelphia (*N. Y. Med. Jour.*, December 24, 1910) both the hereditary and environmental factors were discussed. Since then much of my time has been spent in a study of the question, and more especially of

the environmental factors involved, with the result that it seems manifest to me that the environmental factors are not only of importance in bringing about arrests of development, but also that heredity through defects in the germ plasm plays a much smaller rôle than is currently believed. The broader concept of infantilism of the Germans to which you refer leading to the term "Asthenia universalis congenita" is not only true, but also the real truth is much more general in its nature and more fundamental in its importance than is this concept. The article on Hypoplasia referred to above embraces this concept, but it is too narrow, and likewise the term congenital is unfortunate as tending to interfere with, if not prevent, the apprehension of the actual truth.

Referring now to the environmental factors alone, the subject must be viewed from the standpoint of the influence of unfavorable environment upon the organism in its various periods of development—from its dual existence in the bodies of the parents as ovum and sperm until full development is reached in the adult organism. Thus we must begin with the life history of the "primitive ova" in ovary and testis which produce the ripe, or matured, ovum and the spermatozoon concerned in the impregnation which starts the future man or woman, as a protozoon, on the road of development to become an independent organism. At this period an unfavorable environment is constituted by disease in the parent or parents, whereby protoplasmic poisons in undue amount circulate in the blood and either arrest, or tend to arrest, the development of the primitive ova or the unripe ova and spermatozoa. Thus sterility can be caused; or when impregnation occurs the ovum is defective with a resultant defective adult—from, and with, arrested development.

Likewise after impregnation an unfavorable environment is constituted by disease in the host—now the mother. This may be of two kinds: Local disease in the tube and uterus—more especially in the uterine mucosa, and systemic disease in the mother, whereby protoplasmic poisons in undue amount circulate in the maternal blood, and thus come to poison the germ, the embryo, or the fetus. When the bad environment is local disease, this, when it does not cause abortion, tends to interfere with or arrest the normal relations between the chorion and placenta and the uterus and thus serves to lessen the normal transmission of nutritious matter to the fetus, and of excrementitious matter from the fetus to the mother, and in this way serves to lessen the nutrition of the growing organism and to interfere with or arrest its development; also relatively to cause its poisoning by interfering with the transmission of effete products through the placenta. The consequences of this are: Abortion, premature labor, or arrested development of the growing organism, manifesting themselves in the same abnormalities which are caused by maternal systemic disease. That this is true has been amply proved by the investigations of Moll among others. When the bad environment of the growing organism is systemic maternal disease it exerts its influence by insuring that an excess of protoplasmic poisons—whether exogenous or endogenous in source—pass through the fetal membranes or placenta and so poison the organism and either destroy it or arrest its development. The nature and consequence of the arrests depend upon the degree of intensity of the resultant poisoning, the duration of time during which they act, and upon the period of development of the organism when the malign influence shall be exerted.

The evidence of all the experimental teratologists—Roux, Féré, Wilson, and Stockard, not to mention others—is that when exerted during the germinal period the result is either the death of the germ or the production of monsters or of gross abnormalities.

During the embryonic period the result of the arrest is either the death of the embryo, monsters, or deformities—such as clubfoot, harelip, etc. Experimental evidence does not demonstrate the result of slight degrees of poisoning, but from the collateral evidence it would seem clear that the result is merely a less gross defect—not now of form, but a defect inherent in the protoplasm of the cells of the organism—which I have called Developmental Hypoplasia, which has also been called Constitutional Inferiority and also Asthenia Universalis Congenita.

During the fetal period the result may be either arrest of development or fetal disease, or fetal death.

Disease in the mother may be either acute or chronic; the exanthemata or other fevers or infections; disorders of metabolism, as gout or diabetes; exogenous intoxications, as lead, mercury, alcohol, morphia, cocaine, etc.; or due to the absorption of the products of putrefaction in the intestine; or to disorders of excretion involving the retention of protoplasmic poisons in the blood, as Bright's disease, etc. Whatever may cause the circulation of protoplasmic poisons in undue amount in the maternal blood or may so interfere with the mother's nutrition as to prevent the adequate nourishment of the embryo or fetus (although this influence is far less potent than that of toxic conditions) may either kill the growing organism or arrest its development. It is also true that any physical agency inimical to the functional integrity of living organisms may produce similar arrests, such as the *x*-rays and various mechanical agencies. In the human the rôle of such physical agencies is small, but the evidence of experimental teratology is ample to prove their potency.

The statement above that during the fetal period the result of the action of protoplasmic poisons upon the fetus is death, arrest of development, fetal disease, or the lesser abnormalities will be found well presented and amply supported by evidence in Ballantyne's "Antenatal Pathology."

It is also important to point out that the arrests may be particular as well as general, manifesting themselves as defects in various systems, or organs, as, for example, the nervous system, the circulatory apparatus, the blood-making organs, the lymphatic system, the glandular organs, etc., thus explaining the source of diatheses from environmental causes. Yet it must not be overlooked that in particular instances the general arrest may be due to environmental causes and the particular defect or diathesis to defect in the germ plasm or heredity. That is to say, a woman hereditarily defective may suffer from disease both before and during pregnancy and thus bear children defective because of both bad heredity and bad environment.

The explanation of particular arrests is simple. It is that those systems, or organs, suffer the most marked arrest which are actively developing at the time the toxic agents exert their greatest influence, while systems and organs already developed, and

more especially those which develop at a later period, when the toxic agents are no longer active, suffer less or not at all. Particular arrest may also be caused by the selective action of certain poisons, as, for example, that of lead for the nervous system.

In order that the truth shall be fully grasped it is essential that bad environment shall be recognized as constituting that which in postnatal existence is classed as pathogenic agencies. These agencies during postnatal life when sufficient in degree, cause disordered function or local or somatic death —disease or disordered function or death. Upon reflection it will be found that this is also true of antenatal life. Prior to impregnation the function of the primitive ova and of the ova and spermatozoa is development leading to maturation. Pathogenic agencies arrest this development either relatively or absolutely. During germinal life function or physiology consists of growth or development and leads to the formation of the fetal membranes and of the neoembryo. Pathogenic agencies during this epoch cause arrests more or less profound leading to abnormalities in the membranes, subsequent development of monsters (or lesser defects) or to the death of the organism. During the embryonal period function or physiology consists of growth—organogenesis—and the pathology of the period is the formation of monsters, deformities, or individuals who approach the normal in morphology, but who are defective in *vital energy* and who do not attain to the full the adult state—relatively they are neuters or grownup infants, children, adolescents, etc.

During the fetal period function is twofold, growth and function related to that of postnatal life, and the pathology of the period, induced by pathogenic agencies, is likewise twofold and consists of the lesser abnormalities and of general or more particular hypoplasia and of diseases identical with or related to those of postnatal life.

In order that the concept of arrested development shall be complete the influence of pathogenic agencies in postnatal life during the developmental period must also be included. Function in this period is likewise twofold—growth, and ordinary function; and the result of the influence of pathogenic agencies, or protoplasmic poison, is likewise twofold—arrest of development and disease.

Thus it is seen that there exists a unity in the concept. The type of agencies (all protoplasmic poisons) of bad environment are the same in each period of life, and the results are generally the same —arrest of development—but specifically they are different, and the difference is due to the difference in function particular to the organism in its different periods of existence.

It seems to me also necessary to bear in mind that the facts and principles which apply to the development of a normal impregnated ovum under unfavorable environment are equally applicable to that of an ovum arising from defective stock—bad heredity, or defective germ plasm. Men and women of bad heredity, and therefore defective, are not only as subject to disease as are those of good stock, but also it is generally conceded to be true that they are still more liable to the incidence of disease. Hence it follows that their offspring are more liable to suffer from arrests of development, due to protoplasmic poisons, constituting a bad environment, than is true of mankind in general. This self-evident truth is the basis for the statement above that in my judgment the rôle of heredity in the production of arrests of development, defectives, degenerates, hypoplastics, or by whatever name one may choose to designate them, is less important than is currently believed. Likewise, it would follow that there is a serious error in the methods and, therefore, in the conclusions of those studying the subject of degeneracy among the feeble-minded, epileptic, the insane, etc., in attributing these conditions entirely, or almost entirely, to bad heredity.

Also, Mr. Editor, would it not follow that the first quotation from your editorial, "In the undersized body heredity plays an important rôle. One need only mention the instances of stunted growth occurring in the offspring of the insane, the syphilitic, the tuberculous, the alcoholic, and the underfed," etc., is almost absolutely erroneous? It is thought that certain insanities are due to "endogenous causes"; that is, the constitution of certain stocks is sufficiently degenerate, that even when subjected to a good environment they will become insane, or are feeble-minded from birth. Also it is true that certain other stocks are less degenerate, but sufficiently so that when subjected to the ordinary strains and stresses of life they become insane. Likewise, it is true that in certain stocks, alcoholism or dypsomania is the result of constitutional degeneracy. With these exceptions, are not the statements, quoted above, incorrect, or misconceived? and are not the conditions and results referred to (with the exceptions noted) entirely of an environmental nature?

It seems to me to be both true and unfortunate that there is a widespread misconception in our profession as to what constitutes heredity. This is perhaps best developed by Weismann in his work on the "Germ Plasm," in the chapter entitled, if I remember correctly, "Doubtful Points in Heredity." Therein is discussed the nature of the influence of syphilis, alcoholism, and tuberculosis in the parents upon their offspring, and it is pointed out that biologists are agreed that the heredity-bearing substance in the germ plasm is contained in the chromosomes of the nuclei of both ova and spermatozoa. Hence it follows that as neither alcohol nor the respective germs causing syphilis and tuberculosis is a chromosome, nor yet an integral part of a chromosome, it is impossible for either syphilis or tuberculosis to be inherited in the sense that biologists use that term; and also that the evil effects noted in the offspring of alcoholics are not due to heredity in its true sense. Weissmann discusses how these morbid agencies bring about their undoubted malign influence upon the ova and spermatozoa and classifies them as either "affection" or "infection" of the germ. The necessary limitations of this communication prevent an amplification of these points, but it is right here that the erroneous concept of many in the profession arises, and so the dire consequences of pathogenic agencies purely environmental in nature are charged to heredity.

The more one studies the subject of heredity the more it becomes evident that in general the laws of heredity are benign in their influence—indeed are those which have led, and are leading, to the evolution of the race, and that what is called morbid heredity is largely not heredity at all, but is the influence of bad environment—of pathogenic agencies—in arresting heredity and in preventing the developing organism from attaining that degree of evolution potentially present in the germ plasm of its progenitors

The apparent exception to this concept of the essentially benign nature of the workings of heredity is the existence of certain abnormalities by excess, such as supernumerary digits, and perhaps of certain diseases, due apparently to the addition to the germ plasm of a unit character insuring the development of the defect in the offspring. Further knowledge may show this view to be erroneous.

The defects due to the absence of "unit characters" or "material particles" in the germ plasm are not exceptions. According to Weismann these would be explained as caused by interference with the nutrition of the germ plasm by bad environment over a sufficient number of generations as to cause the loss of certain unit characters, and other authorities have an even more direct explanation. Here it is environment interfering with heredity, and not heredity *per se*, which is malign. Again, by crossing these degenerate, or defective strains, with pure strains—a dominant with this recessive the unit character can be restored (DR) to the germ plasm; and by continued mating with sound stock—simplex with dominants—normal individuals can continually be produced; and probably in time the germ plasm will become normal, or dominant (duplex), as to the particular character.

The further relations of the problems of arrested development, hypoplasia, or degeneration to medicine, rather than the questions discussed above, is the research upon which I am at present engaged, and the light which these studies throw upon the subject of your editorial has led me to send you this communication in the hope that it may prove of interest and of value to your readers and that it may serve to stimulate a greater interest and study of this most fascinating and important field of biology within the profession.

CHARLES P. NOBLE, M.D.

GLADWYNE, PA.

PHYSICAL EXAMINATION AND TREATMENT OF SYMPTOMS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Every well trained physician believes in the great importance of careful, exact, properly instructed physical examination. Without it numerous grave mistakes may, and often do, occur. And this examination must be not only of all organs so far as may be, but must extend to the fluids of the economy and to the excreta. To them are applied all known laboratory investigations with microscope, test tube, chemical or physiological examination. Besides cultures and their developments and inoculations are made valuable and at times essential. Vaccines, too, are brought to bear and utilized in many cases in which other medical treatment is shown to be useless. These vaccines are products of multiplied and varied researches.

When everything is fairly considered and when all the special instruments for improved physical examinations are appealed to, if need be—laryngoscope, otoscope, urethroscope, sphygmomanometer, *x*-ray, electrocardiograph, etc., etc.—it is clearly impossible for one, or even two or three men of average ability to be expert in all. Here, then, we reach advanced specialism. Everyone is entitled to the best available knowledge and in order to obtain it must have perhaps half a dozen physicians at different times. Granted this, we then wish to know, has disease grown less and is mankind healthier and freer from ailments, taking even the limited few who always have what they consider best advice and where expense and time are not considered, or at least do not prevent securing it? Statistics may be obtained to prove that they have; statistics may also be secured to prove the contrary. Why? Because, if for no other reason, it may be credibly shown that habits and professions of our day, lead directly to more disease inevitably. Of what real use then are all our refinements of doing unless we correct causes and make prevention surer?

In apposition to the foregoing, we might say a word in favor of what has been so often, and indeed rightly, shown to be pernicious, *i. e.* the treatment of symptoms. This, however, we must still do in the vast number of cases, if we wish to afford even temporary relief. In doing so intelligently, and with the basis of wise empiricism, not infrequently we obtain apparent cures which no science, even the most advanced, has been able to obtain. I am convinced that every old practitioner, gifted with clear insight as to men's failings and individual peculiarities, has discovered special combinations of drugs, which relieve to greatest degree in largest number of instances. They fail, of course, at times—and so does everything—but not more frequently in the aggregate than anything we get from the schools of the elect. This is no appeal for quackery, or ignorance, but it is an appeal to truth and fact. I know to-day many combinations, which experience of long years has proved invaluable, and without which I should be immensely handicapped in treating patients. These have rarely been discovered in any text book, general or special, but have been found through repeated trials and observations, wholly personal. Thus it is when brought to see a case in consultation, if I merely deal in generalities and indications, I fail to do the good I ought. If, however, I urge the use of a particular combination, which I know to be useful, I can frequently be helpful.

The most scientific observer is not invariably the best physician, and there is a special mental attainment which makes a man the abler practitioner when he would fall short in the laboratory, in hospital ward, or in lecture room, where this sort of knowledge and acquisition, is at woeful discount. Alas, for suffering human beings.

BEVERLEY ROBINSON, M. D.

NEW YORK.

EPIPHYSEAL FRACTURE OF THE UPPER EXTREMITY OF THE HUMERUS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In 1902 a girl seven years of age was brought to the Hospital for Ruptured and Crippled, for an epiphyseal fracture of the upper extremity of the humerus, with the characteristic anterior and upward displacement of the shaft. In this case I first used an adaptation of the abduction method which had proved efficient in the treatment of the similar injury at the hip. The essentials, after disengagement of the fragments, are to place the shaft in proper relation to the separated extremity, leverage and ligamentous tension being utilized in reposition. When this is accomplished, a plaster support is applied to hold the limb in the attitude that assures fixation, or practically in full abduction on the scapula, with such anterior inclination or rotation as the condition indicates.

In a second case in a boy twelve years of age, the abducted arm was still further elevated by rotating the scapula on the thorax, as a more comfortable attitude and one in which gravity might aid in fixation. This patient was presented six years later at a meeting of the New York Surgical Society, to illustrate a perfect functional result (*Annals of Surgery*, December 11, 1911).

The treatment, though demonstrated from time to time, was first recorded in the report of a discussion at a meeting of the New York Surgical Society in January, 1908, and it was described in detail in a paper in the *Annals of Surgery* for May, 1908, under the title of "A Treatment of Epiphyseal Displacements and Fractures of the Upper Extremity of the Humerus, Designed to Assure Definite Adjustment and Fixation of the Fragments."

From this paper I quote: "The details of the method are as follows: The patient having been anesthetized, the adherent fragments are separated by forcible manipulation. The head is then grasped, as well as may be, by the fingers and under traction the arm is abducted gradually to the extreme

limit, the acromion serving as a fulcrum to direct the extremity of the diaphysis downward toward the epiphysis. When the fragments are in apposition the abducted arm may be drawn somewhat forward, if necessary, to assue proper adjustment. One now proceeds to fix the parts in this attitude by means of what may be called a shoulder spica. This, as applied to the original case, is illustrated in Fig. 1. (See illustration above.) A better method, the one used in the second case, that of a boy twelve years of age, in which the reduction undertaken twelve days after the injury was somewhat more difficult, and now recommended, is shown in Fig. 2. The extended arm is raised over the head by rotation of the scapula so that one may better utilize muscular tension and the force of gravity to fix the fragments.

In the MEDICAL RECORD of May 4, 1912, I have read with interest an article by Dr. F. H. Albee, entitled "Juxtaepiphyseal Fracture of the Upper End of the Humerus; A New Postural Treatment," further designated in the text as Albee's position.

Strictly speaking, a juxtaepiphyseal fracture is identical with an epiphyseal fracture and is therefore necessarily limited to youthful subjects. It is used, however, apparently, not in the sense of adjoining, but in the neighborhood of, and several of the reported cases were in patients of mature age. Of the three personal cases described, in two (May, 1906, and November, 1907) the displacement was reduced by open operation. In the third case a fracture of the surgical neck (May, 1909) the fragments were apposed by manipulation. The distinctive attitude is fixation in abduction on the scapula by a plaster support. It differs from the attitude that I have described in that the arm is directed anteriorly, rather than sufficiently forward to appose the fragments. A comparison of the photograph of the patient treated by me in 1902, with that which shows Albee's position will indicate the essential similarity. Dr. Albee states that he first described the treatment in the *Post-Graduate* for June, 1908.

My paper was limited to the class of cases indicated by its title, the essentials being the method of reducing the deformity and the means of assuring the reduction by fixation in the attitude that apposes its fragments—namely abduction with such anterior inclination or rotation as may be indicated. It should be evident that the more extreme elevation would not be advisable in fractures of the middle or upper third of the humerus, nor can they in my opinion be properly included in a paper on juxtaepiphyseal fractures. Furthermore, the substance of Dr. Albee's paper is a description of the classical epiphyseal fracture, of its symptoms and of the difficulty in treatment by ordinary methods, and it is therefore fair to assume that the treatment is primarily concerned with this injury. In view of priority of performance and of publication of the method of treatment in the class of cases to which my discussion is limited, I feel that I shall do Dr. Albee no injustice if I still designate it as an adaptation of the abduction treatment.

ROYAL WHITMAN, M.D.

283 LEXINGTON AVE.

RELAPSES IN TYPHOID FEVER.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In the MEDICAL RECORD for April 27 there appeared a report of my paper on "A Clinical Study of Relapses in Typhoid Fever," which had been read at Albany in the Section on Medicine at the N. Y. State Meeting. In this report are some inaccuracies which I would ask you kindly to correct. There were 25 relapses in 21 out of 166 cases of typhoid fever—one triple relapse, two double relapses, and 18 single relapses. The frequency of relapses in our series was therefore 12.6 per cent. The ages of my patients are reported as having varied between 16 and 56 years; the fact is that 9 of the patients with relapses were under 10 years of age, the youngest having been 6 years, the oldest 56 years and the average 20.4 years. The average interpyrexial period in my series was 7.92 days, the longest was 28 days (occurring after the second relapse of the triple case) and the shortest was 4 days. As to the persistent tumefaction of the spleen after defervescence, I said: "This sign was investigated in 13 of our cases. Of 12 single relapse cases, the spleen remained enlarged during the interpyrexial period in 8; in one of the double relapse cases the organ remained palpably enlarged in both afebrile intervals." Palpable spleen as a symptom of relapse

was present in 88 per cent. In 3 of the relapse cases with a negative Widal during the original attack, the reaction became positive (1:50) during the relapse. To be differentiated diagnostically from the relapse are the recrudescence, the so-called post-typhoid sepsis, typhoid pyelitis, and central or atypical pneumonia developing during convalescence. I am reported as saying that the mortality is nil; I did say that when there are no serious complications with relapses, the mortality is practically nil, also that serious complications are rare; in the only fatal case in the series the patient died of pneumonia during the relapse. I stated that while the administration of vaccines during acute febrile manifestations of typhoid fever is often harmful and is therefore not advised, it would be interesting to note the effect with regard to relapses of employing vaccine therapy during convalescence from the primary attack.

OUR LONDON LETTER.

(From our Regular Correspondent.)

NATIONAL HEALTH WEEK—TUBERCULOSIS COMMITTEE'S REPORT—UNHYGIENIC CONDITIONS ON VESSELS—BOVINE TUBERCULOSIS—LONDON WATER REPORT—INSURANCE ACT—GOVERNMENT INQUIRY ON PATENT MEDICINES—OBITUARY.

London, May 3, 1912.

This week is the "National Health Week"—so named by a new organization formed to direct public attention to questions of hygiene and arouse the conscience of the individual as distinct from the local authority. This object was expected to be promoted by sermons, lectures, exhibitions, etc., in the various cities and towns of the country, and branches were formed for this purpose. Considerable success is reported so far, many localities having been the scenes of much enthusiasm, although others have scarcely been moved from their usual indifference. In London the Borough of Marylebone has led the way. On Sunday in several of its churches and chapels preachers took occasion to press on their audiences the duty to their neighbors as well as themselves of suppressing sanitary defects. The next day "health talks" began in a number of meetings and were illustrated by lantern views and other attractions. Quite aware that it is not an easy task to get people to assemble for instruction, the promoters of the movement have in many places induced employers to grant a remission of work during addresses on health topics. Much help is anticipated from medical inspectors of schools and from lady visitors who go round to various homes when illness is notified and endeavor to instruct mothers and families in elementary facts about fresh air, feeding children, and other points regarding health. Amusements have also been employed in this campaign, of which the cinematograph is very popular.

A letter signed by Sir E. Ray Lankester, Dr. C. Porter, M.O.H., Mr. Owen Leaman, and other well-known persons has been freely circulated to explain the objects of this National Health Week as: (1) The establishment of a definite week when synchronized attention throughout the country should be given to problems of health in and through any agency, official, public, or private, which touches in any way these problems; (2) to combat ignorance and apathy and win intelligent support for the constructive work of medical officers of health and others; (3) to collect, not money, but service to this end; (4) to drive home the facts of waste of national health and life, tragical facts of death and disease; hopeful facts as to what has already been done and what can be accomplished in the way of prevention.

The recently appointed Departmental Committee on Tuberculosis has issued an interim report, being induced to do so because the Insurance Act is to come into operation in July. This committee contains representatives of all the bodies in the kingdom which deal with tuberculosis in any aspect, but on this occasion they profess to consider diagnosis and treatment, leaving over research. It might be objected that research should rather be put before any definite scheme, but the committee is desirous of setting up at once a provision under which "no single case shall remain uncared for"—a rather large order, considering we have no means of knowing whether the act will be effective. Certainly there will not be sanatorium places for every case at first, and the danger of exciting any such expectation is obvious, especially when the report suggests "that half an acre per patient is a fair allowance." The report recognizes that in addition to the medical profession and voluntary societies, other bodies have accomplished much—hospitals, sanitary authorities, county councils, officers of health, and so on. But it adds that the resources for attacking the problem have been strongly reinforced by the passing of the Insurance Act. With an estimate of 14,000,000 to be insured the income for the purpose will be about £800,000 per annum, rising with increase of population. The responsibility of dealing with such a mass of disease does not seem to appall the committee and they go on to say that the principles of the treatment which have been for the most part elaborated in sanatoria can be applied outside special institutions, if under the care of medical men with special knowledge of modern methods.

As to this endorsement of specialism, I must protest against the statement that "at the present time there are comparatively few medical men" and nurses who possess the necessary qualifications for posts in sanatoria, and the report accordingly recommends that appointments be made "on the understanding that those selected should at once invoke adequate arrangements to secure the necessary training and experience." It is a monstrous slur on the profession to which all knowledge of tuberculosis is due, including the sanatorium treatment, which after all is only part of the subject. Moreover, would a committee in any department except the medical recommend the appointment of a staff on the understanding that it should begin the study of its duties, especially when those duties involve the health and lives of the community? The organization proposed by this report comprises dispensaries and sanatoria. The dispensary is to be the receiving house, a center of diagnosis as well as a bureau of information and curative center. It is suggested that at first one dispensary to 150,000 or 200,000 of a certain population would suffice. In scattered rural districts it could only serve a smaller number. These institutions are not to be confounded with the tuberculin dispensaries. The suggestion for the sanatoria at first is one bed for every 5,000 of the population. The cost, it is said, ought not to exceed £15 per bed and the maintenance 25 to 30 shillings per week. The problems

of administration are considered at great length. County councils or similar bodies will be responsible, but it is held that reference must be made to sanitary authorities, insurance committees, and other institutions in the several areas.

In his annual report, Dr. Herbert Williams, Medical Health Officer for the port of London, draws an unpleasant picture of the conditions under which too many seamen live on vessels. He says seamen must degenerate when, as often is the case, they are shut up below deck in unhealthy quarters which are practically in constant use for living and sleeping in, generally dark, damp, and encumbered with clothing, conditions favorable for the dissemination of tuberculosis and which are likely to continue until the Legislature takes some interest in the welfare of seamen.

The Board of Agriculture and Fisheries is intending to carry out an inquiry on bovine tuberculosis. It is known that some stock breeders have made investigations and the Board would be glad to be informed of any results that might be usefully collated with whatever information may be obtained by official agencies. Any such information would be regarded as confidential.

The London Water Board has, after some hesitation, agreed to publish the eighth report of Dr. Houston, their chief examiner. After referring to the cutting down by Parliament of the scheme for extending the reservoirs, Dr. Houston admits that flood water loaded with organic matter and swarming with bacteria is often pumped into the storage tanks, and, though long storage will destroy disease microbes, this should not be. He has frequently urged either the exclusion of river water or special purification. For this last he uses lime both as a germicide and a softener. Part of the water to be purified he overloads with lime to act as an effectual bactericide and then adds this to sufficient untreated water to combine with the excess of lime. In this process the mechanical precipitating effect is obtained, he says, as well as the softening and sterilization, and the method would give us a supply in a degree of purity never attained by any authority in the world.

The Insurance Act has been before the House of Commons and Mr. Lloyd George has been obliged to accept a resolution which is practically a censure on the Government. This he did after speaking strongly against it, but he evidently saw that a division would give him a smaller majority than any of the lately regularly falling number. Thus he avoided a defeat, but not until after he had been plainly told by a member that he had taken advantage of and insulted a noble profession. He protested that he had the greatest admiration for that profession, but was reminded of his outside speeches, and one member told him he ought to go to a medical canossa and spend the night in his shirt sleeves before the Royal College of Surgeons —a taunt which brought down the house.

The Government has appointed a Select Committee on the sale of patent and proprietary medicines and advertisements relating thereto. They are to inquire what amendments, if any, in the laws as to them are desirable. The quacks, advertising agencies, and publishing and allied interests are preparing to defend their enormous pecuniary interests.

Sir Fred. Charles Wallis, B.A., M.B., Cantab., 1885; F.R., C.S., Eng., 1901, surgeon of Charing Cross Hospital, died on the 20th ult., suddenly, aged 54. He was also surgeon to St. Mark's and to the Grosvenor hospitals and held other surgical appointments. He published important papers in the *Pathological and Clinical Transactions*, mostly on abdominal cases and operations. One of them was a case of "chronic intussusception" in which he removed 42 inches of intestine, recovery ensuing. His "Surgery of the Rectum" holds a high position among favorite manuals. He was knighted last year. He was highly esteemed by colleagues, students, and patients; in fact, a general favorite.

Dr. George Mackern, late physician to the British Hospital at Buenos Ayres, died yesterday at Eastbourne. He took M.B. with first-class honors in 1879 at the London University and proceeded to M.D. the next year. He contributed some papers to the journals, including one on "Leprosy of the Larynx" to the *Lancet*, 1882, and another on "Edema," 1886.

3. **Urinary Acidity in Children.**—G. King, employing Henderson's method of determining the concentration of hydrogen ions by the use of a color scale made up of various known acid combinations and standard indicators, determined the urinary acidity in seventy children. A slight increase of acidity was found in cases of adenoids and hypertrophied tonsils, chronic pharyngitis, chronic laryngitis, chronic intestinal indigestion, Jacksonian epilepsy, moderate constipation, and secondary anemia. An intensely acid urine was present in cases of acute endocarditis, acute intestinal indigestion, acute nephritis, acute bronchitis, acute rheumatism, impetigo contagiosa, tuberculosis, acute balanitis, Bronchiectasis, and enuresis. Enuresis formed by far the largest number of the abnormal cases. In the series of fourteen cases of enuresis all had a highly acid urine, *i.e.* from fourteen to thirty times as acid as the average normal for a child, and none was alkaline, none showed any evidence of malformations or local inflammatory affections, all urines were normal in all respects save for the high acidity. Practically all the cases had previously had the ordinary treatment with no definite results. Potassium citrate in doses of from three to eight grains four times a day was administered with definite improvement in all but one case.

4. **Rest and Exercise in the Treatment of Phthisis.**—N. B. Burns states that one cannot overestimate the importance of rest as a remedy to stay the progress of tuberculosis at practically any stage of the disease. With an even temperature of 100 plus, rest in bed is the only way to prevent the occurrence of still more troublesome symptoms. Any muscular or even increased mental activity at this time may cause further wasting of the body tissues, which, together with the action of the fever, produces the effect of "burning the candle at both ends." When a patient reaches convalescence the question of rest still deserves earnest consideration. In the sanatorium this matter is well arranged for his benefit by establishing rest periods, retiring and arising hours, and stated intervals for remaining at meals. The regularity of rest is thereby prescribed, and proves to be conducive to steady improvement. Then with the introduction of exercise the patient may, under such a routine system, gradually attain to five

or six hours' active work daily without ill effect, and eventually be able to take up an outside occupation for eight or nine hours daily.

6. **Value of Russo's Typhoid Fever Test.**—A. J. Grover concludes that, although this test may be demonstrated in the urine of a large proportion of the typhoid fever cases, yet it may be demonstrated in such a large proportion of the urine of normal individuals that it is not a test that has any specific meaning or value as to the presence or absence of typhoid fever. When compared with the reliability of a blood culture it is worthless.

1. **Fundamentals of the Freudian Psychology.**—By W. A. White. (See MEDICAL RECORD, May 11, 1912, page 98.)

2. **Legal Aspects of Anesthesia.**—A. C. Vandiver states that, assuming that the administration of anesthesia is a part of the practice of medicine, it would seem that the Legislature of New York, in passing Section 200, providing that nothing in the act should be considered as conferring any authority to practice medicine, did not intend to grant to trained registered nurses any authority to exercise any of the functions of duly licensed physicians. In the opinion of the author anesthesia should be administered to patients only by registered physicians, and the consent of the patient in all instances should be obtained for the administration of the anesthesia. The delegation of the function of the administration of anesthesia to trained nurses should be deprecated and discouraged. The liability of the physician if negligent is fixed and certain. The negligence of his agent, registered physician, or other person is imputable to the physician and renders him also primarily liable.

Brill's Disease and Typhus Fever.—By J. F. Anderson and J. Goldberger. (See MEDICAL RECORD, May 18, 1912, page 962.)

6. **Bacteria in Fresh Eggs.**—R. C. Rosenberger states that a fresh clean egg is sterile. The bacteria that are present in broken or cracked eggs, in commercial "dirty" eggs, in desiccated eggs, and in frozen eggs, get into the product from nest dirt on the outside of the egg or from the air during breaking of the eggs, in the process of desiccation, or from the hands of those who break the eggs. When an egg is what is termed "dirty," and when it is cracked so that the membrane is also broken, then colon bacilli may gain access to the egg. Or, if dirty eggs are broken carelessly, or if the hands of those who break them are not clean, then colon bacilli may gain access to the egg. The colon bacillus may even gain access to the broken eggs from dust blown about in the air. An egg can be fresh and "dirty." A clean fresh egg will remain fresh (and not show gas-producing bacteria) for at least ten months in the ordinary refrigerator, packed in sawdust or bran, or without being packed in any material.

7. **Conditional Reasoning in Medicine.**—C. F. Bolduan states that one of the great stumbling blocks to progress at the present time is the feeling that the cause, and therefore the essential nature, of many of the infectious diseases is absolutely well established, since the specific microorganism of the disease has been isolated. It is important to bear in mind that the essence, the real nature of any disease cannot be represented merely by a single symptom, be it anatomical, functional, bacteriological, or serological. Neither the presence of a particular bacterium, nor the formation of certain metabolic products, nor yet the presence of any kind of anatomical changes, constitutes the disease, but all of these together should be regarded as factors. To a large extent the false sense of knowledge is due to the loose and incorrect use of the term "cause." In the use of the term "cause" one should adhere closely to the principles so clearly formulated by Hume, namely: Cause and effect are immediately related as to space and time. Cause must precede effect; a like cause always produces a like effect; it should be possible to establish the existence of a constant connection between cause and effect. In nature, however, one hardly ever deals with relationships so simple as to allow one to speak of *one* cause and *one* effect, and yet in medicine this has been done time and time again. In this connection von Hansemann says: "The causative method of reasoning has actually grown to be a dogma, especially because it is so extraordinarily easy. To say that a certain disease has *a* particular cause, and to say that when *the* cause is removed the disease can also be removed, is very plausible when theoretically considered, and also very easy. Unfortunately, in many cases this does not correspond to the facts."

8. **Surgical Anesthesia.**—R. H. Ferguson finds that the phagocytic power of the blood which is lost to a great degree by the inhalation of ether or chloroform can be quickly restored by the proper use of olive oil, and that it is just as certain that without this oil it would not be quickly brought back, and also that there is at present no other known means of restoring it. In order to obtain results the oil must be absorbed as oil and that it is so absorbed from the lower bowel when injected high in the rectum has been proved by several investigations upon the subject of rectal feeding. One should inject six ounces of olive oil high up into the rectum in all septic cases, and in all others in which the patient's power to resist infection may be called into play. One should remember that time is an important factor in restoring the opsonic index, therefore one should not delay in the administration of the oil. In injecting the oil one should "make haste slowly." The sudden deposit of six ounces of oil may cause it to be ejected, and all will have to be done over again. Only pure, limpid olive oil should be used. Absorption to do the most good must take place comparatively quickly.

1. **Pharyngeal Insufflation.**—S. J. Meltzer describes under this name a new method of artificial respiration.

In its simplest form it consists (1) in the introduction of a catheter into the pharynx; (2) pulling out the tongue; (3) pressing the suprahyoid region against the roof of the mouth; (4) putting the abdomen under constant pressure, and (5) connecting the catheter with the bellows. When air is thus introduced into the pharynx its escape otherwise than into the lungs is hindered by pressure on the suprahyoid region and by the abdominal compression. The author has experimented on dogs, cats, rabbits, and monkeys, chiefly on the first two, and has found the method efficient in keeping up the life of curarized animals for many hours in a normal manner. The method has also been found effective in bringing about an ether anesthesia easily and readily. The real test of it will have to be made, however, on human beings, and when carried out with care it can do no harm. The tube to be inserted into the pharynx should be a 15-American (or 22-French) catheter. It should be introduced about 5½ inches from the teeth, the tongue should be pulled out and held by a tongue forceps, a pad about 1 inch thick should be placed under the chin and suprahyoid region and pressed upward by a bandage tied, first only moderately firmly, over the head. A weight, about 13 pounds, is placed over the abdomen; then the tube should be connected with the bellows and the compression begun, not too forcibly, nor over ten or twelve times a minute. Instead of a bellows an oxygen tank might be used with a T-tube in the connection between it and the catheter. The closing and opening of the open branch of the T-tube for about two and three seconds, respectively, will cause inspiration and respiration. For the resuscitation of new-born infants a similar arrangement can be employed, using the rubber bulb of an atomizer and proper sized catheters in the pharynx and stomach. This method would also probably be sufficient for the resuscitation of babies 1 or 2 years old.

4. Chronic Gonorrhea and Arthritis.—F. Kreissl states that gonorrheal arthritis is more common in men than in women, the latter being almost immune, and he believes the cause of this is in the difference of structures and the lesser chance of traumatic injury in the course of treatment. At first glance it would seem that the metastasis into the joints, when occurring in the first week of the disease, might be due to an idiosyncrasy, but the author doubts this. More recently the idea has been gaining ground that the source of the joint infection in the male is chiefly to be found in retention foci of the urogenital tract from the anterior urethra up into the renal pelvis. Such foci may occur in the follicular apparatus of the anterior urethra, in the glandular tissue of the prostate, in Cowper's glands, and in the seminal vesicle. Very few have yet recognized the importance of the seminal vesicle as a contributing factor, but the author believes that retention in these of septic material is responsible in a very large proportion of cases of chronic ever-recurring urethral discharges, relapse of epididymitis and cystitis and joint metastases. If urethritis is due to retention foci, all methods will fail until the septic material is recovered from these pockets, and this can be done only by massage. The ordinary recommendation of using massage for the prostate and vesicles only once in four or five days for five minutes at a time is absolutely incorrect. Massage should be repeated daily, but not for more than one-half to one minute. Chills and fever following the earlier treatment and lasting from a few hours to one or two days are positive evidence of the presence of septic material and may be taken as a favorable sign, but they should preclude massage for not less than twenty-four hours after their subsidence. Other procedures of value in the treatment of gonorrheal arthritis are immobilization, Bier's hyperemia, constriction of the affected joint and the administration of vaccines.

8. Tendon Transplantation.—J. W. Sever concludes that tendon transplantation *per se* is at times useful. Tendons lengthened or reinforced with silk are better in that they are not only stronger, but also can be used to greater mechanical advantage. Silk or linen thread is an excellent material to use to lengthen tendons in suitable cases. The growth of new tissue will penetrate and permeate the silk only slightly (in some cases not at all), and does not absorb it. When the peritendineum and tendon sheath have been removed, some foreign body is essential for regeneration, to serve as a director for the new growth. With the sheath and the peritendineum present and sutured, no foreign body need be inserted. In this case the new growth is true tendon tissue. Without the presence of the sheath and the peritendineum, no true tendon tissue can be regenerated. Such tissue is merely fibrous tissue, lacking elasticity and subject to stretching. The new "tendons" are apt to be larger and stronger than the resected ones, especially when silk has been used to replace the resected portion. Provided the sheath and peritendineum are preserved and function allowed early, adhesions may not occur. Without the sheath, adhesions may and do occur much more frequently.

11. Arthrodesis of the Smaller Joints.—R. E. Soule emphasizes the following facts to be borne in mind in doing an arthrodesis: The operator should be sure that the deformity is a permanent one, not due to temporarily paralyzed muscles or to muscle overstrain or tire. The patient should be old enough—not under 8. All resistance to correcting the deformity should be previously overcome. The operator should strive to cause as little mutilation of the contiguous bones as possible. He should not use a curette. The exaggerated idea of removing a V-shaped piece of bone is overemphasized. Success depends on ability to make a flush joint, as a carpenter would say, and thereby correct the deformity, and also depends on ability to apply a fixing dressing which allows of the least separation of the apposed denuded bony surfaces.

12. The Vertical Rectus Incision.—M. F. Porter has decided to employ the vertical rectus incision only in cases in which its advantages as compared with other incisions are very considerable, and in only exceptional septic cases. This decision is the result of the fact that the author has had two cases of alarming secondary hemorrhage from the epigastric artery, one very nearly fatal. In both cases there was infection. In neither case was the artery injured at the time of the operation, so far as is known. In one case the hemorrhage occurred on the thirteenth day after the operation, and in the other on the tenth day. In both cases the hemorrhage was stopped by clamping the artery with a hemostat. The hemostats were removed after forty-eight hours. In neither case could the hemorrhage be attributed to pressure by the drain, for in the one case no drainage was used until after the hemorrhage occurred, and in the other there was one soft rubber tube placed well to the outside of the vessels through an ample opening, and the tube had been removed seven days before the hemorrhage occurred. In both cases there was considerable fascial sloughing. Both these accidents might have been avoided had the incisions been made well away from the vessels.

1. Cardiac Debility and Cardiac Dilatation.—G. A.

Gibson states that in the management of milder cases of weakness, with little or no dilatation, regulation of rest and diet, as well as attention to digestion and elimination, will suffice to bring about recovery. Even in such instances the employment of some cardiac tonic is helpful as a means of accelerating improvement. Long experience has convinced the author that, for this purpose, small doses of digitalis are beyond comparison most useful. If not causing gastric or enteric irritation the tincture is best, and the dose should not exceed 5 minims twice a day. The remedy may be combined with nux vomica. In graver cases absolute rest and general massage, with careful diet and free elimination, must be employed, as well as larger doses of digitalis and strophanthus. If the arterial pressure is high, it will suggest the employment of the nitrites; if the liver is enlarged the use of mercury, along with digitalis, will be indicated; if the renal secretion is scanty the addition of citrate of caffeine and of citrate of potassium will be helpful.

2. **Cellular Activity.**—By E. E. Goldmann. (See page 993.)

3. **Ligneous Thyroiditis.**—G. R. Murray and F. A. Southam report a case of this condition, which is also known as Riedel's disease, and the symptoms of which are due to the progressive development in the thyroid gland of a dense fibrosis. This fibrosis may not only involve the capsule of the gland, but it may extend to the surrounding connective tissue and muscles. In Jeannel's case the fibrous tissue involved the sheath of the vessels and nerves in the neck and extended up to the base of the skull. This tendency of the fibrosis to extend beyond the capsule of the gland serves to distinguish the condition from the chronic atrophic fibrosis which is found in myxedema, as the latter does not extend beyond the gland itself. This tendency to extend into surrounding tissues accounts for the early compression of the trachea and dyspnea, which are characteristic symptoms of Riedel's disease, but which do not occur in myxedema. Nothing so far is known of the cause of the disease, though the character of the microscopical changes suggests that it may be the result of some chronic infection. It occurs in both sexes and most commonly develops between 30 and 40 years of age. The development of the disease is generally slow, but it may take place within a few months or even a few weeks. In some cases pain has been complained of in the affected gland and radiating to the ears and the back of the neck. Dyspnea and stridor due to compression of the trachea, which is not displaced to one side or the other, are the most important symptoms, and notable because they are associated with a comparatively slight enlargement of the gland itself, which, however, becomes hard in consistency and fixed in position. The skin overlying the gland is not adherent and the lymphatic glands are rarely enlarged. The narrowing of the trachea may be accompanied by a laryngotracheitis, causing cough. One recurrent laryngeal nerve may be involved in the cervical cellulitis, causing paralysis of one vocal cord. It is thus evident that the disease is of great interest owing to the remarkable manner in which it may resemble the harder forms of malignant disease of the thyroid gland. The following points are of value in distinguishing between the two diseases. Dysphagia, which is not uncommon in malignant disease, is rare in ligneous thyroiditis. The uniform enlargement of the gland, the early onset of severe dyspnea, the freedom of the skin from adhesion, the absence of enlargement of the lymphatic glands, and the earlier age at which it usually occurs are all in favor of chronic thyroiditis. No medicinal treatment appears to exert any influence upon the progress of the disease. When once compression of the trachea has commenced, so that there is slight stridor with dyspnea on exertion, a sufficient amount of the diseased gland should be excised to free the trachea completely.

6. **The Temperature in Childhood.**—M. H. Williams recorded the temperature in one thousand children and found that the maximum percentage was that of children exhibiting a temperature of 100° F., and the next two highest were those at 99.6° and 99.8°. Only 13.5 per cent. of children have temperatures below 99° and 55.5 per cent. have temperatures not under 99.6°. Two points are commonly raised in regard to pyrexia in children. First, that the condition is due to nervousness; and secondly, that children's temperatures "run up for nothing." In regard to the first point there is a very definite foundation for it. Nervous children bulk largely among children with raised temperatures—but the typical nervous child is the rheumatic child, and the rheumatic toxin is the agent causing both the nervousness and the pyrexia. In regard to the second point, this is a mere statement that many physicians find raised temperatures in children, after some slight disturbance, without being able to ascertain the cause. It by no means shows that there is not some constitutional cause present, provoked into action by the slight disturbance noted.

6. The Mechanism and Treatment of Shock. H. Tyrrell Gray and Leonard Parsons.

1. **Chronic Intestinal Stasis.**—W. Arbuthnot Lane states that the symptoms of this condition may be divided into two groups: first, the simply mechanical, which are those due to obstructive changes in the gastrointestinal tract and the infective results of them: and second, those produced by the presence in the circulation of a number of poisonous toxins. The simple mechanical group includes symptoms such as result from the distention of the stomach, duodenum, and small intestines, or from ulceration of the mucous membrane of the stomach or duodenum. The symptoms of stasis in the large intestine vary with the abruptness of the obstruction. In some cases there is much pain, distention, tenderness, vomiting, etc., while in others there may be no complaint whatever. This does not make the stasis any the less deadly in its poison-producing effect. Later results of stasis are ulcerative and mucous colitis. The symptoms which ensue from the presence of toxins in the circulation are the results of degenerative changes in the several tissues. The skin becomes thin, inelastic, wrinkled, sticky, and stained. The secretion of the skin is abundant and offensive, especially in the axilla and groins. The circulation becomes much enfeebled and the blood pressure is lowered. The ears, arms, and legs are cold even in the warmest weather. The temperature of the patient is habitually subnormal. The patient loses fat, the muscular system degenerates very rapidly, and various forms of visceral ptosis develop. Headache is a common symptom. The joints are very liable to degenerate with abnormal rapidity and to cause much pain and discomfort. The resisting power is diminished with reference chiefly to tuberculosis and rheumatoid conditions. The changes in the breast are characteristic, beginning as an induration in the upper and outer zone of the left breast, and later in the same area on the right side. As time goes on this induration becomes a more marked feature and extends to the rest of the breast, the change in the upper and outer segment being still in excess of that in the rest of the breast. Later cystic and inflammatory changes arise, followed after an interval of time by intracystic growths or by cancer. In almost every case

of cancer of the breast a previous history of chronic intestinal stasis can be demonstrated. The treatment resolves itself into operative and non-operative. The non-operative treatment consists in facilitating the passage of material through the gastrointestinal tract by sufficient doses of liquid paraffin and by the pressure exerted on the lower abdomen by a spring support. The method of the operative interference varies of necessity with the nature of the factors responsible for the stasis. If the symptoms be due chiefly to obstruction at the end of the ileum by a newly acquired ligament kinking and twisting this portion of the bowel and reducing its lumen proportionately the ligament must be divided and means taken to avoid its reformation. If the delayed passage of the contents through the end of the ileum results from extreme debility, the ileum must be divided and its proximal extremity introduced into the pelvic colon below the last kink. In every case of tuberculous or rheumatoid arthritis, in which simple means have failed, the bowel should be short circuited without hesitation.

3. **Correlation and Distinction Between Symptoms in Abdominal Diseases.**—E. Stanmore Bishop states that if a comparison is made between an ordinary acute appendicitis and one of the relapsing variety, certain similarities and certain differences are at once noted. In both pain is the earliest symptom; in both it at first makes its appearance in or near the epigastrium or, at least, above the umbilicus. In acute appendicitis it becomes in the course of a few hours definitely localized in the right iliac fossa; but in the relapsing cases the history of the first and even of some of the succeeding but early attacks appears to show that a much longer time elapsed between the first appearance of pain and its localization in the appendical region; while in some still less acute cases pain in the earlier attacks was sometimes entirely confined to the epigastrium, and did not show itself at all in the right iliac fossa until a second or even third attack. In both acute and relapsing cases vomiting is usually associated with the pain; but while in acute cases it is usually noted as immediately following, in subacute or relapsing cases its absence in the earlier attacks is not unusual. Probably, in comparison with the almost certain relief to pain obtained by vomiting in gastroduodenal cases, its usual absence in appendical cases is of more importance in differentiation than its occasional presence. It is a matter of common experience that in cases demonstrably gastric—such as, for instance, in "saddle" ulcers affecting and confined to the lesser curvature—the symptoms may closely simulate those of duodenal ulcer. There is frequently the same interval of time between the taking of food and the occurrence of pain, the same vomiting, the same relief afforded by vomiting, by more food, or by alkalies. There are cases of biliary calculi without jaundice or colic, the symptoms of which sometimes fairly closely simulate those of gastroduodenal ulcer. In these cases the gall-bladder may be found to be the seat of a low grade of inflammatory change, around which plastic adhesions have formed, uniting it to the stomach, duodenum, or transverse colon, while the bladder itself may or may not contain calculi, and such adhesions, pulling upon, distorting, and contracting the duodenum, may produce symptoms and results closely simulating those of duodenal ulcer.

4. **Appendicitis and Quickness.**—E. Owen refers to the speed with which appendicitis may run its course, and to the need of the surgeon losing no time in getting to work when once the presence of the disease is recognized. What is the sign by which the surgeon may be made aware of the need for operation? In the author's experience there is none; or, to put it more forcibly, there may be urgent need for immediate operation in any case and yet no danger signal may have been hoisted. The temperature certainly cannot be depended upon as a guide. Indeed, if the absorption of poison has been considerable, the chart may be tracking along the normal line or even below it. Generally, however, the most wilful cases show one sign of danger, in rigidity, tenderness, aspect, pulse, or temperature. It is an unreasonable practitioner who would expect all the danger signals, as described in books, to be hoisted at the same time.

6. **Mechanism and Treatment of Shock.**—By H. Tyrrell Gray and L. Parsons. (See page 994.)

Berliner klinische Wochenschrift.

May 6, 1912.

Congenital Tuberculosis.—Dietrich describes the following case: A servant girl aged 21 was admitted with fever, cough, and expectoration of ten days' duration. A sister had died of tuberculosis. The patient was in a miserable state of nutrition, was eight months pregnant and strongly cyanosed. There were no dull areas to chest percussion, but diffuse rales and bacilli in the sputum were positive finds. Examination of the eyes showed tubercles in the choroid. Blood tests negative. The patient lived long enough to be confined, dying three days later. The case evidently presented an exceptional opportunity for a research into congenital tuberculosis, as the mother had suffered from typical acute miliary tuberculosis. The placenta was subjected to exhaustive tests. Serial sections revealed no tubercles, but when the entire organ was treated with antiformin, dissolved and centrifuged, many bacilli were found in the sediment. The infant took kindly to artificial feeding and grew for a time. It thrived until a small abscess formed over the sacrum. The pus contained no bacilli, but the incision wound healed poorly, leaving a fistula and the child ceased for a time to thrive. It again gained in weight, but fever next appeared and did not subside. Râles developed over the chest and death took place on the 84th day. A second subcutaneous abscess formed some days before death. The two abscesses were looked upon as tuberculous from their destructive character. The first abscess was regarded as the primary manifestation. This was followed by bacilluria with eventual deposition of tubercles in the lungs, spleen, ileum, omentum, etc.

Chemotherapy of Tuberculosis.—Kapsenberg first mentions the fact that but little has been done toward a chemotherapy of tuberculosis, the field having been monopolized by the use of serums and vaccines. Naturally this kind of research is readily carried out in animal experiment. In order to find a bacteriotropic substance the author experimented freely with cultures and prepared from the latter a so-called "iodaffin" solution, which resulted from the affinity of some constituent of the bacillus with iodine. The latter is of course recognized as a specific of no mean power in surgical tuberculosis. Experiment with guinea pigs and rabbits showed that the iodaffin substance behaves as an antigen. The protocol of one experiment is as follows: Rabbit received an intravenous injection of a milky emulsion of tubercle bacilli. Four days later it received a second injection of the iodaffin substance with iodine addition. An anaphylactic shock occurred. The animal remained healthy. It received several more injections of the remedy, the reactions becoming progressively less marked. When the animal was eventually killed no evidences of tuberculosis were found. The intravenous injection of bacilli emulsion normally causes fatal miliary tuberculosis.

Histological Eye Studies of the Berlin Methyl Alcohol Victims.—Pick and Bielschowsky report their finds in three of the Berlin outcasts who were poisoned with methyl alcohol last Christmas. Two of the three had been stricken blind before their death. In brief the finds agreed throughout with those of Wood and Buller in the United

States, and also with the finds of animal experiment. The lesions can hardly be regarded as inflammatory, despite the hyperemia present. They occupied the ganglion cells of the optic ganglia, the entire retina and the optic nerve. The lesions in the fibers of the latter were clearly primary, coordinate with those of the ganglion cells and not secondary thereto. The affection, the authors hold, is to be conceived as an acute primary degeneration of toxic causation.

Münchener medizinische Wochenschrift.

April 30, 1912.

Staphylococcus Sepsis from Small Peripheral Suppurations.—Nurnberger refers to our increasing knowledge concerning this subject, the modern literature of which is barely ten years old. The peripheral pyogenic lesions known to cause general sepsis comprise furuncles, whitlow, and the like. Our increase in knowledge, however, lies purely in the fact that general sepsis may not result at all in these cases, but instead local internal suppurations such as at first and naturally behave themselves like primary lesions. Thus small, subcapsular abscesses may form in the kidney as a metastasis from ordinary furuncles, and by perforating the capsule give rise to a phlegmonous paranephritis fatal if not promptly operated on. The author has seen two cases recently. The first patient injured the tip of his finger and infected it. Shortly after he developed a pneumonia which ran its course in two weeks. While ill an abscess appeared on the back of his affected hand. He never recovered from his pneumonia, and suffered from cough, night sweats, and debility. In about a month he began to have symptoms referred to the chest and abdomen, but the most complete physical examination led to no definite conclusions. The blood was now cultivated and staphylococci recovered therefrom. Soon after this evidences of crural phlebitis appeared. The fever course was septic in character and death resulted from exhaustion. The kidneys were found to be the seat of paranephritic suppuration from the perforation of subcapsular abscesses, with secondary nephritis and eventual thrombosis originating in the renal veins. The pneumonia had evidently been a mere coincidence as no evidences could be found of intrathoracic metastases. The fever, sweats, etc., could not have been connected with a persistence of the pulmonary mischief. A second case reported was one of a type which has long been recognized, to wit, an intracranial sinus thrombosis following the occurrence of a furuncle on the face and dependent on the extension of a local thrombophlebitis.

Endocarditis Lenta.—Lorey refers to the comparatively new type of disease termed by Schottmüller endocarditis lenta and associated oftentimes with a peculiar microörganism, the *Steptococcus viridans*. Two cases are reported which were septic in character and due apparently to the aforesaid coccus, but instead of pursuing the mild course ordinarily mentioned the symptoms were acute and pronounced. The first patient gave the impression of a very sick woman who presented a high fever with daily remission and daily rigors. The endocarditis gave rise to several embolisms and infarcts. As in the majority of cases of septic endocarditis, the malady began as an acute articular rheumatism. Death occurred with the full picture of severe general sepsis. The second patient developed endocarditis without any antecedent or associated acute rheumatism and soon presented the complete picture of sepsis but eventually recovered. In comparing these two acute cases with the insidious and mild course of endocarditis lenta the author believes that the affection is practically the same for both types but that a very unusual degree of virulence was present in each of the two cases concerned.

Deutsche medizinische Wochenschrift.

April 25, 1912.

Plethora Vera.—Hart mentions the great vogue of the conception of an essential plethora and the reaction which sought to deny its existence. As a pathological anatomist he has sought light on the subject. Naturally a question must arise as to the possible identity of plethora and polycythemia. Certain cadavers appear to show an excessive amount of blood which is in no sense hydremic, and not associated with cardiac or renal lesions. These subjects are robust men at the most vigorous age, with strongly developed musculature and osseous system. The typical plethoric of a past age was corpulent, but in the class of subjects under consideration there was a relative absence of adipose. When these cadavers come to autopsy not only the veins but the arteries and heart appear surcharged with blood. Both ventricles are the seat of an essential hypertrophy, which is, as it were, physiological in character. To the microscope the heart muscle is absolutely intact. The kidneys are the seat of a similar physiological hypertrophy. The spleen and bone marrow show alterations which suggest an excessive functioning. Everything points to an overproduction of blood, which is habitual and which induces a certain degree of compensatory activity on both heart and kidneys. The only alterations mentioned which might be regarded as pathological are certain sclerotic areas in the pulmonary artery which bear no relation to ordinary arteriosclerosis. This goes to show that the pulmonary artery cannot accommodate itself to this plethoric state as readily as does the aorta, which exhibits no corresponding lesions. The author discusses this subject exhaustively and decides that two principal factors are at work in such cases, namely, a constitutional disposition and overfeeding. Some men who are noted for their overeating and overdrinking never put on fat, while notably small eaters do. It is naturally in the former case that we should expect to find essential plethora. As for polycythemia, the affection in question cannot be the socalled Vacquez's disease nor the beer plethora of certain writers, although plainly having affiliations with them. It is undoubtedly a rare affection.

Duodenal Ulcer.—Prof. Ewald as internist and Prof. Bier as surgeon contribute twin studies of this subject from their respective viewpoints. Both are in agreement as to the absolute infrequency of this affection in Germany as compared with the United States and England. It is probable that the affection is on the increase, and that this increase is making itself felt earlier in some countries than in others. This reacts by leading to increased ability to recognize and operate promptly. Prof. Bier, after between four and five years' experience in the Berlin University Surgical Clinic, has operated but twenty-three times, a small series compared with the figures of the Mayos and other leading surgeons in the United States and England. In private practice but few cases have come to him, and most of these were in foreigners. Nevertheless Bier admits that in Germany the disease is doubtless often overlooked and less rare than has been believed. Another important distinction is found in the fact that duodenal ulcer when so termed in Germany is commonly the isolated form, while in England and America the duodenal ulcer of the statistics is often a pyloric ulcer which extends into the duodenum. Hence in Germany many cases set down as ulcus pylori would, according to the Anglo-Saxon nomenclature, be classed as duodenal. The great numerical disparity, then, is due to a complex of several factors, viz., much greater incidence, superior diagnostic facility, and confusion in terminology. As already stated, any superiority in diagnosis by Anglo-Saxon surgeons is the direct outgrowth of great opportunities for study.

Insurance Medicine.

Medical Aspects of Life Insurance.—In a third lecture on this question delivered in London on March 8, 1912, Sir Richard Douglas Powell treats of various diseases which must be considered by the physician who examines applicants for life insurance. In reference to arteriosclerosis it is remarked that this condition should not exist in any appreciable degree until the later sixties. Its premature appearance is frequently associated with hereditary gout, with alcoholism or syphilitic or renal disease. In the absence of any of these favoring conditions and *a fortiori* in association with one or other of them, it may be brought about by mental strain attendant upon certain kinds of work. The mental strain involved in the management of large mercantile affairs, as on the Stock Exchange, and in certain professions, especially the medical profession, tends to favor its occurrence. Fatal occurrences as a result of arteriosclerosis tend to cluster about the ages of 50 to 65. When applicants present themselves in early life, the risk of arteriosclerosis can be guarded against only by reckoning for any contributing pathological factor—syphilis, alcoholism, albuminuria, should any of these exist, or by taking note of any strong inherited or personal tendency to gout. In many cases there is to be observed a distinct family tendency to premature death in middle or later middle life.

Such cases as present an early degree of arteriosclerosis without other defect are probably best met by the endowment form of policy calculated for about the period of especial risk with an addition appropriate to the individual case; or the premium on the endowment scale may be calculated for an age on the proximate side of the period of special risk, but remain payable during the whole of life. Much allowance must be made for the tumultuous heart of young people nervous under examination. The impulse from cardiac action may in such cases be diffused far beyond its normal limits, and murmurs may be heard at more than one orifice which are yet of purely hemic nature. A systolic murmur is not infrequently recognizable at and outside the apex beat during inspiration only, giving to it a peculiar wavy character; the murmur is not heard at the end of the inspiration nor during the respiratory pause. This murmur, the mechanism of which is difficult to explain, is not due to any cardiac lesion and may be ignored. As a general rule in cases of unsoundness of heart which are insurable, the danger zone is approached after middle life, the period when degenerative change tends to set in and the nutrition of the laboring muscle is less perfectly maintained. To meet this, the endowment scale of insurance premiums may be adopted, the proposer being charged a premium for his age, as reckoned on the scale for an endowment at 55 or 60, but the premiums to be continued through life. As for syphilis Powell thinks that the external lesions of syphilis are of little consequence from an insurance point of view in comparison with the gravity of those of internal parts. A history of syphilis, per se, requires an addition of 5 to 7 years. Any further risk must be estimated by the evidence of efficient treatment and by any signs of specific lesion.

Cases of permanent albuminuria require a decided addition to the premium. Clinically, apart from any obvious dropsy or complications that would render any further investigation unnecessary, the condition of the cardiovascular system is of most importance. The main mortality from diabetes falls at middle and later middle life, so that most cases have already been insured some years before the malady appears. The test for sugar in the urine is that usually relied on, and in addition the build, life, and general history of the applicant provide valuable indications as to fitness for insurance. In any case of appendicitis, supposing there had been within the past five years a definite attack of appendicitis and *a fortiori* a second attack, however complete the recovery may have been, an extra five or seven years according to the age would be necessary to cover the risk of relapse and operation. In cases in which the appendix had been successfully removed and a healthy scar alone remained, the life would be accepted without addition. In cases, again, in which there had been abscesses requiring operation, but the appendix had not been removed, no conclusion could be arrived at until the lapse without further symptoms of at least two years, and then an addition would be necessary in accordance with the conditions present. In the opinion of Powell, persons who refuse to be vaccinated or to allow their children to be so are an appreciable danger to insurance offices and the public, insomuch as they add much to the fatality from, and favor the spread of, smallpox. In all cases, therefore, an addition of five or at least three years, according to the age of the applicant, should be required unless he accepts vaccination and brings satisfactory evidence of its performance.

Finally, physicians examining for insurance are urged to note the features of health as well as any departure from it. A qualitative examination to satisfy as to functional integrity need not be labored; a good examiner will not tax the patience of an applicant by laboriously exploring every square inch of an obviously sound lung. The insight of clinical experience must be the guide as to where to concentrate attention while rapidly assuring oneself that each organ is sound; only where a defect is found is its full exposition necessary, and this is especially so in those cases in which such defect may be covered by a reasonable adjustment of the premium payments.—*The Practitioner*, April, 1912.

Industrial Accidents and Diseases.—The Quarterly Bulletin of the New York State Department of Labor shows that during the last three months of 1911 employees were injured in accidents reported to the department to the number of 10,322 in factories, 153 in mines and quarries, and 4,520 in building and engineering work, or a total of 14,995 in these three branches of industry alone. Of the above, 42 in factories, 3 in mines and quarries, and 93 in building and engineering, were known to have resulted fatally. That there is a special hazard of disease, as well as of accidental injury, in industrial occupations is evidenced by the returns under the law of 1911 requiring reports by physicians of cases of poisoning by lead, arsenic, phosphorus, or mercury and cases of anthrax and caisson disease. During the first six months under this law, which took effect last September, 122 cases were reported, 5 of which are known to have been fatal. These 122 cases included 87 of lead poisoning (2 of which were fatal), 2 of arsenic poisoning, 1 each of phosphorus poisoning and mercury poisoning (both fatal), 2 of anthrax, and 29 of caisson disease (only one of which was fatal).

Book Reviews.

The International Medical Annual. A Year-Book of Treatment and Practitioner's Index. Thirteenth Year. Price $3.50. New York: E. B. Treat & Company. 1912.

Those who are familiar with this unique publication will welcome its appearance for this thirteenth time. To others it will know that it contains just what they want, put in the most convenient form, to refresh the memory concerning the year's happenings in the entire range of medical science. There are thirty-three contributors, five of whom are Americans, one Austrian, one French, and the others British, and, as in previous editions, they have done their work excellently. The plan of the annual is the same as in former years. Part I consists of a general review of therapeutics with a consideration of new remedies and new applications of older drugs, "606" naturally occupying the chief place in this section. Part II, entitled "The Dictionary of Treatment," is a review of medical and surgical progress for 1911, with a synopsis of treatment of the various affections recommended during recent years. In Part III various topics—Medicolegal Medicine, State Medicine, and Industrial Diseases—are treated of, and the book closes with an article by a barrister, H. Wippell Gadd, on "The National Insurance Act as it Affects the Medical Profession." An excellent index makes all the facts in the 618 pages of the book readily accessible.

Essentials of Surface Anatomy. By Chas. R. Whittaker, F.R.C.S. (Ed.), F.R.S.E., Senior Demonstrator of Anatomy, Surgeon's Hall, Edinburgh. Second Edition, Revised and Enlarged. Price $1.40 net. London: J. & A. Churchill; Philadelphia: P. Blakiston's Son & Co., 1912.

This volume is small, containing only 56 pages of text, but the quality of the work is distinctly good. In subsequent editions we should like to see the scope of the work extended. In general arrangement the book reminds us very much of Holden's Landmarks, but it does not contain nearly as much as the older work. The outline illustrations (twenty in number) add to the usefulness of the volume. As an introduction to Surface Anatomy this little book can be commended to the medical student.

The Immediate Care of the Injured. By Albert S. Morrow, A.B., M.D., Adjunct Professor of Surgery in the New York Polyclinic; Attending Surgeon to the Workhouse Hospital and to the New York City Home for the Aged and Infirm. Second Edition, Thoroughly Revised. Price $2.50 net. Philadelphia and London: W. B. Saunders Company, 1912.

In spite of the addition of much new matter, this volume is little larger than the former edition. This work is eminently safe and sane, and can be placed in the hand of patients and lay friends without hesitation. In places where medical aid cannot be obtained for a considerable time, this volume may be of the utmost value. The author constantly emphasizes the fact (too often overlooked) that first aid should never supersede or take the place of proper medical or surgical attention. In the first part of the book a brief outline of the structure and functions of the human body is presented; the second part is devoted to bandaging, dressings, etc., and the methods of their application are thoroughly explained; the last part deals with accidents and emergencies, the author telling exactly what to do and how to do it.

Filariasis and Elephantiasis in Fiji. Being a Report of the London School of Tropical Medicine. By P. H. Bahr, M.A., M.B., B.C., D.T.M. & H., Cantab., M.R.C.S., Eng., L.R.C.P., Lond. With Many Colored and Monochrome Plates, Numerous Charts, and a Map. Supplement No. 1 of the Journal of the London School of Tropical Medicine. Price six shillings net. London: Wetherby & Co., 1912.

It would be superfluous to emphasize the importance and interest of the work which has been done, and is being done by the schools of tropical medicine of London and Liverpool. The investigating excursions sent by these schools to tropical lands have resulted in the discovery of the origin of many diseases and have made possible the colonization by white men of various parts of the torrid zone. Of not the least value has been the publication at intervals of papers, books, and journals treating of the diseases investigated. Most of those publications, in addition to their scientific and practical importance, have been true works of art. The supplement under consideration is a striking example of these united qualities. Dr. Bahr has not only given a vivid word picture of filariasis and elephantiasis in Fiji but has also succeeded in bringing these diseases clearly before the reader's eyes by means of beautifully executed plates and photographs.

Modern Theories of Diet and Their Bearing Upon Practical Dietetics. By Alexander Bryce, M.D., D.P.H. (Camb.), Author of the "Laws of Life and Health," etc. New York: Longmans, Green & Co., 1912.

The great importance of diet in the preservation of health is now receiving the wide recognition which is its due. This is shown by the large number of works published dealing with the subject. The book by Dr. Bryce considers the question of diet from the common-sense point of view. He does not unduly exalt the virtues of any particular kind of food nor does he depreciate the possibilities of a special diet. In fact, to a great extent he keeps an open mind on the subject, although, of course, on certain points his views are decided. In this volume practically all the important systems of diet which are entitled to serious consideration are discussed. The author pays particular attention to the dietetic theories of this country and must be looked upon as somewhat of an authority, having gained his knowledge of these principally at first hand. As for vegetarianism Bryce delivers himself of the opinion that the chief value of the practice is the inculcation, tacit or expressed, of the principle of moderation. He does not, of course, deny that flesh eaters, or rather the mixed feeders, frequently eat too much when intestinal auto-intoxication may and does supervene, but he does not think that sufficient proof exists to show that flesh in moderation is necessarily productive of this condition. A very interesting chapter is that which partly treats of the influence of diet on character. The entire subject of dietetics is considered succinctly, sanely and suggestively and the volume should serve as a good textbook.

Home Hygiene and Prevention of Disease. By Norman E. Ditman, M.D. New York: Duffield & Co., 1912.

The writer in his introduction emphasizes the fact that the object of this volume is not to displace the family physician but to place before the readers general medical information that will enable them to give the most efficient help in cases of incipient or of slight illness. Such knowledge will assist the individual better to determine when expert medical attention is necessary. The book should be of great aid to those living far from a physician and knowledge gained from it will often serve to relieve "the human gad-fly, 'minor ailments.'" The subjects are arranged alphabetically, often a great convenience, especially to the busy house mother. There is a good index.

Modern Urinology. A System of Urine Analysis and Diagnosis. By Clifford Mitchell, A.B., M.D., Professor of Chemistry, Clinical Urinology and Renal Diseases, Hahnemann Medical College, Chicago, Ill. Price $3.00. Philadelphia: Boericke & Tafel. 1912.

One method of book writing, essentially a mild form of plagiarism, is known as compilation. Gathering about him the standard authors on a subject, the writer culls what seems good and rounds out the work with criticism and comment. If the authorities are well chosen and the extracts wisely selected the resultant book is frquently not altogether devoid of value. This volume is obviously a compilation from many of the well-known works on uranalysis, and the author's unfamiliarity with many of the tests and methods is only too evident. His own contribution to the volume consists in numerous "Clinical Notes" and a chapter on "Essentials of Diagnosis by the Urine." To a careful reader the statements in this part of the work are not infrequently in conflict with the accepted theories of modern medical science. The book is atractively published, but the text is marred by many typographical errors.

Who's Who in Science (International) 1912. Edited by H. H. Stephenson. New York: The Macmillan Company, 1912.

There is room, almost a need, for a book of this description. In arranging such a work, however, much care and discretion should be exercised in choosing those deemed worthy of a place in its pages. The claims made for "Who's Who in Science," that is, in international science, are scarcely so thoroughly fulfilled as the title and preface would lead one to expect. Too great space is given to British men of science and discrimination is lacking in selecting representative names of other nations. The sins of commission and omission in this respect so far as American medical names are concerned are palpable to any one who is conversant with the subject. The book is useful so far as it goes and aided by discreet revision might be made yet more useful.

Society Reports.

NEW YORK ACADEMY OF MEDICINE

Stated Meeting, Held April 18, 1912.

THE PRESIDENT, DR. WILLIAM K. POLK, IN THE CHAIR.

THIS meeting was held under the auspices of the Section on Obstetrics and Gynecology.

Fibromyoma of the Ovary, Complicated by Abdominal Ascites, Subacute Appendicitis, and Gallstones.—Dr. C. C. SICHEL reported this case. The patient was an Italian woman, 55 years of age, the mother of seven children. The menopause had occurred at the age of 52. She had had pain in the sacral region for several years and pain in the abdomen, which had been increasing in size, for about two years. The abdomen was found markedly distended and tender, with a circumference of 43 inches. A paracentesis was done and about one and one-quarter gallons of brownish serum removed. A large mass was found in the lower portion of the abdomen, moving by bimanual examination of the uterus. At laparotomy dense adhesions were found between the intestines and tumor; these were separated and a large amount of fluid evacuated from the abdominal cavity and a large pedunculated tumor of the right broad ligament removed. No ovarian tissue could be found in the right broad ligament. The left ovary was intact. The appendix was removed for a chronic catarrhal appendicitis. The gall-bladder was palpated and the presence of stones demonstrated; 240 stones were removed. The patient made a normal recovery. Pathological examination of the tumor showed that it was a fibromyoma of the ovary.

Right Pyosalpinx, Left Tubo-Ovarian Abscess, Complicated by Embolism of the Femoral Artery.—Dr. SICHEL reported this case. At the time of admission to the hospital, the patient, a woman 44 years of age, complained of pain and tenderness in the right iliac fossa. The abdomen was rigid and bi-manual examination demonstrated a mass on both sides of the uterus. A pyosalpinx and an enlarged plexus of veins were removed from the right side and a tuboovarian abscess from the left side. Four days after the operation the patient complained of pain in the right foot and loss of feeling; the pain extended up into the leg and increased in severity in spite of all local measures. A diagnosis of embolism was made and on cutting down to the popliteal artery no blood was passing through it. A probe was introduced for some twelve or fourteen inches before the clot was dislodged. The circulation returned, the popliteal was sutured, and the circulation reestablished. The circulation was kept under observation before closing the wound. Within a few hours the clot formed again at its original site in the femoral artery. They again cut down on the popliteal, as gangrene had set in. They dislodged a clot about one and one-half inches in length. After reestablishing the circulation an amputation was done at the knee and the popliteal artery tied off. The patient made a perfect recovery.

Postpartum Sepsis, Complicated by Rupture of an Old Pus Tube into the Mesentery, Rupture Through the Mesentery into the Abdominal Cavity, Diffuse Peritonitis, Death.—Dr. SICHEL reported this case. The patient, a woman 35 years of age, who had been confined ten days previously, was admitted to the hospital with a temperature of 104.4 F., pulse 120, and respiration 44. Blood examination showed: Red cells, 1,140,000; hemoglobin, 45 per cent.; leucocytes, 5,200; differential polymorphonuclears, 71 per cent. The patient died five days after admission, the temperature going as high as 106° F. At post-mortem an old pus tube was found on the left side, probably of some years' standing. It had become attached to the mesentery and had ruptured into it, distending the layers until the pus broke through, producing a diffuse peritonitis and death. This case was another example of the fact that old pus tubes could be started anew on an acute course and not infrequently ruptured into the peritoneal cavity with fatal result. Dr. Sichel said he had now on record over a dozen cases of a similar nature.

Case of Induced Abortion. Pyocyaneus Blood Culture, Antistreptococcus Serum Used without Success.—Dr. SICHEL reported this case. The patient, a woman 30 years of age, had two living children and had four abortions produced within the last four years. In the present instance the abortion had been produced by a midwife and was followed by a chill. She was curetted by the midwife. Two days after this the patient became alarmed and called in a physician, who treated the case as one of typhoid pneumonia. On admission to the hospital the patient had a mucopurulent discharge from the vagina, but no abdominal tenderness or rigidity. There was a presystolic murmur at the base of the heart. The uterus was swabbed out and iodine gauze packing inserted and allowed to remain for twenty minutes. This treatment was repeated on the following day. Four days after admission the patient developed a right sided hemiplegia, involving also the right side of the face. She ran the usual septic course and did not respond to treatment. She died two weeks after admission. Aphasia was present with the paralysis. A laparotomy was performed and the right broad ligament was removed, which contained an enlarged plexus of veins. At the time of the operation the uterus was small and contracted, and there were no signs of local peritonitis; the tubes and ovaries were apparently normal. One hundred and fifty c.c. of antistreptococci serum were given without any apparent reaction. In justice to this form of treatment it should be said that it was not employed until the patient had been ill some days. The blood culture showed pyocyaneus infection and a few colon bacilli. The autopsy findings were: abortion in the third month; recent soft yellowish thrombi in the mitral valve of the heart; bacterial endocarditis with infarctions of the kidney and spleen; chronic interstitial nephritis; parenchymatous degeneration of the liver with a probably cerebral embolism, the latter to be determined after hardening of the brain.

Pregnancy, Complicated by a Fibroid of the Anterior Wall of the Uterus with Varicosities of the Broad Ligament.—Dr. SICHEL reported this case. The patient, a woman 28 years of age, had had a normal labor one year before her admission to the hospital. After her confinement she suffered from edema of the legs and pain in the broad ligaments and a diagnosis was made of marked varicosities in the broad ligaments and the patient warned against becoming pregnant again. She came back pregnant in September, 1911, all the symptoms having returned in a much more severe form. At laparotomy a pedunculated fibroid was removed from the anterior wall of the uterus and a tremendously distended plexus of veins together with an ovarian cyst on the right side. The left broad ligament containing a number of large veins was left intact, the tube and ovary being in good condition. The appendix was inspected at the time of the operation but in no way handled. There was a marked amount of postoperative distention and on the fourth day a sudden gush of clear serum from the lower end of the wound. On the fifth or sixth day the patient's condition suddenly became serious. A gangrenous appendix was removed and the abdomen drained. The patient made a stormy convalescence, complicated by secondary anemia, but was to-day in splendid health. The swelling of the right leg had entirely disappeared, the veins in the right broad ligament having been removed. On the left side where this was not done there was at times a small amount of edema. In spite of the adhesions existing on the right side the patient had a small inguinal hernia which was easily reducible. This case was interesting as demonstrating how rapidly an appendicitis might take place, and it also showed the bearing that a large varicosity in the broad ligaments had upon the return venous circulation of the lower limbs.

Specimen of Craniothoracopagus.—Dr. ISADORE SEFF presented this specimen, a fetus having one head and two trunks. The trunks were joined on their thoracic aspects from the neck to the umbilicus, and there was no sulcus either anteriorly or posteriorly. The head was attached directly to the trunks, there being no neck. The upper and lower extremities, external genitals, and that part of the trunk below the umbilicus, showed no abnormality. The length of the specimen from the crown of the head to the soles of the feet was 33 c.m.; the width in the mid-dorsal region, from side to side, was 8 c.m.; from front to back, 6½ c.m. The measurements of the head were: fronto-occipital, 8½ c.m.; bitemporal, 7 c.m.; occipitomental, 9½ c.m.; bimastoid, 7 c.m. The ears were prominent and in the median line posteriorly at the junction of the head and neck there was an apparently double ear, formed by the joining of two ears in the median line. Between the parietal and occipital bones of the cranium were two small bones, triangular in shape and about the size of a dollar, the border of which formed the base of the skull. On opening the cranial vault the posterior fossa was found to consist of two lateral halves. These cavities were bounded by the petrous portion in front; by the accessory bones already described above; laterally, by a small portion of the occipital bone; posteriorly and toward the median line, by a large pyramidal shaped bone. In the anterior part of each cavity was a large opening, the foramen magnum. All the cranial nerves appeared to be in their normal situation, and, in addition, there were two cranial nerves making their exit through the accessory petrous bones. The accessory petrosal bones were attached directly to the posterior

wall of the intundibular fossa. There was a deep transverse groove between these bones and the pituitary fossa. On the superior ridge of the accessory petrosal bones, at the junction of the middle and posterior third, were a pair of large foramina which were pierced by a large plug of connective tissue rising from the dura. Through the accessory double ear the probe passed into a canal which led directly forward in the median line for a distance of two centimeters. The umbilical cord was large, flattened, and contained two distinct sets of vessels, one for each half of the fetus. The sternum was entirely absent anteriorly and the space between the ribs of the joining fetuses was occupied by six short ribs which bridged the space where the sternum was normally situated. These ribs articulated with the main ribs on either side. The posterior half of the hard palate and the soft palate were ununited and formed an arch opening posteriorly, exposing the nasal cavity and the base of the sphenoid superiorly. There was a broad tongue attached to the posterior wall of the nasopharynx by a ridge-like fleshy process which divided the pharynx into two lateral fossæ, each of which led into the esophagus. There was no apparent opening into the larynx and no tonsillar structure could be made out. The larynx was separated from the tongue by a cartilaginous structure, which was manifestly the epiglottis, and was closed off at its superior opening by a fibrous membrance which separated it from the epiglottis. There was one trachea. The thyroid glands were two in number and situated at either side of the larynx at its junction to the trachea. The right lung consisted of three lobes; this was also true of the left lung, which was irregular in shape; in the left the lobes seemed to be formed by two fissures which extended from the anterior margin upward and posteriorly to a distance of a little more than half the anterior posterior diameter of the lung. The heart appeared rather broad, the apex being downward and to the right. The anterior fissure divided the anterior aspect of the heart into equal parts. The auricle was one large cavity having no septum whatever. In the ventricles the septum extended upward for two-thirds the length of the cavity and the upper part of the ventricle was a large common cavity. The superior vena cava emptied into the auricle at its normal site, and there was only one. The inferior vena cava coming from the right half of the fetus entered into the auricle at the normal site, while that from the left half of the fetus entered the auricle posteriorly and directly opposite the inferior vena cava of the right side. The aorta came from the right ventricle and gave off the pulmonary arteries just above the semilunar valves; it then continued as the arch of the aorta giving off the subclavian of the upper extremities. Coming from the left ventricle from a common atrium was the aorta of the right fetus, which gave off in its course the common carotids for the head and the subclavian for the right upper extremities. The stomach was pouch-shaped like a Maltese cross. The upper arm of the cross was very short and led into the esophagus. The lower arm contained a thickening, apparently the pylorus, and led into the small intestine. The lateral arms of the cross were two pouches each about the size of a bean. From the pylorus there extended a portion of the small intestine which was 87 cm. in length and at this point it divided into two parts each 67 cm. in length: at the termination of each of these portions the cecum, appendix, and large intestine arose. Both anuses were patent. There were two distinct livers, the larger one situated on the right side, extended partly over the median line, and was divided into three or four smaller lobes. The second liver was about one-third the size of its fellow and was situated posteriorly in the median line; it also was divided into three or four small lobes. The small liver had no inferior vena cava and the portal vessels of the two livers communicated by a narrow bridge which crossed in front of the upper portion of the small intestine. There were two spleens, the one on the left side normally situated and normal in size and shape; the one on the right side situated at the upper and right corner of the posterior wall of the abdomen, just over the left kidney, but also normal in size and shape. There were two pancreases, one on each side between the liver and the spleen. The kidneys, adrenals, and genitourinary systems were double and situated in their normal sites. There were two distinct spinal columns and the ribs were articulated posteriorly the same as anteriorly.

The Earliest Recorded Case of Ectopic Gestation.—Dr. SAMUEL M. BANDLER reported this case and presented the specimen, which he thought was one of the earliest cases of tubal gestation recorded anywhere in the literature, if not the earliest. The impregnated ovum was probably ten days old and was imbedded in the tubal mucosa. It had an envelope of trophoblast cells, contained a beginning embryo, and there was as yet absolutely no suggestion of chorionic villi. The patient had been married two months and for a few days after her last menstruation had had severe cramp-like pains on the left side. Examination showed a mass the size of a walnut on that side. There were no signs of uterine pregnancy, though the uterus was somewhat enlarged. The patient was operated upon abdominally and a hemorrhagic ovary found with the tube apparently normal. The ovary suggested the possibility of an ovarian pregnancy and was removed together with the greater area of the tube. On palpation the tube felt as though it contained within the lumen a very tiny kernel. It was hardened and cut into sections and the specimen which was presented had been found.

Endosalpingitis Tuberculosa.—Dr. SAMUEL M. BANDLER reported this case. The patient was an Italian woman, 26 years of age, who had been married five years. She had had no children and no miscarriages. Shortly after marriage she began to complain of pain in the left lower abdomen, frontal headache, backache, and a gradual loss of strength. Examination showed a small, soft uterus and a tender mass to the right with the left adnexa not clearly palpable. At operation the right adnexa were found to be converted into a thin walled cyst about the size of a small orange, adherent to the lateral pelvic wall. There were associated with it several smaller daughter cysts. The left tube was somewhat distended and there were a hard nodule about one inch from the uterus and small soft nodules along the course of the tube. Both tubes were removed, as the condition was recognized as one known by the term "salpingitis isthmica nodosa," and its tuberculous nature was anticipated. Microscopical examination showed a typical picture of an endosalpingitis tuberculosa. There was no fluid in the abdominal cavity and no trace of tubercles upon the uterus or adnexa or upon any part of the peritoneum. The case was of interest because only the microscopical examination proved the character of the lesion.

Three Cases of Ectopic Gestation Removed by the Vaginal Route.—Dr. SAMUEL M. BANDLER reported these cases. The first case had been operated upon by Dr. Bandler seven months previously for a typical ectopic gestation, the right adnexa having been removed. The left adnexa showed a chronic salpingitis and was just the kind of a tube that would lend itself readily as a nest for an ectopic gestation. The patient and her husband were warned that conception should be avoided, but seven months after the first operation the patient missed a menstrual period and began to stain and to have attacks of cramp-like pain in the left side. A diagnosis of ectopic gestation was made and an anterior vaginal celiotomy was performed. As soon as the vesicouterine fold of peritoneum was reached, a distinct bluish discoloration was noted, showing that free blood or clots were present in the peritoneal cavity. The peritoneal fold was incised, the uterus drawn into the vagina, and an ectopic gestation was found in the left tube which was readily delivered into the vagina and was removed without difficulty. The patient made a smooth convalescence. The other two cases had both been diagnosed, before coming under Dr. Bandler's observation, as incomplete abortions. Owing to a retroflexed uterus held in that position by an adherent fixed tube in one case and to the fact that only an indefinite mass could be made out in the other case, and that while ectopic gestation was suspected, a differential diagnosis could not be positively made, a vaginal celiotomy was done in both these cases. In both instances as soon as the vesicouterine fold of peritoneum was reached by the inverted T-shaped incision the typical bluish discoloration was observed, and, on incising the peritoneum, the uterus was delivered into the vagina and an ectopic gestation found. The affected tube was brought into view in both cases, blood clots removed, and the tubes exsected without difficulty. Dr. Bandler said that during the preceding six months he had operated on thirteen cases of ectopic gestation and in five of these had done an anterior vaginal celiotomy for diagnostic reasons. The anterior vaginal section was preferable to the posterior for diagnostic purposes for the reason that if one saw the vesicouterine fold of the peritoneum he could make a diagnosis of ectopic gestation by getting up to the peritoneal reflection without incising it. If the fold of peritoneum was incised the pelvic peritoneal cavity might be readily examined, the uterus brought into the vagina, and the tubes palpated and brought into view, and this rendered diagnosis so definite that error could seldom occur. If it appeared that the tube lent itself readily to removal, the operation could be completed through the very incision through which the diagnosis was made. If the removal of the tube appeared to be too difficult, or if there was much free blood in the peritoneal cavity, or if active bleeding was going on, the vaginal in-

cision was closed and the operation completed through the abdominal route.

Special Meeting, Held April 25, 1912.

DR. FRANKLIN A. DORMAN IN THE CHAIR.

THIS meeting was held under the auspices of the Section on Obstetrics and Gynecology.

What Can Be Done to Improve the Teaching of Obstetrics in This Country?—Professor J. WHITRIDGE WILLIAMS, Johns Hopkins University, Baltimore, Md., made this address. He said that some of those present might have read his paper entitled "Medical Education and the Midwife Problem in the United States," which was read in abstract before the American Association for the Study and Prevention of Infant Mortality and was published in the *Journal of the American Medical Association*, January 6, 1912. In order to get information on this subject he had sent a questionaire, containing some fifty questions regarding obstetric teaching and the midwife problem, to the professors of obstetrics throughout the country. Forty-three replies were received, representing one-half of the acceptable medical schools and one-fifth of the non-acceptable ones, which indicated a most deplorable condition of affairs. This deplorable state of affairs was indicated briefly as follows: 1. Generally speaking the medical schools were inadequately equipped for teaching obstetrics properly, only one having an ideal clinic. 2. Many of the professors were poorly prepared for their duties and had little conception of the obligations of a professorship. Some admitted that they were not competent to perform the major obstetric operations, and consequently could be expected to do little more than train men-midwives. 3. Many of them admitted that their students were not prepared to practice obstetrics on graduation, nor did they learn to do so later. 4. One-half of the answers stated that ordinary practitioners lost proportionately as many women from puerperal infection as did midwives, and over three-quarters of the answers stated that more deaths occurred each year from operations improperly performed by practitioners than from infection in the hands of midwives. 5. Reform was urgently needed, and could be accomplished more speedily by radical improvement in medical education than by attempting the almost impossible task of improving the midwives. These were part of the conclusions drawn in the paper referred to above and no one familiar with doctors and medical schools could doubt the accuracy of such conclusions. It was generally admitted that much difficulty was experienced in teaching obstetrics in medical schools. New York had two of the largest lying-in hospitals in the country and for this reason conditions were better here than elsewhere, but, so far as institutions and ideals were concerned, they by no means approached that degree of perfection that they should. No one could deny that conditions in general were in great need of improvement. In the ordinary medical school the professor of obstetrics was looked down upon while greater respect was shown the professor of gynecology. One of the most eminent professors in the country had said "There is no likelihood of getting good men to go into obstetrics." As for the medical student, he did not regard obstetrics very highly and it was hard to get a first rate graduate to go into obstetrics. If one did go into it he deserted it for gynecology and surgery as soon as possible. If this country was compared with Germany in this respect, the contrast would not be favorable to the United States. One reason that students did not regard the science of obstetrics more highly was that they were not taught its importance or to regard it as a wide branch of scientific knowledge. Students could not be blamed for this. When the professor showed no interest except in the purely practical aspect of the subject one could scarcely expect the student to be impressed; again, when one looked at it from the financial side, he would find that obstetrics was the poorest paid of all branches in medicine. The trouble was also due to the fact that many schools had no facilities for teaching obstetrics and a considerable number of schools had no lying-in hospitals connected with them, and while others had the hospitals they were poorly supplied with material. In many of the schools less than one hundred women were delivered in a year and these had to serve for the instruction of seventy-five or one hundred students. Many professors took up the teaching of obstetrics as a stepping stone to the teaching of gynecology. With regard to the remedy, they would have to face a radical departure. If obstetrics was to be properly taught there should be a reorganization of the medical schools and of the lying-in hospitals and an even more drastic change in the character of the men holding professional positions. In considering hospitals Dr. Williams said that outside of New York he did not know of a single large well equipped lying-in hospital in the United States. He had looked up conditions existing in Germany and found that even in the smallest universities there was always a well-equipped women's clinic. In the hospitals there should be facilities for teaching both obstetrics and gynecology. They should be able to take a woman and treat her for everything, whether normal or pathological. He did not believe that this would solve the problem unless the professor was paid sufficient to give practically his entire time to the care of hospital patients, teaching, and research. If he attempted to carry on an extensive private practice at the same time the result would be failure. Medical colleges with seventy or eighty students in a class should have a women's clinic with seventy-five or one hundred beds. In such a hospital there was not only the practical side of taking care of women in labor and performing various operations but also the training of assistants and advancing knowledge. In most lying-in hospitals the assistants remained but six months or a year; he had had much experience with assistants and found that they were not really well trained until the end of the third or fourth year. In proper women's clinics a longer term of service would be necessary, even five or six years. The number of cases the student saw was very important and with but few exceptions the schools in this country did not have enough material of this kind. The cases should be followed before and after labor and the students taught the rudiments of gynecology and the ordinary diseases of women and their connection with child bearing. Last year there were one hundred and twenty medical schools in the United States while there were but twenty-one in Germany. It was desirable to get rid of many of these schools. The teaching of clinical medicine in connection with a university was a very expensive proceeding and some of the universities were recognizing their obligations to medicine and were facing this problem. The ordinary professor of clinical medicine in this country did not take his professional duties to heart; he devoted a few hours a week to teaching but had no idea of giving most of his time to teaching, properly training his assistants, and advancing knowledge. Such reforms were bound to come and they would gradually develop a body of men who were not going into medicine primarily to practice, but because it offered them a scientific career. If such a body of men could be developed, who would not practise outside a hospital or limit their practice to consultations only, great good would result. Every clinical professor of this kind should be trained not only to be an accomplished practitioner but to be proficient in the scientific aspects of his work and he must be prepared to work in the laboratory and to conduct researches himself. Dr. Williams considered the following reforms most important: 1. Reduction in the number of medical schools with adequate facilities for those surviving. 2. Insistence in university schools that the head of a department be a real professor, whose prime object was the care of hospital patients, the proper training of assistants and students, and the advancement of knowledge, rather than to be a prosperous practitioner. 3. Recognition by medical faculties and hospitals that obstetrics was one of the fundamental branches of medicine, that the obstetrician should not be merely a man midwife, but a scientifically trained man with a broad grasp of the subject. 4. The requirement by state examining boards that every applicant for license to practise should submit a statement certifying that he had seen delivered and had personally examined under appropriate clinical conditions, at least ten women. 5. Impressing university authorities and institutions that a medical school was most expensive, and that they were not justified in conducting one which was not along ideal lines. Each main clinical branch would require a separate clinical institute, which if properly equipped for the care of the patient, teaching students, and furthering of research, would require a large endowment. It was the duty of those interested in medical education to impress upon philanthropic persons the needs along such lines.

Dr. EDWIN B. CRAGIN said that Professor Williams did well in laying so much emphasis upon the fact that the way to improve the teaching of obstetrics was to improve the obstetrical teachers. Many of them had been obliged to train themselves in obstetrics as well as in the teaching of the subject. Twenty-five years ago many medical students graduated without having seen a case of labor. When one contrasted the teaching of obstetrics to-day with that of twenty-five years ago it showed marked progress. At the College of Physicians and Surgeons the student himself delivered from four to nine women and

saw from thirty to fifty confinements. Obstetrics had developed along surgical lines. The old teacher of obstetrics developed from the general medical practitioner without special surgical training. Modern gynecology then came on the field and developed along surgical lines, and finally obstetrics had developed along surgical lines. This made very little difference between modern obstetrics and gynecology. The two had rewedded after being long divorced. This tendency was seen in the union of the two chairs under one head in many of the medical schools to-day. It was the duty of every teacher of obstetrics to leave behind him a better trained man than he himself had been. The obstetrician and the teacher of obstetrics of the future must be a man with surgical training. He had noticed that the men on the staff at the Sloane Maternity as internes who had had a previous surgical service made better obstetrical internes than those with a purely medical training. Dr. Cragin believed that the college should have its own Frauenklinic and that the teacher of obstetrics and gynecology should spend a large part of his time in this hospital and in teaching, but he doubted if he would be a good teacher in a practical subject like obstetrics and gynecology unless he kept himself in touch with private practice. Furthermore, if the teacher of obstetrics would devote his entire time to research work, his wards, and teaching, his support would throw upon the trustees of the university a financial problem which might be more easily solved in Baltimore than in a city like New York. There was a happy medium that would work to the advantage of everyone. Dr. Cragin believed that in having an obstetrical and gynecological hospital in connection with the college and in giving the students both theoretical and practical instruction along these lines, with a sufficient number of cases to train them well in the methods they should follow and in allowing them to put into practice in the tenements the methods they had learned, a distinct advance had been made along the path of progress and that an optimistic view was justified.

Dr. J. Clifton Edgar said that all workers in obstetrics would appreciate what the guest of the evening had done and would be grateful to him for it. He then referred to the work of the Council on Medical Education of the American Medical Association, which had awakened them to the deficiencies of medical education in the United States. Dr. Edgar thought that one reason why obstetrics had not profited by the reform in medical education to the extent that it should have done was due to the fact that it was the last of the seven fundamental subjects in medicine. Reform had reached anatomy, surgery, physiology, and it was only a matter of time when it would reach obstetrics. The subject of obstetrics stood so much higher to-day than it did a decade ago that he felt most optimistic regarding the future. There should be higher requirements in State examinations for obstetrics. The Regent's Examinations belittled obstetrics by combining obstetrics, gynecology, and diseases of children in one examination. The State should require that the applicant for a license should have attended a definite number of confinements before he was admitted to examination. So far as the speaker was able to find out few states made any such requirement. There had been a change in the attitude of the general public during the past five or six years; the public was demanding better obstetrics and was beginning to appreciate its own responsibility and the responsibilities of the attendant. The public appreciated the fact that a case of obstetrics was a case of surgery; it grasped the importance of unfavorable symptoms. The prejudices and traditions surrounding obstetrics were passing away with this generation. This had been brought about by the work in preventive medicine, by the movements for the prevention of tuberculosis and infant mortality, by child welfare conventions, popular literature, and the educational influence of the newer maternity hospitals with teaching staffs. There was a tendency at present to establish more lying-in charities. Within the last few weeks application had been made to the State Board of Charities to establish two more such institutions in New York. In one of these the privilege of teaching students was asked, and in the other that of teaching both students and midwives. Dr. Edgar then considered the midwife problem and said they should not become discouraged as the Midwife Bill of 1902, in England, was the result of thirty years' work on the part of the British Medical Association. In this country 33 out of 49 states and territories had no laws on this subject. Scarcely a year ago a school for midwives was established in connection with the Bellevue Obstetric Service and at the end of six months eight midwives were graduated; each of these had seen sixty or seventy cases of confinement and had personally delivered eight. In conclusion, Dr. Edgar said that he was in favor of what might be called the personal equation in teaching. He did not think a professor should hold his position who gave but casual attention to his work, and he made a plea for what were known as obstetric conferences, that was, an open-minded and free discussion of the cases seen in which each student was asked to join and to discuss and criticise the diagnosis and treatment. As a result of such conferences at Cornell, one third-year student had proposed a simplified method of geometrically obtaining the posterior sagittal conjugate diameter of the pelvic outlet following the teaching of Rudolf Klein of Munich. A student had also invented a much simpler apparatus than the Draeger infant pulmotor for resuscitating newly born asphyxiated infants.

Dr. James W. Markoe recalled the fact that, no further back than 1850 Dr. James P. White delivered a young Irish girl before the graduating class of the Medical Department of the University of Buffalo, and while it greatly pleased the students, it was taken up by the medical profession throughout the country and raised such an uproar that it was proposed to pass laws forbidding physicians to deliver women and to limit the practice to midwives. Within the last twenty-five years there had been a great improvement in the methods of obstetric teaching, but the system was by no means perfect. Not many physicians would take up obstetrics and limit themselves to that alone, as not much could be made out of obstetrics alone. At present it was believed that the best way of teaching obstetrics was not only in the hospital wards, but in the tenements as well. In the last twenty-two years the Lying-in Hospital had cared for between eighty and ninety thousand students and eight hundred internes. An indoor house surgeon who completed the four months' service cared for approximately three hundred confinements, but the man who received the most satisfactory training was the house surgeon of the out-door service, where in six months he had under his direct supervision some fifteen hundred cases. The Lying-in Hospital had persistently endeavored to supplant the midwives by carefully supervised medical students, and this could be done throughout the country by increasing the number of such lying-in charities. He did not believe that any person not a physician should be allowed to care for women during confinement whose only training had been a six months' course of instruction with but ten or twelve cases during that time. Obstetrics should be elevated to the same plane as surgery or medicine. The question of allowing students of medicine to act in cases of midwifery had been very carefully gone into and decided in their favor, provided proper supervision was maintained.

Dr. John O. Polak said that he agreed with Dr. Cragin and Dr. Edgar that there had been a marked improvement in the teaching of obstetrics during the past twenty years. As matters stood in this country to-day efforts for improvement should be along two lines. They should endeavor to turn out students who were competent and practical enough to be first-class male midwives, and they should train assistants so that they could improve the obstetric teaching. At the present time it was difficult to turn out students who were able to handle women in confinement. This was brought about by two factors, the subject of obstetrics had not attained the high position it should hold and the remuneration received for obstetrical services was inadequate. Men received three years of instruction in obstetrics, were shown how to confine women, and confined women themselves under the instruction of a resident or assistant, and, yet, when they went out to practice, they were unsafe. They should first develop the student so that he would become a safe physician and then they should instruct assistants so that they might be safe teachers. These two points together with an increase in the lying-in charities would result in the greatest good.

Dr. Robert L. Dickinson said that Dr. Williams had omitted one of the strong points of his January paper, namely, that the best stimulus to induce strong men to take up obstetrics was to bracket it with gynecology. The speaker said that he had been informed that even in Germany the professors at the head of combined departments sometimes exhibited in the wards an ignorance of detail that showed that they left most of the midwifery to assistants. The student would never get good obstetric teaching until the obstetrician was both gynecologist and surgeon in his training, his opportunities, and his fees. At the Brooklyn Hospital the two departments had been combined. The chief who had come into gynecology through the door of obstetrics, but up a surgical staircase, was senior over both. The personnel of the two departments changed places on the first of January of each

year, and thus it was hoped all would be better obstetricians and better gynecologists.

Dr. George P. Shears said he was inclined to agree with those who regarded Professor Williams as being too pessimistic. It had recently been his privilege to examine forty candidates for the position of interne at the City Maternity and he had been surprised at the good showing that they made. Dr. Shears asked by what method of psycho-analysis Dr. Williams discovered the motives of of those who took up obstetrical teaching. Certainly the fees were less than in surgery and gynecology and the responsibility was greater, as the obstetrical operator held in his hands the fate of two lives. Dr. Shears had taken up obstetrics because he thought it the highest and finest of all branches of medicine. As to the surgical tendency in obstetrics, the obstetrical teacher ought to be qualified in surgery, but the man who thought surgery the most important thing was apt to be weak in subjects purely obstetric. The surgical tendency had not always been productive of good. New operations were dropped almost as fast as they were taken up. A thorough knowledge of the axis traction forceps would save more fetal lives in one year than would the various cutting operations in a decade. In Germany they had the advantage of State endowments which they did not have here, nevertheless, it was in this country that the first cesarean section and the first ovariotomy were done and there was no reason to despair of future obstetrical teaching.

Dr. Williams in closing the discussion, said he was sorry that he had given the impression that he was pessimistic, because he was not; but he was more or less skeptical. He wanted to see things develop along proper lines in this country. They should develop obstetrics, teach obstetrics, combine surgery with obstetrics, and science with both of them. He could not believe that a man could be a competent teacher of obstetrics who was a general practitioner. What they had to do was to educate the trustees of the universities to the fact that obstetrics was an important branch of medicine and that they wanted men "who had the goods and could deliver them" as teachers of obstetrics. Such men should have a good salary, one proportionate to those paid to professors in other branches of medicine. With regard to midwives, they could not be properly trained in four months. He had followed them in Germany and in France and was told that they were failures. The only way was to get rid of them gradually by extending out-door medical charities. The first thing was to take care of all people who could not afford to obtain medical attention. The rich man got attention because he paid for it; the poor got this attention because someone else paid for it; but the man of middle class who could only pay a little for attention usually got what was bad. To care for this latter class he knew of nothing unless it were out-door obstetric charities.

Stated Meeting, Held May 2, 1912.

The President, Dr. William M. Polk, in the Chair.

Is the Control of Embryonic Development a Practical Problem?—Dr. Charles R. Stockard read this paper in which he attempted to show that the proper development of the individual was dependent upon two main factors: first, the physical qualities of the parental germ cells; and, second, the environment in which the embryo developed. One at first sight might be apt to think that deformities and defects were rare among men and other animals, but closer observation would show that in reality the structurally perfect individual was rather exceptional. Gross anatomical defects were found among all animals, while lesser defects were to be observed in a majority of individuals. These defects in construction must be considered a disease which caused the death of about 23 per cent. of the human race before or shortly after the time of birth, and they also handicapped a proportion of the survivors throughout their lives. Experiments had proven that the great majority of monsters were due to the action of unusual conditions upon either the parental germ cells or the developing embryo. The writer then considered the modifications induced in the developing egg or embryo by alcohol or any strange chemical environment and found that the eggs of a number of animals that developed normally in sea water would, when certain chemicals were added to their environment, develop into various unusual forms. He had succeeded in producing a definite type of monster in great numbers by a given treatment. Alcohol, ether, chloroform, etc., were employed and cyclopean monsters resulted from eggs developing in these substances. Alcohol gave the most decided effects and inhibited the normal production of eyes in almost all cases. The writer had repeated Féré's experiments with hen's eggs and found that when these eggs were exposed to the fumes of alcohol many abnormal chicks developed. Many workers had shown the effects of environment on the developing egg. Furthermore, it was only necessary for the egg or embryo to be exposed to the unfavorable conditions for a very short time, just previous to the critical moment in development when the neural canal began to close and the central nervous system to differentiate. The egg or embryo might be returned to perfectly normal surroundings, yet it never recovered from the treatment and formed a monstrous individual. It was thus extremely important to guard the early stages of development, since when these steps were interfered with gross defects were certain to occur. The action of alcohol and other poisons on the embryo during the later stages of development was incapable of producing gross deformities but tended to cause minor defects, which manifested themselves in epileptic, feeble-minded, or idiotic conditions. Children were born which exhibited the same types of deformities as those described for lower animals, and there was much evidence to show that an alcoholic mother was more apt to produce an abnormal child than was a non-alcoholic mother. Tubal pregnancies were common among women with venereal diseases; in such cases the embryo must necessarily develop under abnormal environment. Mall found that only 7 per cent. of uterine pregnancies contained pathological embryos, while 66 per cent. of the embryos in tubal pregnancies were pathological. This was strongly indicative of an abnormal environment as the cause of abnormalities. The speaker then reviewed the study made by Sullivan relating to the influence of inebriety on offspring and said that that authority had concluded correctly that the influence of alcohol was due to a permanent effect of the poison on the maternal organism, inducing a transmissible degenerate condition; and that, further, alcohol had a direct toxic effect on the developing embryo and fetus, owing to the continued excesses during pregnancy and lactation. In regard to the second point as to whether abnormal chemical environment might act on the parental germ cells in such a manner as to cause them to change and become incapable of giving rise to a normal individual, it was well known that certain disease toxins and substances such as alcohol and lead affected various body tissues so as to render them unfit for normal physiological activity. It was, therefore, only logical to suppose that the same or similar substances might affect the germ cells and so derange their chemical constitution as to cause them to give rise to offspring of peculiar structure and qualities. Bertholet had found that alcohol had a peculiar affinity for the reproductive glands, just as it did for the nervous system. In examining the testicles from a large number of alcoholics it was shown that spermatozoa were entirely absent or degenerate in form in a majority of the cases. It was doubtless true that the ability of the spermatozoa to accomplish a normal fertilization would be affected long before any definite structural change could be observed. The author cited instances that indicated that when the cause was known for defective development the cure might often be established by its removal. Dr. Stockard then related his experiments with guinea pigs. He found that in 24 matings of normal females with alcoholic males only two gave normal results, whereas in the control animals the matings had all resulted in normal offspring. Of 14 matings made between alcoholic males and females, 10 gave no results or aborted very early, while 4 cases showed the following records: One young was born weak and died in convulsions on the sixth day after birth, two cases of premature birth of dead young occurred, and one female had young *in utero* when killed. The records of the control animals all showed normal conceptions and normal offspring. Finally, the author concluded that the experimental evidence went to show that the development of an offspring might be modified by either treating the parents with alcohol so as to affect their germ cells or by subjecting the developing embryo itself to the unusual and injurious alcoholic conditions. The causes of many congenital defects were therefore known. It was possible to control embryonic development in such a way as to produce abnormal structures. Might not the proposition be reversed and unfavorable environments be treated in such a way as to render them favorable to normal development? While protective measures were being used to protect the postnatal life of the individual, why not guard as far as possible its prenatal development?

The Mentality of the Alcoholic.—Dr. Smith Ely Jelliffe read this paper. He said that there was no such

thing as the mentality of the alcoholic, that a lesion rested upon no one mental type, but that he had chosen this title because if one was to understand the problem at all it must be approached from the mental side. The problems of the alcoholic were fundamentally mental problems. Approaching the subject from a long way off science had more or less employed the anecdotal method. One gathered from the alcoholic what he thought about it. Why did he drink? The answers were surprising, if not amusing, and rarely were two alike. The speaker repeated a number of these answers, which were full of inconsistencies and seemed to lead nowhere. It was evident that the real reason was more intimately bound up in the personality. The individual got something from alcohol. When wounded, or thwarted, or maimed in life's battle, relief was found by the instinctive self, and alcohol was the thing found by many. It was profitable to inquire, therefore, what alcohol gave. Alcohol was the great dissociator of function. It reduced man to the elementary principles. The effort of intelligence to supplant and augment instinct, which was the great principle in creative evolution, was thwarted by the action of alcohol and man returned by successive stages along the path he had traveled in his upward evolution. This referred not to the deterioration of the chronic alcoholic but to acute alcoholic intoxication. From the stages of gradual loss in the higher intellectual coordination, the gradual loosening of the instinctive repressions, man descended, under the influence of acute alcoholic intoxication, to the more or less rapid perceptional numbing, the gradual loosening of reflex activity from cortical control, on down through the scale until he was no longer a man, a highly complex, closely integrated, coordinately working, efficient machine, but a decomposed series of organic reflexes, a lower vertebrate, a reversion of types from the highest to the lowest. Therefore alcohol changed the outside world for the individual; it pushed facts and verities away from consciousness, and enabled the individual to get away from realities. Dr. Jelliffe then discussed memory, not as a faculty of putting facts away in a register, but as a faculty working without relaxation automatically piling up past upon past until all one had felt, thought, or willed from his earliest infancy was there leaning over the present, and that character was the condensation of the history which he had lived. Thus it took very little analysis to see the major outlines of the difficulties which caused perhaps the majority of mankind to seek forgetfulness. The grinding struggle, the fierce contest of self-preservation in a large social complex, might possibly be met with better fortitude, for a time at least, if reality could be changed to phantasy. Herein lay the usefulness of a substance that man had employed as far back as history reached. The author assumed that alcohol was of value to the instinctive reactions of the animal even if it was shown that for the intellectual animal it was a detriment. He emphasized the point that instinct and intelligence were not the same; intelligence was not a higher form of instinct. They were different guiding principles meant to do the same work in a different way. Had not that which was called intelligence been evolved man's reactions would always have been instinctive and he would never have needed alcohol to rob him of the restraining hand of his more fluid and modifiable evolutionary aid, when, as an instinctive animal, he would avoid life's problems and dodge responsibilities. This led to the consideration of some of the character anomalies which were the indices of the complexes with which they had to deal. The author then discussed alcoholism and old age, what the artistic temperament represented, sexual problems, financial dishonesty, and political crookedness as among character anomalies predisposing to alcoholism.

The Medical Control of the Alcoholic.—Dr. ALEXANDER LAMBERT read this paper and considered the subject from two standpoints: That of the personal control which the physician had over his patient, and that control which the State took or permitted under certain restrictions over the individual, whether the individual was willing or not. Broadly speaking, the failure of the physician to deal with the victim of alcohol had been due to the fact that he had endeavored to reason and deal with a mind poisoned by a narcotic through normal standards. The psychology of the alcoholic was vastly different from that of the normal mind. Dr. Lambert said that it made no difference whether they employed the method that he had suggested or some other so long as they realized the fact that an individual suffering from narcotic poisoning must be unpoisoned before he could be given a fair opportunity and before one could reasonably expect him to respond to one's endeavor to control. It was useless to endeavor to instil in these people any idea of confidence in themselves, in the endeavor to shake themselves free from their narcotic, unless one had faith in their ability to do so and could inspire this confidence in them. These victims of alcohol could not be controlled against their wills. They could not be helped unless they were willing to be helped. If willing to help themselves, this class, if given a chance, were easily controlled and would make every endeavor to free themselves from their addiction. When the alcoholic had no desire to free himself, the only alternative was State control. The real State control of the alcoholic had been slow of development in this country. A mind which had become degenerate from alcohol had also lost its normal connection with the past and did not answer normally to the ordinary stimuli of daily existence; the mind thus poisoned must be protected until it could recover its normal balance. This was realized some years ago in England, and in 1879 retreats were founded where people could voluntarily go to rid themselves of their narcotic addictions. This had proved so successful that they now had certified reformatories which received drunkards from the courts and State reformatories. The Commission appointed to investigate the workings of the inebriate's acts had more than ever become firmly convinced of the wisdom of the plan they were following and had recommended further legislation along these lines. Some such plan must soon be followed by the various States of this Union. Dr. Lambert spoke of the work done at the institution at Foxboro, Mass., and of the laws in respect to the committment of inebriates in various States. In regard to industrial forms of drinking, the medical endeavor must be directed to the improvement in the environment in which these men worked. Convivial drunkenness could be controlled only by public opinion and by teaching the individual the dangers of his case. In closing, Dr. Lambert made a plea for a close study of eugenics and the improvement of the race. While it had been known from Plutarch's time that drunkards begat drunkards, we had insufficient scientific data from which to draw accurate conclusions and to study the forms and tendencies in which this degeneration showed itself; the relations of this inheritance to the various forms of insanity were also very unsatisfactory, and urgently demanded prolonged and definite study.

Dr. EDWARD D. FISCHER said that he agreed with what Dr. Jelliffe had said in regard to alcohol; that was, that many of the cases were really those of mental disease in which the abuse of alcohol was "accidental or incidental," in fact, were not true cases of alcoholism. Many such instances had come under his observation during the past twenty years in the psychopathic and alcoholic wards of Bellevue Hospital. The commonest form of mental disease in which this abuse of alcohol occurred was manic-depressive insanity. While this was true, the percentage of alcoholic cases where a distinct mental disease was present was comparatively small, and the majority were due to lack of stability, idleness, viciousness, and especially hereditary tendencies. The explanation offered by Dr. Jelliffe that many resorted to alcohol to produce amnesia of their present misery or disappointment was also very true, but, again, he thought Dr. Jelliffe placed too great weight on this as a factor. Many of the younger persons had had no previous burdens in life and yet they as easily fell victims to the habit. He was glad to hear Dr. Hutchinson speak so positively from the statistical standpoint of the relatively small proportion of alcoholics and also to state, that from well-authenticated data, the offspring, unless other conditions were present, as syphilis, hereditary nervous disorders, malnutrition, etc., were not so seriously affected either in numbers or in the proportion of defectives as was generally supposed. Dr. Fischer expressed himself as thoroughly in accord with Dr. Lambert's plan of treatment, especially the colony and parole systems, which had been so successfully carried out in Massachusetts and other States.

PHILADELPHIA NEUROLOGICAL SOCIETY.

AT a stated meeting held April 26 Dr. ALFRED GORDON presented the brain from a man who died suddenly. The patient was a man, 32 years old, previously healthy, who for a short time had suffered from headache, and without obvious signs of disease. Following his evening meal he lay down to read and suddenly lost consciousness, with evidences of slight right hemiplegia, followed by coma and death. Post-mortem examination revealed a copious extravasation of blood into the left lateral ventricle. Dr. TOM A. WILLIAMS reported "A Case of Cerebellar Disease of Malarial Origin." The patient was a man, 38 years old, who had served in the army in Cuba during

the Spanish-American War, and who suffered a pernicious malarial infection. There was a history of gonorrhea, but none of syphilis, and the Noguchi test yielded a negative response. The man exhibited difficulty in the control of all four extremities, with ataxia, vertigo, incoordination of movement in the hands, and preservation of reflexes and of the action of the sphincters. Dr. Williams reported also "An Unusual Case of Dystrophy of Optic and Pyramidal Systems." The patient had difficulty in walking, with exaggerated reflexes, coarse infection-tremor, inequality of the pupils, one of which reacted but sluggishly to light, atrophy of the optic nerves, more marked on one side, but without nystagmus. Syphilitic infection was denied, and evidence thereof could not be detected. Dr. D. J. McCarthy presented a communication entitled "Hemosiderin-infiltration of the Wandering Cells of the Pia-arachnoid." He reported the results of clinical observation and experimental study showing that in cases in which hemorrhage occurs within the cranial cavity cellular infiltration with hemosiderin is likely to take place, giving rise to alterations in structure and at times also in function. Dr. Chas. H. Frazier read a paper entitled "Rhizotomy for the Relief of Gastric Crises in Tabes Dorsalis, with the Author's Experiences." He reviewed the literature of the subject and reported an illustrative case in which the seventh, eighth, and ninth dorsal roots on one side and the tenth in addition on the opposite side were cut within the dural canal, affording relief from the intense suffering to which the patient had previously been subjected. In the discussion Dr. Wm. G. Spiller suggested the possibility of injecting alcohol into the roots of the nerves involved for the purpose of controlling lightning pains or crises when present. Dr. Williams B. Cadwalader presented "Two Cases of Hereditary Spinal Paralysis." The patients were boys, one about eight and the other about eleven years old. Both presented spastic gait, with increased knee-jerks and extensor toe reflex, but without mental disturbance or involvement of the upper extremities. There had been no difficulty in birth and there was no history of syphilis, and the Wassermann test yielded negative results. Another brother and also some ancestors on the paternal side were said to present similar symptoms. Dr. Milton K. Myers made "A Report of a Case in Which Epilepsy Developed after Overuse of Thyroid Gland Extract." The patient was a woman who had used a preparation of thyroid gland for the reduction of obesity and in whom there developed convulsions of an epileptiform character, without other obvious cause.

Books Received.

The Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Progressive Medicine. Vol. XIV, No. 1. By Hobart Amory Hare, M.D., and Leighton F. Appleman, M.D. 377 pages; paper; price $5.00 per annum. Lea & Febiger, Philadelphia, Publishers.

Digest of Comments of the Pharmacopœia of the United States of America (Eighth Decennial Revision) and on the National Formulary (Third Edition). For the calendar year ending December 31, 1909. By Murray Galt Motter and Martin I. Wilbert. 735 pages; paper. Government Printing Office, Washington, Publishers.

Arbeiten aus dem Hygienisch-Chemischen Untersuchungsstellen. Vol. V, No. 52. 100 pages; paper; price 3 M. August Hirschwald, Berlin, Publisher.

Filariasis and Elephantiasis in Fiji. By P. H. Bahr, M.A., M.B., B.C. 102 pages; illustrated; paper; price 6 shillings net. Witherby & Co., London, Publishers.

Recent Methods in the Diagnosis and Treatment of Syphilis. By Carl H. Browning, M.D., and Ivy McKenzie, M.A., B.Sc., M.B., Ch.B. 302 pages; cloth. Lea & Febiger, Philadelphia and New York, Publishers.

Home Hygiene and Prevention of Disease. By Norman E. Dieman, M.D. 333 pages; cloth. Duffield & Company, New York, Publishers.

Emergency: A Manual of First Aid. By Ernest A. Wells, M.D. 48 pages; illustrated; paper. Aetna Life Insurance Company, Hartford, Conn., Publishers.

Surgery of Deformities of the Face. By John B. Roberts, A.M., M.D. 273 pages, illustrated with 273 figures; cloth; price $3.00 net. William Wood & Company, Publishers, New York.

Late Epilepsy.—C. Migliucci has seen a number of cases in which epilepsy, not of the Jacksonian type, came on in later life, that is after thirty years of age, without any history of injury. These are cases similar to those that occur in earlier life, with the same form of attacks, and the same course. The author questions whether these attacks are not caused by syphilis. There can be no doubt that in some of these cases syphilis is the etiological factor, and the author questions whether this is not always the case. In young children epilepsy has for its cause some radical defect in the psychocerebral development by virtue of which the child does not react normally to its environment. Alcohol in itself would not cause epilepsy if there were not at its basis a disturbance of the nutrition of the nervous system. A syphilitic intoxication aside from any lesions of the nervous system may act as a cause of late epilepsy. In some cases there are lesions of the vessels of a syphilitic nature, giving conditions which may be placed midway between cerebral syphilis and general paresis. Some authors liken these disturbances to the appearance of the secondary skin symptoms, and think that they take their place, being due to infiltration of the meninges with syphilitic new tissue growth, the infiltrations being so small as not to be visible except to the microscope. Syphilis in a predisposed individual has been the last factor to cause cerebral irritation and the manifestation has been an epileptic one. *Giornale Internazionale delle Scienze Mediche.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended May 18, 1912.

VERTIGO AS A SYMPTOM OF DISEASE OF THE NERVOUS SYSTEM.*

BY JOSEPH COLLINS, M.D.,

NEW YORK,

PHYSICIAN TO THE NEUROLOGICAL INSTITUTE.

THE division of the subject allotted to me, viz., vertigo due to lesions of the central nervous system, I shall assume to be warrant for discussing vertigo as an indication or symptom of disease of the nervous system. Strange as it may seem, or unlikely as it may sound, vertigo is a symptom that does not bulk very large in the neurologist's work. Aside from tumor and abscess of the brain, disseminated sclerosis and basilar arteriosclerosis, it rarely occurs as a leading or diagnostic symptom of disease of the brain. I have recently gone over the histories of all the patients admitted to my service in the Neurological Institute in the year 1910. There were 425 and of this number only 22 complained of vertigo. When it is borne in mind that the hospital has an extremely rich and varied material, and that many of the patients are admitted for study and diagnosis, these figures may be taken to corroborate my statement as to the rarity of the symptom in nervous diseases.

Naturally the neurologist frequently encounters vertigo, but in the vast majority of instances it is a symptom of disease of the middle ear, the labyrinth, the sinuses in connection with the nasal passages, or of the digestive and blood elaborating organs.

Vertigo is a symptom of such manifold causation that it is rarely of any diagnostic value until after the most searching investigation has been made to determine its dependency. Even then its origin, in other words its significance, often eludes us. There is no symptom which is so baffling to the physician who is unprepared to make technical and oftentimes elaborate examination of the eyes, the ears, and the circulatory apparatus.

I shall confine my remarks on this occasion to an attempt to set forth the knowledge that I have gained from intercourse with patients with diseases of the nervous system who have had vertigo as a prominent symptom, and to state what there is about such vertigo that leads one to suspect the existence of the nervous disease. Before this is done a paragraph must be devoted to the connotation of the word vertigo.

"It is dizzy before my eyes," is one of the commonest complaints of our clientèle in the dispensary. This does not by any means signify that the patient has genuine vertigo, and in every instance it is necessary to make a careful inquiry as to the meaning of this complaint. It signifies in the majority of instances a disagreeable subjective sensation consisting of more or less blurring of vision, of minute black spots in the visual field, and of disagreeable sensation of mental confusion. It is rarely accompanied by any sensation of rotation or of profoundly disturbed equilibrium, and it is most frequently an expression of disordered circulation. In the same way many people complain of giddiness or of dizziness, when in reality genuine vertigo does not exist at all.

The term vertigo should be restricted in its application to describe a sensation of disturbed equilibrium accompanied by a subjective sensation of impaired static security.

The sensation is extremely disagreeable, at times terrifying, and frequently accompanied with nausea and vomiting. It is always a manifestation of disorder of the cerebellum and the subordinate cerebellar centers, which disorder is mediated by direct irritation or indirectly by abnormal stimuli reaching them through the auditory, the visual, or the kinesthetic pathways. Indeed it may be that vertigo is the result solely of cerebellar disorder and that the only part which the higher center plays in its genesis is cognition of it.

It would be advantageous to limit the application of the word vertigo to true rotatory vertigo which occurs only when the organ of static equilibrium is in some way irritated, and to call the various disagreeable phenomena occurring with ocular disorder, especially muscular inadequacies, digestive disorders, elevations and depressions of blood pressure, some nervous diseases such as disseminated sclerosis, asthenic conditions, etc., of which dizziness and giddiness are symptoms, vertiginous states. One is a very clear cut symptom of pathognomonic significance, and the other is a vague, rather conglomerate sensorial interpretation.

Vertigo is a symptom of very little specificity. Aside from the labyrinthine variety there is nothing about it, save its ancillary phenomenon that suggests its causation, or the seat of the disease of which it is a symptom. For this reason the physician cannot from a consideration of the vertigo alone materially advance the diagnosis of any disease. It is from the company it keeps that one may draw diagnostic conclusions.

Vertigo is often a symptom of:

1. Organic Brain Disease—*a*, tumors, abscess or other lesions that materially increase intracranial pressure; *b*, disseminated sclerosis; *c*, endarteritis and arteriosclerosis; *d*, meningitis; *e*, general paresis.

2. Functional Nervous Diseases—*a*, epilepsy; *b*, hysteria; *c*, dementia precox; *d*, neurasthenia; *e*, habitual vertigo.

In addition to these, vertigo may accompany any disease of the nervous system that disorders the ocular muscles such as tabes, grave myasthenia,

* Contribution to A Symposium on Vertigo. Read before the State Medical Society, Albany, N. Y., April 17, 1912.

any condition or disease that abruptly or profoundly disturbs the intracranial circulation such as anemia or hyperemia of the brain, and the taking of drugs and intoxicants.

When the physician encounters vertigo the only safe way for him to proceed in its interpretation is to make an examination of the ears, the eyes, and the blood vessels. If he can exclude middle ear disease, labyrinthine involvement, palsies of the ocular muscles, and exalted blood pressure, then he may legitimately search for disease of the nervous system that I have enumerated. To diagnosticate the organic diseases of this list requires the use of the opthalmoscope, an inexpensive instrument, whose use is readily learned but which is treated disdainfully by the medical profession.

Vertigo associated with papilloedema, optic neuritis, or optic atrophy is undoubtedly dependent upon organic brain disease which may be diagnosticated by virtue of the association of symptoms subjective and objective, rather than from the consideration of any one symptom. And of diseases causing such detectable objective symptoms or pathological states brain tumor is by far the most common.

It has been variously estimated that vertigo accompanies brain tumors in from 30 to 50 per cent. of the cases, but it is with tumors of the two poles of the brain that vertigo is most common. Tumors of the frontal pole are accompanied by vertigo in the majority of instances; and tumors of the posterior pole if they encroach upon or involve the cerebellum are invariably accompanied with vertigo. Indeed, profound vertigo of the rotatory type is frequently allowed to have some weight in suggesting the localization of the tumor to the cerebellum. In the same way attacks of vertigo associated with irritative or paralytic manifestations, whether of the sensory or of the motor functions, suggest tumor of the central convolutions.

Tumors and abscesses of the brain cause vertigo in one of two ways, either by interference with the auditory nerve or by causing ocular palsies. The view that the vertigo in such cases is the result of increased intracranial pressure has lost credibility, in view of the fact that after lumbar puncture in such cases which diminishes intracranial pressure the vertigo often increases.

Vertiginous manifestations, but not true vertigo, is a constant and early symptom of disseminated sclerosis. In 21 cases of this disease that came to the Neurological Institute in 1910, vertigo was complained of by the patient 17 times. Disseminated sclerosis occurs much more frequently than one would conclude from examining the literature. In the so-called atypical clinical cases vertigo is likely to be a conspicuous symptom. It is commoner in the early stages of the disease than in the later. There is nothing characteristic about it and its diagnostic value is entirely dependent upon its association and especially upon its association with transient ocular palsies, with nystagmus, and absence of the abdominal reflexes.

In every case of vertigo occurring in individuals above 40 years of age there should be a careful and meticulous examination made of the blood vessels, the heart, and the kidneys, unless the vertigo is associated with such distinctive phenomena as it is in Menière's disease.

Vertigo is the most common prodromal symptom, and one of the most constant accompaniments of cerebral arteriosclerosis. Its occurrence and its intensity stand in relation to the distribution of the sclerotic process in the vessels. If this is of the focal variety and the focus happens to be in the equilibratory center then true rotatory vertigo may be the result. This is comparatively a rare condition. On the other hand generalized arteriosclerosis with participation of the basilar arteries is likely to produce a vertiginous state subject to exacerbations or remissions, and accompanied with symptoms and physical signs which permit the diagnosis. Of all the cases of vertigo or vertiginous states that come to the neurologist for interpretation these constitute by far the greater number. As an illustration of such vertigo the following case is quoted briefly:

The case was that of a man, a clergyman, 62 years old, whose early life was one of great toil and hardship both physical and mental, *i.e.* in the building of a church in a poor mining district and giving aid to the members of his parish throughout a large and sparsely settled country. He began to complain on or about October 31, 1911, of attacks of vertigo, heaviness in the back of the head, occasionally getting out of breath. He also noticed a great change in his disposition, having become quite irritable. He complained also of a sensation of uncertainty as if he could not keep his balance. The attacks were apt to occur when rising from a lying posture, as early in the morning and after he had made any particular effort, but on the other hand they occurred apart from such experiences.

He had his eyes examined and one doctor stated that he found sufficient abnormality to account for the vertigo, but wearing glasses gave him no relief from the attacks.

His blood pressure was 185 (Stanton), the peripheral arteries were palpatable and tense, the heart enlarged so that the left border was ½ inch outside the nipple line, and the urine contained at times a faint trace of albumin, all unequivocal signs of the arteriosclerosis. Under treatment for a short time on a purin, salt-free diet, carbonic acid baths, high frequency electricity, and general massage he made marked improvement with regard to his dizziness, but says apart from this when walking on the street he is suddenly seized with a sense of unsteadiness and a fear of falling in one direction or other. On several occasions after walking a few blocks he has suddenly been seized with a sensation of being "all gone" in the abdomen during which time he feels too weak to walk, symptoms which indicate beginning loss of compensation in the heart.

Vertigo preceding, accompanying, or replacing the attacks of convulsions in epilepsy is a common occurrence. The frequency with which vertigo occurs in epilepsy is, however, variously estimated. There are some writers who maintain that it occurs in upward of one half the cases. But as a matter of fact the percentage depends entirely upon what we admit to be vertigo. If we limit the application of the word to instances in which there is true rotation of the individual or of objects surrounding him, then vertigo is a rare occurrence in epilepsy. If on the other hand, the slight disturbance of equilibrium, of confusion, and of darkness just preceding an attack of unconsciousness are grouped under that head, it must be admitted that vertigo occurs in nearly every case of epilepsy. As a matter of fact epileptic vertigo occurs in 15 to 25 per cent. of the cases, displaying itself either as the aura of an attack, or as the chief manifestation of the attack. That is, when the patient recovers all that he knows is that he has been profoundly dizzy.

It is difficult to distinguish epilepsy from vertigo

and particularly from labyrinthine and aural vertigo. They are both abrupt in onset and are both attended by loss of consciousness, but aural vertigo is usually accompanied by a sensation of violence, of being hurled or struck to the ground, tinnitus and impaired hearing which does not occur in epilepsy. Moreover, with our present day tests to determine the functional state of the labyrinthine and auditory nerve the dependency of auditory vertigo can readily be made out.

The occurrence of vertigo in hysterical individuals, or as a manifestation of hysteria is very well substantiated. Occasionally it occurs with migraine either accompanying or replacing an attack.

Vertigo likewise occurs in neurasthenic individuals, and Oppenheim has pointed out that there is a permanent vertigo which occurs in neuropathic or psychopathic individuals without apparent cause, and often in a very severe way, associated with nausea and vomiting. He maintains that he has met cases in which this vertigo has remained for years, subject to amelioration and exacerbation. In none of the cases has labyrinthine or cerebellar diseases been found, and neurasthenic symptoms are always present. Oppenheim believes it to be a genuine vertigo; not psychical, not dependent upon any demonstrable organic change, and probably due to perversion of the perceptive center of the cerebrum rather than to disorder of the cerebellar or of the vestibulary nuclei.

As a matter of fact it may well be that there is a neurosis of the vestibular branch of the eighth nerve which is responsible for many obscure cases of vertigo in which no organic disease can be found, quite the same as a neurosis of the motor branch of the fifth or the seventh nerve causing tic, and of the sensory branches of the fifth nerve causing pain.

The common apparent cause of what is alleged to be vertigo by the sufferer is false projection of the fields of vision induced by palsies or paralysis of some of the ocular muscles and by refractive error. Such false projection inducing vertigo is frequently seen in patients after they have had a tenotomy of some of the eye muscles. In reality as I have said before, this is not a true vertigo. Mendel some years ago attempted to show that in every case of vertigo there was some disturbance of the oculomotor nuclei, circulatory in the majority of instances. It has been satisfactorily proven that Mendel's contention is untenable. A vertiginous state may accompany palsies of the ocular muscles whether they are peripheral or of central origin. Thus it is at times a conspicuous symptom of tabes, of nuclear ophthalmoplegia, and of syphilitic meningitis, and of those mysterious transitory ocular palsies whose origin is unknown but which are sometimes spoken of as rheumatic. Practically in every instance in which vertigo accompanies ocular palsies the vertigo disappears when the individual learns to suppress the false projection of the visual field, that is when he acquires the capacity to suppress psychical cognition of it, which is usually in a short time. However, in some instances such a gratifying termination is not the result. Thus I have seen states of dizziness, giddiness, and slight mental confusion remain for several months in the wake of a tenotomy done for hyperphoria.

Vertigo is complained of by many patients who have experienced bodily injury that has not caused a definite lesion; such as fracture, laceration, and contusion, particularly in individuals who develop symptoms that lead to the diagnosis of traumatic neurosis. I have at the present time such a patient under observation. A lady 50 years old was struck and knocked down by an automobile. Aside from some bruises on her back and limbs, she was objectively injured. But since that time, now upward of two years, she has complained in addition to symptoms of nervousness, lowered vitality, and easily induced exhaustion, of subjective vertigo which though more or less constant is liable to exacerbation, especially in the early morning. It was this matinal occurrence in conjunction with our utter inability to attribute the vertigo to any disorder of her vestibular apparatus, her visual or kinesthetic pathways, that suggested its interpretation, namely that it is dependent upon a lowered blood pressure which was invariably below 100, on the Stanton apparatus.

The administration of substances which lifted the blood pressure such as adrenalin, a diet rich in proteid matter, stimulation of her heart, and peripheral neurovascular apparatus and appropriate hydriatic procedure apparently relieved her.

I have seen a number of cases in which vertigo seemed to be dependent upon lowered blood pressure, both with and without arteriosclerosis. I venture to call your attention to it as a cause of vertiginous states in every instance in which the dizziness and resulting disagreeable mental sensations occur in asthenic individuals in whom organic disease can be eliminated. It is quite possible that the subjective disorder of equilibrium which is sometimes more or less constant in these individuals but always subjective to paroxysmal exacerbation, the direct result of inadequate stimulation of the center of static equilibrium and in the cerebellum or in the interpretative area of the cerebral cortex.

Of the vertigo that accompanies intoxications such as alcohol, urea, etc., I shall say nothing, as they probably will be considered in this symposium by Dr. Stockton, nor shall I discuss that enigmatic disorder known as paralyzing vertigo, Gerlier's disease, which affects herdsmen living in the winter in closest intimacy with cows, in certain parts of Switzerland. Of the so-called reflex vertigo, the less said about it the better, in order that we may not magnify its importance. I am of the opinion that there is no such disorder, though there may be vertiginous states and transitory disturbance of consciousness and equilibrium arising from irritation of any highly sensitory organ. Finally, from a study of vertigo alone no conclusion can be reached as to its causation which is essential for its intelligent and successful treatment. We may apply certain rules of thumb which will enable us to guess shrewdly as to its origin, but really to determine it we must examine the patient.

THE SURGICAL MANAGEMENT OF NASAL ACCESSORY SINUS DISEASE.*

By LEWIS A. COFFIN, M.D.,

NEW YORK.

In opening the discussion on this broad subject, the limitations of time compel me to confine myself to the discussion of general principles, as well as to the expression of my personal experience and conclusions.

Disease of the accessory sinuses may be classified as follows: According to type, the disease may be catarrhal, empyemic, or malignant.

*Read before the Section on Diseases of the Eye, Ear, and Nose of the Medical Society of the State of New York, April 17, 1912.

According to stage, acute or chronic. (There may be an acute exacerbation of a chronic process, and, of course, an acute case may become chronic.)

According to objective signs the disease may be active or latent.

According to location the disease is named from the sinus involved.

In this connection should be mentioned the mucocele as a diseased condition sufficiently peculiar to be in a class by itself.

What I shall have to say in this paper on the surgical management of accessory sinus disease, has reference solely to the empyemic form of sinusitis in its various manifestations.

I have used the term "active sinusitis" in contradistinction to "latent," although I feel that neither is a good term, for I consider that by "latent" sinusitis is meant not so much a dormant disease of one or more of the sinuses, as a disease which presents no objective signs. It might be termed an "occult" sinusitis. Such a disease may exist in the sinuses of persons whose noses present a practically normal appearance.

It may involve any of the sinuses, and is of the utmost interest and importance because of the difficulty of diagnosis. It is, for the most part, a chronic process. When involving the frontal or antral cavities transillumination and the radiograph materially aid in the diagnosis, but existing independently in the ethmoids or sphenoids or confined to those two cavities, the diagnosis must rest upon symptoms and possibly the study of the eye. In a suspected latent sinusitis other causes which might account for the symptoms must be excluded. The suspicions confirmed and diagnosis made, one proceeds as in ordinary or active sinusitis of the involved cavity, except that no temporizing with washings and applications should be done. The diseased cavity must be opened and the disease eradicated.

I have dwelt somewhat at length upon this subject because I feel that many such cases are unrecognized, and the rhinologist should be on the lookout and alert to relieve a greater number of people who suffer from obscure or latent sinusitis.

An active sinusitis might be called "an apparent or evident" sinusitis. It is easily diagnosed as such, the difficulty being to decide as to which or how many sinuses are involved.

Just what surgery shall be done on a particular case depends largely upon the stage of the disease, on the structural deformity of the nose, and especially upon the condition of the membrane lining the sinus, which may depend upon the variety of infection or the constitutional vice of the patient.

The condition of the membrane lining an infected sinus varies from a simple, round-cell infiltration, to granulation thickening on to polypoid degeneration, which condition continuing may end in devitalizing of the membrane and bone necrosis. Probably in some constitutional conditions, notably syphilitic, the trouble may begin in the bone, in which case the disease of the membrane is secondary.

Whereas there is undoubtedly a great difference in the degree of the pathological changes which take place in the diseased lining membrane of the accessory sinuses of different individuals, as well as in the time in which the changes occur, it may be said, on general principles, that the changes are greater in the same length of time than take place in almost any other part of the body. This is due to the peculiar structure of the normal membrane. A certain number of fulminating cases develop so rapidly as to fall almost at once into the emergency class. Such cases present evidence of great pressure, on account of which one sees danger to the eye or brain. A thorough operation should be done at once, under general anesthesia, and through an external opening, if the frontal is involved. If the disease be confined to the ethmo-sphenoidal group, the attack may be made through the nose, under local anesthesia. Such a case was brought to me from the Eye Department of the Manhattan Eye, Ear and Throat Hospital, on March 11, 1912. A man, forty-five years of age, laborer, had come to the eye clinic about one week earlier on account of a swollen left upper eyelid and lowered vision. He suffered no pain, complained of no nasal discharge, and the oculist felt that he had some kind of a tumor in his orbit; but conditions grew so rapidly worse, that it occurred to him that there must be an acute process somewhere, and he asked me to examine the man as to the condition of his sinuses. The whole left side of the head was swollen and edematous to below the prominence of the malar bone. The upper lid could not be raised sufficiently to see any part of the eye. His nose was clean with the exception of the smallest bead of pus at the top of the middle meatus. When this was wiped away no more appeared. The man could not be transilluminated. A radiograph showed cloudy, but we thought the edema of the external parts might account, at least to some extent, for that. My willingness to open his frontal was based largely on the above picture, in connection with his statement that about six weeks before he had suffered for several days from an intense frontal headache. There was no history of syphilis, and a Wassermann test was negative. His frontal was filled with granulation tissue and his ethmo-sphenoidal tract filled with a polypoid membrane. Each cell seemed to yield up individually its contents which looked like the pulp of a grape expressed from its covering; there was no pus, nor was there pus in his orbit. A Caldwell-Luc operation was done on his antrum, the lining of which had likewise undergone the same polypoid degeneration. A complete and rapid convalescence was established.

I have related the above history because it shows with what rapidity this complete metamorphosis may take place. The absence of pus is interesting and lends to instructive reflection on some of our cases of latent sinusitis.

The majority of acute cases tend to recover of themselves, but this tendency may be enhanced by proper treatment, which is pretty much summed up in the establishment of free drainage. Symptoms may be relieved and a cure hastened by washing out the diseased cavities with some of the simple aseptic washes. Drainage of the frontal sinus and anterior ethmoid is generally sufficiently established by the removal of the anterior third of the middle turbinal. Much and speedy relief is frequently afforded by applying suction to the diseased sinus. This is a procedure of great use also in differential diagnosis. It may be necessary to straighten the septum, which is crowding the middle turbinal against the body of the ethmoid. Such a case was that of Mr. S. H., aged thirty-seven years, who presented himself at my office on January 6, 1912. He was suffering intense pain in the left frontal region, left frontal very tender on pressure and palpation, and dark on transillumination. A large quantity of pus was draining off through the throat. The left nostril was completely occluded at the vestibule by a deviated septum, which deviation was seen, by examin-

ing the right side, to extend well back. I put her into the hospital and temporized with inhalations and heat for three days, debating whether I should do a Killian operation and a submucous resection of the septum at the same time. I decided to do an ordinary resection of the septum and await developments. This I did on January 10. My incision was made on the left or diseased side; the cartilage was removed so that the flaps hung straight. I did not pack. The turbinal was pried toward the median line and not removed. Fearing sepsis, the nose was frequently douched from the right side. I never knew a resection of the septum to do better, nor a frontal sinusitis to clear up more promptly. He left the hospital on January 15, five days after the operation, and resumed work about ten days later.

To show the difference in handling an emergency case, I will give one other history. An Italian, about thirty-five years of age, came to the eye clinic of the Manhattan Eye, Ear and Throat Hospital, about one week later than the previous case. His left eye was exophthalmosed and closed, lids purple, vision so lowered that he could count fingers but about eighteen inches from the eye; had the same occluding deviation as the former case, but it did not seem to extend so far backward. He was placed at once on the operating table, the knuckle of cartilage obstructing the nostril was removed by knife and saw, making a large opening through the septum, and a radical Killian was done on the frontal ethmoids and sphenoid. A Caldwell-Luc operation was done at the same time on the antrum. Recovery was complete and uneventful. Vision became normal as soon as the swelling about the orbit had subsided.

Most of the mooted questions as to the method of operation on the accessory sinuses concern the treatment of the chronic cases, especially those involving the frontal, and giving histories of more or less acute exacerbations, not reaching such a state as to be considered emergency cases.

Any one of the sinuses may be independently diseased or they may be associately diseased in almost any of the possible combinations. Any of the sinuses may be reached by either intranasal or extranasal routes. Were it possible to explore and eradicate the disease of any sinus as thoroughly by the intranasal as by the extranasal route, or did the establishment of drainage ensure a cure of the disease, there would be no extranasal surgery for the cure of accessory sinus disease. One who has much to do with the treatment of these diseased cavities knows, however, that frequently the establishment of thorough drainage will not cure the disease, and certain of the sinuses can never be explored ocularly or thoroughly by instruments through the nose. On the other hand, well established drainage often does lead to a complete cure of a diseased sinus, and some of the sinuses in which it would not may be thoroughly explored and the disease eradicated through the nose; therefore, we have of necessity two operative procedures—namely, intranasal and the extranasal.

Now, again, it may be said, were it not that any scarring and any deformity which result from an extranasal attack on the accessory sinuses are on the face, there would be much less of intranasal work. The extranasal operation is done under a general anesthesia. Every operated area is within easy view, so that diseased areas are more easily made out and eradicated, and, to the writer's mind, with as little or less danger than accompanies radical intranasal surgery. But scarring and deformity of the face are great drawbacks, and both patient and surgeon are loath to have such results, if cure can be effected in any other way.

There is no doubt a greater ability at present to operate the various sinuses intranasally than a few years ago, and, consequently, I believe fewer extranasal operations are done. But many cases present as attested by the titles of the two succeeding papers on this program, in which nothing short of a most radical operation through an external opening will produce a cure.

In doing an extranasal operation for the cure of a frontal sinusitis, one makes the same incision as is made if the ethmoids and sphenoids are also to be exenterated, and, therefore, if the frontal is to be operated externally, the ethmoids and sphenoids, if diseased, should be operated at the same time, saving thus much time and pain to the patient. It often happens, however, that one feels that all can be accomplished intranasally, in' which case the ethmoids and sphenoids are cleared up and drainage from the frontal improved before it is found that, to effect a cure, the frontal must be opened externally.

On account of the bridge left by the Killian operation, the deformity is much less than by any other equally as radical procedure. The Killian operation has therefore, I believe, become the operation of choice by most operators.

We often hear of a modified Killian having been done. In a majority of cases this refers to the leaving the anterior wall of the frontal intact. While not decrying this procedure in suitable cases, the writer believes that the majority of those cases that can be cured in this way could have been cured by intranasal work. Watson-Williams has recommended this as the safer and more surgical method for establishing drainage from the frontal in acute cases. In those cases of frontal sinusitis, in which the lining membrane has become much degenerated and polypoid, the anterior wall should be removed and every nook and corner thoroughly curetted out. In the case of frontals so small that they do not extend above the upper border of the ordinary bridge the anterior wall should be preserved.

It sometimes happens that the surgeon having done what he considers a thorough Killian operation, has inadvertently failed to find some accessory cavity or offshoot from the frontal. Such a case, when the membranes are thoroughly and chronically diseased, seldom recovers until a secondary operation is done, at which time the overlooked focus of disease is generally more easily found by tracing the pus to its source.

These cases, to my mind, prove conclusively the uselessness of talking of curing all cases by the establishment of drainage. Certainly, it does not do it in the antrum, ethmoid, or sphenoid. Some operators (and Killian advises it) when there is much pus, especially if it has flowed over the cut surface, leave the wound but partially closed for two or three days and complete the suturing of the flaps after the reaction has subsided. To this, there can be no objection. Personally, I close the wound at once. The operated cavities are not packed. The soft parts over the frontal area are pressed against the posterior wall of the frontal by a compress held in place by a head bandage for about twelve hours. When the bandage is removed the compress is now held in position by adhesive strips,

and two or three thicknesses of gauze, saturated with Burows' solution, are laid over the wound. Stitches are removed in from forty-eight to seventy-two hours. The wet dressing is continued for three or four days and the compress is kept in position until the soft parts have become adherent to the posterior wall. Should the dura be exposed, the wound should be left open until granulation is well established. In cases where because of excessive hemorrhage from the bone or for other reasons, it seems advisable to pack the operated field, I leave the wound open in order to have a better control of affairs at time of removing packing and dressing.

In independent disease of the ethmoids or sphenoids, or in their associated disease, a practically radical operation may generally be done intranasally. There are various methods of opening and exenterating these cells.

Ballinger's ethmoidal knives, right and left, are constructed to cut upward and forward from the anterior face of the sphenoid encompassing the body of the ethmoid. In a thoroughly diseased condition of the ethmoid, with considerable bone necrosis, this is an expeditious and fairly easy procedure, not, however, unattended with danger, and in my hands, unless the parts be in the diseased condition just described, it is very painful.

Dr. R. C. Myles, in order to solve the question of safety, has invented a set of centripetally cutting chisels. They are safe, but on account of being necessarily small, compel one to use a great deal of time—a matter of much importance to the patient, if not to the surgeon. My own preference is to begin the exenteration of the ethmoids by the use of a Luc's forceps. One blade of the forceps can generally be pushed into the ethmoid body, the other being free in the middle or superior meatus. Closing the blades and rotating the forceps allows one to remove large masses, and but few bites are necessary in order to open up the entire middle and posterior portions of the ethmoid tract. The middle turbinated may be included in the grasp of the forceps, but unless much diseased it is better to remove it previous to attacking the cells of the ethmoid body. If I wish to begin anterior to the bulla, I generally open that cell by means of a chisel which I push or tap into the cell, and then by using the chisel as a lever, break down the wall of the bulla, thus making an opening through which one blade of the Luc's forceps may be made to enter the ethmoid body. The cells anterior to this and those cells higher up, or extending outward in such a way that they cannot be opened with the Luc's forceps, must be broken down by a small curette or some of the small angular cutting forceps. In a certain number of cases some of the ethmoid cells may extend well over the orbit. These cells cannot be entered through the nose. They can be cleaned out only through an external opening. The ethmoid tract having been opened up by any of these methods, the sphenoid is easily entered, and if necessary its opening may be easily enlarged by curette, burr, or biting forceps. The time consumed for thus opening the ethmoid and sphenoid cavities is very short, with, as a rule, very little hemorrhage. The pain is considerable, but quickly over.

The antrum, whether diseased independently or in company with other of the sinuses, presents an independent surgical problem. Acutely diseased, it tends of itself to recovery. A considerable relief from pain and acceleration of cure are accomplished by first washing it out a few times, either through the natural opening or through a puncture in either the inferior or middle meatus.

Chronic empyema of the antrum may recover from washing if kept up for a considerable time. This is easily done if a fairly large opening is made in the inferior meatus through the naso-antral wall which allows the patient himself to make more frequent washings than can be done in the surgeon's office, and through this opening applications, such as some of the silver or zinc salts, can be made.

If the disease has progressed to the extent that the lining membrane is covered with granulations or has become polypoid, a Caldwell-Luc operation should be done and the diseased lining membrane thoroughly removed. The entrance into the nose should be made sufficiently large to ensure permaneney.

156 West Fifty-eighth Street.

THE TREATMENT OF CARCINOMA BY SELENIUM.*

By EUGENE G. KESSLER, M.D.,

NEW YORK.

The application of the exact natural sciences for the relief of human ills has ever been the ideal of medicine. The progress in physics and chemistry within very recent times has brought us nearer to this ideal; these sciences now help us to solve some problems in diagnosis and therapeutics. Not empirical generalization, but exact conclusions from these sciences must lead us onward to progress in medicine.

Every disturbance of the vital functions and every sickness expresses itself in an equivalent disturbance of metabolism; the demonstration of these metabolic disturbances aids us in diagnosis, and the cognizance of these disturbances aids us in establishing a rational therapy, as shown by Dr. von Oefele.[1]

A number of rare elements, heretofore regarded as chemical curiosities, have recently been called into use and have already shown valuable therapeutic results. Some of these rare elements, not yet used medicinally, will, no doubt, find much employment within the next decades; among these is selenium.

A number of independent investigations have now put selenium in the foreground as a remedy for carcinoma. This, however, is by no means the limit of its usefulness as a remedy. The variety of uses to which selenium can be put will be appreciated by a knowledge of its chemical properties. These properties must ever be kept in view, if we do not want to fall into an aimless therapeutic empiricism.

Among the elements of the six-valent group of the periodic system (to which also belong oxygen, sulphur, and tellurium), selenium occupies the middle position. Within this group this position is the height of toxicity.

Combinations of selenium have, contrary to those of sulphur, the tendency to impart their oxygen to organic combinations and to be transformed into metallic selenium. Sulphur, on the other hand, has the tendency to take up more oxygen, and its great-

*Read before the German Medical Society of New York as a part of a Symposium on the Modern Treatment of Carcinoma, March 4, 1912; also in part before the American Pharmaceutical Association, at the New York College of Pharmacy, March 11, 1912

est degree of oxidation can take place in the body. It is the only element that can burn up within the system to a higher degree than in the air.

Some selenium combinations can easily be detected even in traces. Among these is the finely divided reduced selenium shown by its striking red color, and the methylate of selenium and selenieted hydrogen by the peculiar odor of rotten horseradish. On the other hand, the salts of selenious acid formed with the metals of the alkalies, which form the main bulk of selenium combinations in the body, are detected with the greatest difficulty.

Those preparations of selenium, easily soluble in the body fluids, and which through reduction or oxidation, pass rapidly over into metallic selenium, are the most poisonous. The toxic strength of other combinations (selenates, etc.) lies between the toxicity of selenieted hydrogen and metallic selenium.

Selenium was discovered in the year 1817 by Johann Jakob Berzelius. He was nearly poisoned by selenieted hydrogen.

Among the homeopaths Stapf[2] in 1833 was the first to make experiments on the effects of selenium on his own body.

The first reports of experiments on the animal organism were made by Japha. In 1842, at the request of his teacher Krugenberg, he made observations on the effects of metallic selenium, selenious acid, and potassium selenate on animals. They suffered from diarrhea and finally convulsions; some died within several hours and others after six days.

Eulenberg[3] in his discourse on poisonous and noxious gases, during the middle of the sixties, made an extensive study of the effects of selenieted hydrogen.

Weil in 1885 began the study of the toxic effects of selenium, and Czapek continued his investigations in 1892. The important results of these two investigators were published in 1893.[4]

One of the most important facts pertaining to the effects of selenium was demonstrated by Rabuteau.[6] After the ingestion of selenious salts, he found that these were in the main excreted as such; while after the ingestion of selenic salts, he found them reduced and excreted as selenious salts. Besides this a small amount was reduced to selenieted hydrogen, which combines with methyl. The smallest trace of this methyl selenite can be perceived by its odor and was found by various investigators in all organs.

Rabuteau has observed this odor in the air of respiration. But it was Hofmeister[5] who proved that some substances which in their passage through the animal body easily take up methyl, become methylated, as far as they escape combustion, and are excreted in this form. Among these substances we find pyridin, also selenium and tellurium.

According to this selenium is a powerful oxidizing agent. The same action was demonstrated by Binz and Schultz[2] for the arsenic group. The postmortem findings in poisoning with selenium and tellurium, therefore, resemble very much those found after arsenic, antimony, and bismuth, and also vanadium, especially those in the gastrointestinal tract.

Sulphur and its combinations are oxidized in the body to sulphates. They are not reduced, and therefore do not belong to this group of selenium, tellurium, arsenic, etc.

The investigations of Scheuerlen[7] in the year 1900 have also proved that the toxic effects of selenium rest entirely on the oxidizing effect. He made a pure culture of the *Bacillus anthracis*, excluded athmospheric oxygen and added sodium selenite to the medium. The selenious acid was reduced by the anaerobic bacillus, the bacteria continued to grow and were colored red by selenium.

These results induced Klett[7] to investigate further and he found that the reduction took place within the protoplasm of the bacterial cell, and not, as might be thought, through the indirect effects of the metabolic products outside of the cell body. Tellurium in this respect acts in the same way but weaker. This shows that selenium, even highly concentrated, is not a protoplasmic poison, but acts by its oxidizing power.

Rabuteau in 1869 describes as the symptoms of poisoning vomiting, profound weakness, watery, even bloody, stools, and death from paralysis of respiration with continued heart action. At the same time the breath smells of rotten horseradish.

Heinz[9] classifies selenium among the substances which paralyze the vasomotor center. He also emphasized its great similarity to the action of arsenic.

As special symptoms he mentions decreased blood pressure, irregularity of respiration, dyspnea, weakening of the reflexes, and sopor. The decreased blood pressure is due to the paralysis of the vasoconstrictor apparatus of the splanchnic area. The kidneys never show any pathological changes.

Before we enter on the indications for selenium we would point out a peculiar property. In spite of the similarity of the oxidizing energy between arsenic and selenium, arsenic acts more readily on combinations of members of its own family as nitrogen and phosphorus; selenium, on the other hand, oxidizes more readily members of its family such as sulphur. From this we derive the indications for arsenic and for selenium.

Aside from the frequent usage of selenium in homeopathic practice for 80 years, it has been sporadically recommended in scientific medicine for external local use. In very old books of recipes we find a salve containing 7 per cent. of precipitated selenium, recommended for prurigo, pruritus, and eczema. This dates from a time when every oxidizing substance was recommended for use in such salves. We see from this that selenium, for decades, has also been empirically classed with the oxidizing remedies having local effect.

The chemical anomalies of carcinomatous metabolism, and the physiological studies quoted above, made the use of selenium in carcinoma a logical sequence.

The three elements arsenic, vanadium, and selenium stand out most prominently, when we want to bring about a powerful oxidation in the organism. These three elements stand in a certain sense in direct opposition to copper, iron, and manganese. The latter, including vanadium, facilitate the transmission of oxygen from the outer world to the living cell. Arsenic, vanadium, and selenium increase within the living cell the exchange of the supplied oxygen for oxidation of carbon, hydrogen, and sulphur.

As far as the oxidation of carbon and hydrogen is concerned, arsenic and vanadium are undoubtedly superior to selenium. To be sure one could use selenium in all those cases in which arsenic and vanadium have given good results, but it would seem irrational to substitute the weaker for the stronger and more certain substances.

As soon as we are concerned with the problem of enforcing the oxidation in the sulphur metabolism, arsenic and vanadium must unconditionally give place to selenium. Arsenic and vanadium never have the faculty of entering combinations parallel to sulphur, and of oxidizing sulphur to a higher stage within these combinations.

In olden times auripigment ($As_2 S_3$) was a popular symptomatic remedy for cancer. Vanadium preparations are now advertised for local use. But why use such substances when we have in selenium to a certain extent a specific?

The specific indications in carcinoma are the following: The urine is of low specific gravity, has a high content of sodium chloride, a low amount of ozidized sulphur, a high amount of insufficiently oxidized sulphur; there is also a constant loss of body weight. The latter observation shows us that the oxidation of the non-sulphur containing substances is so high that a deficit results. A reduction is therefore indicated in the total oxidation, while there should be an increase in the oxidation of the sulphur metabolism.

The specific gravity in the presence of the high content of sodium chloride shows that the excretion through the skin is reduced and a correspondingly increased excretion takes place through the kidneys. This is expressed in the pale gray anemic skin of the carcinomatous patients.

Permit me here to make a short digression. It must have come to the notice of one or the other among those present that the sulphur group contains sulphur, selenium, and tellurium, and that tellurium up to a certain degree can also increase oxidation. In my previous discussion I omitted to mention tellurium, for the reason that I wished to emphasize the fact that tellurium has no future as a carcinoma remedy, because, as shown by the experiments of Gies,[10] it further depresses the excretory function of the skin.

Arsenic would have the same unfavorable action on the function of the skin. The removal of the sulphur, fully oxidized in the urine, the increase of the body weight, the prevention of further diversion of the cutaneous secretion to the kidneys, can be brought about only by the use of selenium.

The theoretical proofs for this action of selenium have already been shown in the pharmacotoxicological part of this paper, and need not be repeated here. That these deductions are correct can be seen by the histories of the carcinomatous patients successfully treated with selenium.[12] The details need not be mentioned here.

For the practical use of selenium we have to consider selenium preparations which are easily soluble, not toxic, and which can be effectively carried by the blood stream to the carcinomatous tissue. We are acquainted with quite a number of old effective remedies for carcinoma, for example hydrogen peroxide, pyoktannin, etc., but it was never possible to bring these substances in contact with every carcinomatous cell, particularly not with the peripheral extensions.

The selenium preparations do not easily lose their effectiveness as oxidizing agents. Once within the body they constantly move between the higher and lower stages of oxidation, between selenic acid and selenieted hydrogen or at least selenious acid. In this way they constantly regenerate their oxidizing power. The selection of useful selenium preparations is for that reason a very wide one.

Administration and Dosage.—I have used selenium dioxide, sodium selenio-cyanate, potassium selenio-cyanate, and potassium selenio-eosine, and see no reason why in individual cases the proper preparations should not be selected.[12]

The selenio-eosine used by Wassermann[11] is so slightly toxic that a single dose, large enough for therapeutic dose in man, was given to a mouse, without causing death. The selenium cyanates and other preparations are about seventy times as poisonous. However, no advantage is gained through this relative innocuousness for practical therapy, as the deaths of mice in Wassermann's experiments were due to the too rapid absorption of the products of decomposition of the carcinoma. Therefore it seems that, if we use a preparation of which very large quantities can be given intravenously, we do not gain anything, on account of this too rapid absorption.

The administration of small quantities, often repeated and long continued, seems to be the best method. The selenio-cyanate serves best and will no doubt remain also for the future the preparation to be recommended. It is easily soluble in the body, readily absorbed, and enters with ease into every cell. These qualities are due to the close relationship with a substance that is widely distributed throughout the entire body, and occurs in the saliva principally, namely, sulphocyanic acid. The only difference is that here selenium has taken the place of sulphur. Later on perhaps the selenates will also be used.

The dosage of these preparations is best started with 1 milligram, three times a day. A dose of 4 milligrams three times a day has so far not been exceeded.

The eosine derivatives of Wassermann should be given in doses four times that amount.

The preparations can be given in the form of pills, solutions, or capsules.

The treatment as regards both the oxidation of the sulphur metabolism and the special effects of the selenium on the keratin bodies is best controlled by an exact quantitive analysis of the urine. This should be done about once in five weeks. It will also indicate whether the dose of selenium should be increased or perhaps be interrupted for a week or ten days.

So far the indication for the use of selenium is in inoperable cases of carcinoma or inoperable metastases and relapses after operations.

Later on, no doubt, the indication will be extended to the after-treatment of every case of cancer operated on. Likewise, in an operable cancer the field of operation will be reduced as soon as we know that the remaining cancer can be made innocuous by the selenium treatment.

THE TREATMENT OF DISEASES OF VEGETABLE PARASITIC ORIGIN BY DEEP MUSCULAR INJECTIONS OF MERCURIC SUCCINIMIDE.

REPORTING SIX CASES OF PNEUMONIA AND SIX CASES OF GONORRHEAL ARTHRITIS.

By BARTON LISLE WRIGHT, M.D.,

SURGEON, UNITED STATES NAVY.

In a paper* which appeared in the Medical Record December 2, 1911, I advanced the theory that *for every vegetable organism mercury is the chemical affinity*, expressed by chemical formula as follows: (Vegetable antigen + Hg) + antibody = complement = complement fixation (cure). In support of this theory I reported twenty-six cases, divided as follows: One case of acute miliary tuberculosis of pulmonary type, two cases of pulmonary tuber-

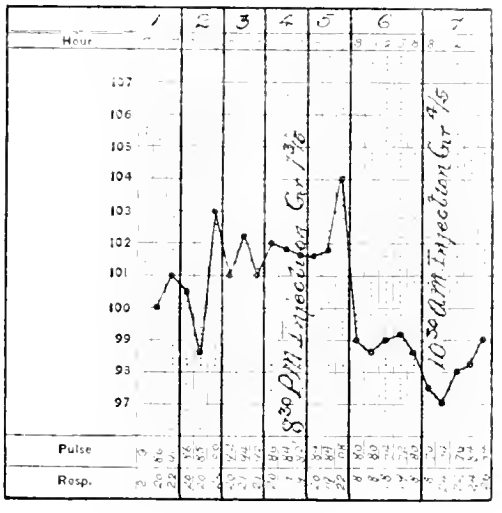

Chart 1.

culosis, one case of bronchopneumonia, three cases of typhoid fever, and the following cases of staphylococcic origin: five cases of epidemic catarrh, ten cases of follicular tonsillitis, one case of cystitis, one of cellulitis, one of chronic otitis media, and four cases of furunculosis, practically all of which, excepting the tuberculous cases were aborted by one or two injections, while the results obtained in the tuberculous cases were equally as brilliant, considering the disease. It is to be noted also that these twenty-six cases were treated in the sick bay of a battleship, most of the time at sea, when the ventilation was poor and the dietary restricted to canned soups, evaporated cream, malted milk, etc., minus the comforts and attention to be obtained in the home or hospital ashore.

Since writing the former paper I have treated three cases of croupous pneumonia, one case of bronchopneumonia and six cases of gonorrheal arthritis. With these, through the kindness of Dr. L. V. Dawson, of Odessa, Missouri, it is my privilege to report one case of bronchopneumonia and one case of croupous pneumonia treated by him according to the theory advanced. All these cases resulted in such brilliant cures that I feel justified in the hope and belief that it is strongly probable that my theory is correct. I formerly stated that "0.091 gram (1 2-5 grains) of mercuric succinimide is the most satisfactory dose for the average adult male patient," but later experience leads me to modify this statement, in so far as that under certain circumstances a larger dose is desirable, these circumstances embracing severe infection and profound toxemia. In one instance I have injected 0.117 gram (1 4-5 grains), and would have no hesitancy in injecting 0.130 gram (2 grains) should the severity of the disease or profoundness of the toxemia indicate the necessity.

Broncho Pneumonia (Lobular Pneumonia).

Case XXVII. ——, age 19. Admitted in the morning of January 12, 1912; diagnosis: Acute follicular tonsillitis, associated with slight bronchitis. The lungs were carefully examined, but at this time were negative for other signs than those of bronchitis. The patient was put in bed, magnesium sulphate 30 grams (one ounce) was administered. Solution silver nitrate (15 per cent.) applied to tonsils twice daily, Dobell's solution gargle every hour, and acetphenetidin, salol, and quinine 0.130 gram (2 grains) every two hours prescribed. His throat lesions gradually improved, on the fourth day of the disease the tonsils were healed, but the cough worse, on the fifth day, January 13, cough much worse and severe pain in left lower lobe—physical signs of pneumonia negative. At 7 P. M. the temperature suddenly rose to 104°, pulse 108, respiration 22 (see chart No. 1), and physical examination revealed scattered areas of consolidation throughout the left lower lobe. At 8:30 P. M. an injection of mercuric succinimide 0.104 gram (1 3-5 grains) was given; within an hour the crisis began and was completed by 11 A. M. the following day. On this day (January 14) the sputum contained large numbers of pneumococci. Convalescence was established and continued without interruption. On January 17th resolution was complete and he was discharged to duty on January 20th. Crisis took place in this case probably on the second day of the disease.

Case XXVIII.—Case of Doctor Dawson: Girl, four years of age, developed whooping-cough on December 18, 1911. January 4, 1912, bronchopneumonia developed, the entire area of both lungs being involved; temperature 104.6°, plus 140, respiration 57. The usual treatment with an abundance of fresh air was begun and continued until January 12, the child failing progressively. On this date the patient was in a profound stupor, the morning temperature being 102.6°, pulse 140, respiration 65; at noon an injection of mercuric succinimide 0.026 gram (2-5 grain) was given. By 5 P. M. the respiration had fallen from 65 to 33. On the following morning the crisis was complete; temperature 97.6°, pulse 132, respiration 30. A second injection of 0.026 gram (2-5 grain) was given on the 15th, the child made a rapid recovery, and on January 21 was playing about the house as usual.

*"The Treatment of Tuberculosis and Other Diseases of Vegetable Parasitic Origin by Deep Muscular Injections of Mercuric Succinimide. A Theory and the Results of Its Application in Twenty-six Cases."

These two cases of bronchopneumonia with the case reported in my previous paper make three presenting the extremely rare termination of this disease by crisis, which in each case followed immediately after the administration of the initial injection. They also present an extremely early termi-

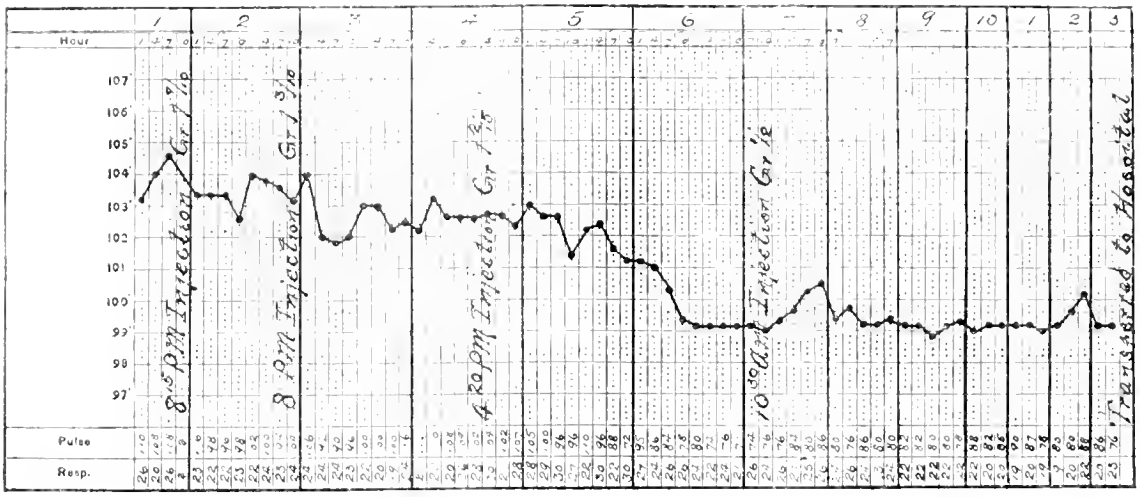

Chart 2.

nation, one on the second, one on the fourth, and one on the eighth day of the disease.

Croupous (Lobar) Pneumonia.

Case XXX ——, age 18 years. Admitted January 20, 1912. Patient presented himself as having had a chill in the early morning, severe pain in lower left lobe, with troublesome cough and expectoration. Physical examination revealed consolidation of entire lower left lobe, with prolonged expiration throughout the major portion of the right lung and left apex. Bed. Magnesium sulphate 30 gram (an ounce). At 1 P. M., temperature 103.2°, pulse 110, respiration 26, sputum positive for pneumococci, negative for tubercle bacilli. Urine normal. Blood presented the following: Total white count 10,800, polys. 55 per cent., small lymph. 17½ per cent., large lymph. 8 per cent., transitional 5½ per cent., mast 3½ per cent., eosinoph.

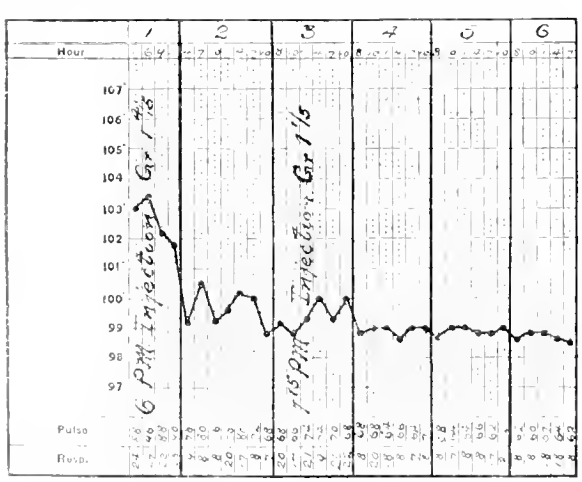

Chart 3.

2 per cent., large mononuclears 7 per cent. Diagnosis: Lobar pneumonia involving entire lower left lobe complicating pulmonary tuberculosis (semilatent). At 8 P. M., an injection of mercuric succinimide 0.110 gram (1 7-10 grains). January 21, all symptoms improved, sputum characteristic, rusty and frothy, containing numerous pneumococci, no blood examination made; severe pain in lower left lobe had disappeared. 8 P. M., mercuric succinimide 0.084 gram (1.3 grains.)

January 22. Further improvement in all symptoms, blood examination as follows: Total white count 13,000, polys. 72 per cent., small lymph. 12 per cent., large lymph. 5 per cent., trans. 5 per cent., mast 1 per cent., large mono. 4 per cent. The marked improvement on this date is well shown by the reduction in the total white count by 6,800 cells and the increase in the polys. from 55 per cent. to 72 per cent. No injection given on this date.

January 23. Patient worse, all symptoms increased (see chart No. 2). Blood examination as follows: Total white count 10,200. No differential made. It is to be noted that the white count was increased by 3,200. At 4:20 P. M., an injection of mercuric succinimide 0.091 gram (1 2-5 grains) was made. January 24. Marked improvement in all symptoms. Blood: Total white count 11,400, polys. 75 per cent., small lymph. 10 per cent., large lymph. 4 per cent., mast 2 per cent., trans. 5 per cent., eosin. 1 per cent. The improvement in symptoms following the injection is well sustained by the blood count; a reduction of total white count by 4,800. At 3:20 P. M., an injection of mercuric succinimide 0.065 gram (1 grain) was given; at 4 P. M., a slow crisis began.

January 25. Pneumonic crisis complete by 1 P. M. (see chart). The symptoms which followed this date were entirely due to the patient's tuberculous involvement. Blood: Total white count 9,800, polys. 72 per cent., small lymph. 14 per cent., large lymph. 4 per cent.

January 26. 10:30 A.M., injection mercuric succinimide 0.032 gram (½ grain). No further injections were given in order that the drug might be eliminated. January 26, patient quite comfortable. Blood: Total white count, 8,400. January 31, 4:30 P.M., fluid in left pleura; 8:15 P.M., 740 c.c. of serum removed by aspiration. Examination of this serum showed lymphocytes largely predominating. On February 1 he was transferred to hospital, Chelsea, Mass., for further treatment in relation to the tuberculous involvement. This case in itself shows the marked beneficial and curative action of mercury in the two infections present, and even under these bad conditions the pneumonic crisis occurred as early as the fifth day.

Case XXXI.—Admitted February 3, 1912. Age, 23 years. Complaint: Severe pain in right and left lower lobes, troublesome cough and expectoration. Temperature 103°, pulse 88, respiration 24. Physical examination revealed early consolidation of right and left lower lobes. Sputum characteristic containing numerous pneumococci. At 6 P.M., temperature 103.5°, pulse 96, respiration 27. Diagnosis: lobar pneumonia, involving right and left lower lobes. 6:15 P.M., an injection of mercuric succinimide 0.117 gram (1¾ grain) was given and the crisis began within an hour. At 8 P.M., blood examination as follows: Hemoglobin 90 per cent., total white count 10,800, polys. 60 per cent., small lymph. 20 per cent., large lymph. 6 per cent., trans. 6 per cent., eosinoph. 2 per cent., bas. 1 per cent., large mono. 4 per cent. February 4: Patient feels well; 10 A.M., temperature 99.3°, pulse 70, respiration 18. The slight temperature registered this day was considered to be due either to an endotoxemia or to mercurialism, but there was not the slightest evidence of salivation. Blood: Hemoglobin 85 per cent., total white count 8,000, polys. 72¼ per cent., small lymph. 15 per cent., large lymph. 5 per cent., trans. 3 per cent., eosinoph. 1 per cent., basoph. 1 per cent., large mono. 2 per cent.

February 5: 8 A.M., temperature 99.2°, pulse 68, respiration 20, consolidated areas undergoing resolution rapidly; 1.15 P.M., injection mercuric succinimide, 0.078 gram (1⅕ grain), given as a precautionary measure; 7:30 P.M., mercurialism, in the form of a severe gingivitis, developed. February 6: temperature remains about the same; a potassium chlorate mouth-wash was prescribed, the slight temperature evidently being due to mercurialism. Blood: Hemoglobin 95 per cent., reds 6,312,000, total white count 6,000, polys. 70⅛ per cent., small lymph. 12 per cent., large lymph. 3 per cent., trans. 2½ per cent., eosinoph. 1 per cent., basoph. 1 per cent., large mono. 3⅛ per cent. From this time on convalescence was uneventful, his lungs being entirely clear on February 10. For temperature, pulse, and respiration curves see chart No. 3.

Case XXXII. ——, admitted March 4, 1912.

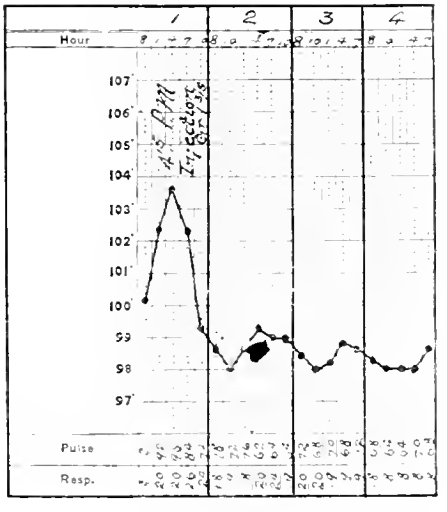

Chart 4

Complaint: severe pain in both right and left lower lobes, cough and expectoration. Temperature 100.2°; owing to the noise made by workmen repairing the ship a physical examination was impossible. Magnesium sulphate 30 gram (one ounce) was given at 1 P.M. Temperature 102.4°, pulse 92, respiration 20, sputum characteristically rusty and frothy, containing numerous pneumococci; 4 P.M., physical examination revealed consolidation of the left lower lobe, and the preconsolidation stage of the right lower lobe; 4.15 P.M., injection mercuric succinimide 0.104 gram (1⅗ grain), crisis began within an hour; 5.30 P.M., blood examination as follows: Hemoglobin 85 per cent., total white count 11,200, polys. 74 per cent., small lymph. 10 per cent., large lymph. 4 per cent., eosinoph. ½ per cent., trans. 2 per cent., basoph. ½ per cent., large mono. 2½ per cent.; 10 P.M., crisis almost complete, temperature 99.2°, pulse 72, respiration 18. March 5, 8:30 A.M.: Convalescence established; temperature 98.6°, pulse 78, respiration 18. Blood: Hemoglobin 95 per cent., total white count 8,600, polys. 71 per cent., small lymph. 17 per cent., large lymph. 6 per cent., trans. 2½ per cent., eosinoph. ½ per cent., basoph. ½ per cent., large mono. 2 per cent. Convalescence was uneventful, resolution of the involved areas being complete on March 11.

Attention is invited to the fact that in the two foregoing cases crisis began in each case about eight hours after the onset of the disease, immediately following the initial injection, a record, I believe, unparalleled in the history of the disease.

Case XXXIII.—Case of Dr. Dawson. —— (woman), age 25 years, married. Onset 12 noon, January 26, 1912. Chill lasting about two hours. 6 P.M. developed severe pain in lower right lobe, troublesome cough and expectoration. First seen by Dr. Dawson at 7:30 A.M. January 27, 1912, patient had not slept during night; temperature 103.2°, pulse 122, respiration 42. Severe headache and pain in lower right lobe, troublesome cough and bloody sputum. Physical signs of consolidation lower right lobe.

Fresh air treatment combined with the usual supportive measures was instituted at once and continued until January 31, the patient growing worse; the patient did not sleep, extreme nervous symptoms had developed, respirations were extremely shallow, temperature had reached 104.5°, pulse 132, respirations 51.

At 9 A.M. January 31, temperature 103.6°, pulse 166, respirations 42. At 10:45 A.M. a consultant saw the patient with Dr. Dawson and at this time an injection of mercuric succinimide 0.065 gram (1 grain) was given. Crisis began shortly after the injection. At 5 P.M. temperature 100°, pulse 90, respirations 32, and the patient was feeling very much better.

February 1, 9 A.M., convalescence, temperature 98.4°, pulse 90, respirations 30. From this time recovery was rapid. Out of bed February 6 and resumed her household duties on February 10.

Gonorrheal Arthritis.

Cases XXXIV to XXXIX (six cases) inclusive. All being cases of typical gonorrheal arthritis, one in which both shoulder joints were involved, two in which both knee joints were involved, one in which right hip joint was involved, one in which right shoulder and left ankle joints were involved, one in which the right wrist was involved.

Two of them had been under treatment in hospital or on board another ship. All had received previous local and general treatment without permanent relief. The first three each received two injections of 0.091 gram (1⅖ grains) and 0.052 gram (⅘ grain) with a day intervening. All symptoms disappeared immediately and have not returned. The remaining three received one injec-

tion of 0.091 gram (1⅖ grains) in the latter part of February, 1912. All symptoms immediately disappeared, and so far have not returned, results most gratifying to the patients as well as to me.

U. S. S.S. Georgia.

THE RESULTS OF RENAL DECAPSULATION FOR CHRONIC NEPHRITIS.*

By SAMUEL LLOYD, M.D.,

New York.

When it is remembered that the number of deaths from chronic nephritis in the City of New York alone approximates 7,000 annually, any procedure that offers hope of decreasing this number is worthy of careful consideration.

It is difficult to find any two authorities who thoroughly agree in their classification of the varieties of chronic nephritis; parenchymatous nephritis, or inflammation of the secreting structures—the tubules and the glomerules—of the kidney, and interstitial nephritis, or inflammation of the renal connective tissue form the basic pathological entities upon which all agree. Confusion results because neither of these conditions ever exists absolutely by itself. The variations in degree in which parenchymatous and interstitial nephritis are associated are almost infinite, and explain the great variety of classifications.

Edebohls, in outlining the work he had done in decapsulation of the kidney, suggested the following, and this has been followed in my work:

1. Interstitial nephritis includes those cases in which the gross evidence of inflammation of the connective tissue predominates.

2. Parenchymatous nephritis includes those cases in which involvement of the secretory apparatus predominates.

3. Diffuse nephritis includes those in which both the parenchyma and the connective tissue are involved in fairly equal degree.

The diagnosis of these varieties of chronic nephritis in the living kidney, when exposed at operation, is easy after some experience, pathological changes being more readily appreciated then than they are after death. The adherent capsule, nodulation, granular condition of the subcapsular surface, shrinking, unequal contraction, and occasional cyst formation of chronic interstitial nephritis; the enlargement, cloudy swelling, mottling, and discolorations due to circulatory and degenerative changes of chronic parenchymatous nephritis; the thickening, general or localized, of the capsule proper of the kidney, and the secondary inflammatory changes in the perirenal fat, common to both varieties of chronic nephritis, are readily recognized. The variations in density and hardness of the kidney, occurring widely in different parts of the same organ, are easily appreciated. Brewer (*Am. Jour. Med. Sci.*, May, 1908) says that while he has never seen a cure result from decapsulation in chronic non-febrile nephritis, he has observed marked improvement in two instances. In the second, the change after operation was so striking and so prompt, and presented such a marked contrast to the progressive deterioration of health before operation while under medical treatment, that it convinced him that in this case at least the operation had been of decided benefit to the patient.

The nephritis in any given case may be unilateral. Weir found this so in 17 per cent. of his cases, and Edebohls found eight cases where both kidneys were exposed at operation in which one organ was healthy and the other diseased. In seven other cases only one kidney was operated upon, and four of these patients remained well for periods varying from five to fourteen years. I have had the same experience, finding a nephritis on one side only at operation, and several times have found the disease present at the time of operation upon one side, and yet all symptoms have disappeared without touching the other kidney. Other observers have noted this condition so often that recently in cases of chronic nephritis coming under my observation I have advocated catheterization of the ureters and examination of the urine from each kidney separately in order to determine whether one or both kidneys were involved. In cases where we have not been able to make this preliminary examination of the urine from each kidney separately, it is advisable, in my opinion, to follow out the practice that Dr. Edebohls and I adopted in all of our previous experience—of always decapsulating the other kidney when a nephritis is found on one side, without any local apparent reason for the change, for it is reasonable to suppose that occasionally a systemic cause may act primarily on one kidney and the other become involved later on.

It is, of course, thoroughly understood that I do not advocate operation in any cases of nephritis not already *in extremis*, in which the most careful hygienic and dietetic measures have not already been thoroughly tried. I recognize the fact that chronic nephritis, under intelligent medical care, may be arrested for a long time, and perhaps a few patients taken early enough, may be even clinically cured; but all cases that are steadily progressing, in spite of rational medical treatment, should be given the benefit of operation. When we speak of cure, in connection with nephritis, we must of course be understood to mean clinically cured; we recognize the fact that sclerotic and degenerative tissues cannot be returned to the normal by either medical or surgical measures. As Porter has said, "The lesions of Bright's disease can never be cured to the eye of a pathologist and histologist, but to the physiologist and clinician the cure of the disease in a physiological sense is both possible and probable."

Tyson (*N. Y. Med. Jour.*, July 8, 1911), after reporting four cases that had been operated upon without cure, said: "I claim that the operation is so serviceable in certain instances that it ought to be done more frequently. The conditions which demand it are not far to seek or difficult to recognize. They are simply these: Stubborn persistence of symptoms, causing great inconvenience or danger to life, such as permanently obstinate dropsy which refuses to yield to ordinary treatment thoroughly carried out; uremia, manifested by convulsions or other unmistakable signs, such as intense headache, anuria, and large albuminuria, resulting in anemia and loss of function and strength; obstinate hematuria, perinephritis with miliary abscesses, hydronephrosis, and pyonephrosis.

Miller (*Am. Jour. Med. Sci.*, Sept., 1911, p. 360) says that in the majority of cases of recovery the physiological cure was complete in form thirty to forty days. This does not correspond with either Edebohls' or my own experience. Edebohls said that some who are either unable or unwilling to believe in surgical treatment for chronic Bright's disease have explained the immediate good effects

*Read before the Medical Society of the County of New York, April, 1912.

of renal decapsulation—the return of color and of strength, the disappearance of dropsy, headaches, backaches, digestive and circulatory disturbances, the improvement in the condition and action of the heart and cerebrospinal centers—undeniable and striking as they are—to the rest in bed for three weeks subsequent to the operation. The fact is ignored or overlooked that many of these patients had already spent months, and in a number of instances even the greater part of a year, in bed without experiencing the slightest improvement. The changes in the patient's condition and general health after the decapsulation, on the contrary, are nearly always impressive, and in some instances simply marvellous. The improvement, moreover, is progressive, continuing and increasing even after the patient has left his bed and resumed his place and work in life. The cure of chronic nephritis is only started by renal decapsulation, and the element of time is essential to obtain the full advantages of the operation. In some patients the health of the kidneys is restored in a few months after operation; while in others the same result is reached only after a period of three years.

My own experience bears out these statements. One of my patients, operated upon seven years ago, spent the night after the operation wandering about the hospital in a nephritic delirium. She then became comatose, with occasional convulsions during the next two weeks, and was not free from a trace of albumin and occasional casts until after a lapse of two years. She is, however, still living and well, and free from all signs of nephritis.

Another patient, who was operated upon November 19, 1908, was rapidly going down from interstitial nephritis. He did not show a clear urine report until last spring, and has but just fulfilled the requirements necessary to put him down as cured. His urine examination was practically normal for the first time May 25, 1911, and the urine report of December 5, 1911, was: Specific gravity, 1023; reaction, acid; albumin (heat, nitric acid, and Esbach's reagents), negative; sugar, negative; urea, 2.3 per cent, 397 grains in twenty-four hours; indican, normal. Microscopic examination: Casts, none; crystals, none; epithelium, occasional vesical cell; blood, none; pus, very occasional pus cell. There were a few microscopic threads and cylindroids present. It is thus seen that almost three years elapsed after the operation before the patient fulfilled Edebohls' rule with regard to the cure of his nephritis. This rule is: "The urine must remain free from albumin and casts, and the daily urea output be normal (or approximately so) for a period of at least six months following the verification of the disappearance of the albumin and casts, and the patient must be free from all the symptoms of chronic Bright's disease from which he or she formerly suffered."

It is therefore evident that these cases should have the most careful observation and medical treatment after they recover from the operation. The urine should be examined frequently, and the functional activities of the kidney be tested from time to time.

Following the decapsulation of kidneys in rabbits, in normal dogs, in dogs with induced nephritis, in dogs with infarcts of the kidneys, and in dogs with normal kidneys but with additional work thrown on them, Thorndike (*Boston Medical and Surgical Journal*) found that in all his cases of two days and under, and in controls, where the capsule was removed for over two-thirds of the surface, there was a certain amount of immediate increase in the size of the decapsulated kidney, persisting up to one month at least, and afterwards a decrease to approximately normal size which was complete at the end of six months. There was congestion, moderate in degree, most marked in the intertubular blood vessels in the cortex, lasting from three to five days after the operation. No histological change in the renal epithelium was noted, but a new capsule, very vascular at first and from two to four times the thickness of the old, was well marked at the end of eight days. The new capsule arises chiefly from the connective tissue cells in the intertubular connective tissue, but in part from the retroperitoneal connective tissue, which is present in the new bed of the kidney. No new vessels are formed which anastomose with those of the kidney. The increase in size is due, primarily, to the increase in blood supply, possibly resulting from the removal of the capsule. The evidence at hand proves that a new capsule forms within a few weeks after operation, but that the establishment of collateral circulation sufficient in degree materially to affect the renal tissue, may at present fairly be doubted.

Guiteras (MEDICAL RECORD, Feb. 10, 1906, p. 240) obtained reports from forty-two surgeons who had operated upon 120 cases. Of these, 16 per cent. were reported cured; 40 per cent. improved, and 11 per cent. unimproved; 33 per cent. died. In interstitial nephritis, the results appeared to be brilliant, as the casts and albumin disappeared, although the amount of solids excreted was not brought up to normal. The mortality in these cases, however, was 26 per cent.; in parenchymatous, 25 per cent.; in chronic diffuse, 75 per cent. Two and a half years later he asked for a report from these same surgeons—only one-half replied, reporting 40 cases, with 1 recovery, 3 improved, 3 unimproved, and 33 deaths, 82 per cent. He said, therefore, that it was evident that at that time capsulectomy was not a popular operation among the surgeons in the United States, while in Europe it had been thoroughly tried and had but few followers.

Tomaso Costa (*Giornale internazionale delle Scienze Mediche*, Nov. 15, 1906) considers that we may regard decapsulation of the kidneys as of the greatest value in most varieties of kidney diseases, acute as well as chronic. It is contraindicated in old age, cardiac disease, and albuminuric neuroretinitis which is the precursor of a fatal ending. He believes that the benefit is due to a new formation of the capsule which allows the tissue of the kidney—before bound down by the contracted capsule—to expand. New blood-vessels are formed with the new capsule. The epithelial elements are not regenerated, but the better nutrition makes them change within themselves so as better to perform their function. The hyperemia and polyuria which follow the operation aid in the absorption of morbid products within the kidney and render the urinary tubules permeable. He has produced an artificial nephritis in dogs by the injection of chlorohydrate of hydroxylamine which produces a nephritis very similar to that seen in the human race. Fifteen dogs were treated in this way; a part were then submitted to decapsulation or capsulotomy, while others were left untreated. Eight of those operated on were cured of the neph-

ritis, while those not operated upon died. The cure is more rapid in capsulectomy than in capsulotomy. After forty days the capsule is found reformed and thicker and more vascular than before. A unilateral operation by means of the renal reflex results in a cure of bilateral nephritis. This bears out Edebohls' experience and his claim that the kidney derives a new blood supply through the new capsule. In one of my cases of redecapsulation this was shown most markedly. When the thick capsule was cut away from the kidney innumerable small vessels were seen bleeding, both in the capsule and on the surfaces of the kidney. This fact has also been demonstrated by Larkin at the Laboratory of the College of Physicians and Surgeons.

Grande reports (*Revista de Medicina y Cirurgia*, 1908) 85 cases, 62 cures, and 32 deaths; but in his table, except Edebohls—who is credited with 51 cases, 37 cures, and 14 deaths—no one has more than five cases, many reporting but one or two. Such statistics are of little value in considering this operation. For operative experience must go hand in hand with the most careful after-treatment. This is the difficulty in trying to cull material from literature, as operators who have handled but one or two cases of nephritis cannot be expected to have the same results as those who have had a large number.

In Dr. Edebohls' last paper, which I read for him before the Surgical Section of the American Medical Association in Chicago, June 3, 1908—he reported 102 decapsulations of the kidneys for chronic Bright's disease; 50 of these patients were males and 52 females. The youngest was 4½ years, the oldest 67 years of age, the average being 30 years and 8 months. The majority of patients at and before the time of operation presented all or nearly all of the most serious well-known features of nephritis. Of these 102 patients, 10 died within two weeks following the operation; 30 died at times more or less remote from the operation; 3 disappeared from observation after leaving the hospital, and 50 are known to be living. In reality, however, as seven patients were operated upon twice, 109 operations were performed on one or both kidneys; one of these patients died after a second decapsulation. There were therefore eleven deaths in 109 renal decapsulations for chronic Bright's disease—an operative mortality of 10.1 per cent. In this paper Edebohls advised renal decapsulation for every sufferer from chronic Bright's disease who had a reasonable expectation of not less than a month of life without operation. The three conditions which led him to advise renal decapsulation were: First, the clear and unequivocal diagnosis of chronic Bright's disease; second, the absence in a given case of absolute contraindications to any operation; third, the possibility of securing the services of a surgeon practically familiar with the surgery of the kidney. As soon as nephritis has become chronic it is an absolute indication for decapsulation. The earlier in the course of chronic nephritis an operation is performed, the better will be the patient's chances of a perfect cure.

These cases of Dr. Edebohls' were tabulated up to May 31, 1909. From that time to the time of his death he operated upon six additional cases—one, decapsulation of the right kidney, the other kidney being done later by me; three, for chronic diffuse nephritis; (*a*) April, 1907, at the Post-Graduate Hospital. This patient had anasarca and made a very complete recovery. In a paper read before the Southern Surgical and Gynecological Association in Washington, D. C., December, 1911, and published in the *Southern Medical Journal*, April, 1912, I stated that this patient has since remained well and has been through a normal pregnancy without any appreciable kidney lesion. Since that time she has come to me in the eighth month of a pregnancy with very marked kidney symptoms. She was delivered at the end of the eighth month of a dead fetus and left the Post-Graduate Hospital on Friday, April 19, 1912, improved, but with a still active kidney lesion; (*b*) June 6, 1907. This patient was perfectly well at the time of the last report, October, 1911; (*c*) February 14, 1908; died, April 8, 1908; (*d*) one decapsulation of the right kidney for chronic diffuse nephritis, October 3, 1906, the other kidney having been previously removed. January 3, 1912, urine normal. One, November 6, 1907. Present condition, unknown.

In addition to these I have personally operated upon thirteen cases, and including these with Dr. Edebohls' last six, the nineteen cases show:

Improved, 5—31.8 per cent.; died within 2 weeks of operation, 2—10.5 per cent.; died later, unimproved, 2—10.5 per cent.; cured, 8—42 per cent.; unknown, 1—5.2 per cent.

Compared with Dr. Edebohls' statistics, this makes the operative mortality slightly more. In his 102 cases the immediate mortality was 10.1 per cent.; in this series it is 10.5 per cent., or for the whole 128 cases, a little over 10 per cent. This is very different from the mortality given by Dr. Miller, when he says that despite an immediate mortality of 30 per cent., and 44 per cent. remote (within a short period) it cannot be gainsaid that the results of operative treatment have been other than hopeful. In referring to the table it will be seen that our remote mortality in this last series of eighteen cases is, up to the present time, the same as the immediate mortality—10.5 per cent. This is a rather striking difference.

The mortality, however, will always remain high in this operation. The condition of many of these patients is such that it is surprising often that they do not die on the operating table.

It is not the mortality but the question of curability that is important. In Edebohls' 102 operative cases 33 were cured at the time of his report, while in these last 19 cases, 8 may be recorded as free from all clinical and urinary symptoms for six months or more. This makes 41 cured out of 128 patients, surely a good enough showing to make the operation well worth while.

12 West Fiftieth Street

TONSILLAR HEMORRHAGE, CAUSES, PREVENTION, AND TREATMENT.*

By GERHARD HUTCHISON COCKS, M.D.,

NEW YORK

ASSISTANT SURGEON MANHATTAN EYE, EAR AND THROAT HOSPITAL.

The daily performance of dozens of tonsil operations in the private office and hospital dispensary affords evidence that this operation is considered by many surgeons a trivial affair, with but slight risk to the patient. The object of this paper is to emphasize the dangers with which this practice is surrounded, in the hope that in the near future, in this city at least, patients subjected to tonsillar

*Paper read before the section on Laryngology and Rhinology of the New York Academy of Medicine, February 28, 1912.

surgery will be more carefully guarded against the possibility of post-operative bleeding.

A brief review of the literature shows a considerable number of fatalities from hemorrhage alone, not including deaths from shock, status lymphaticus, pneumonia, and other causes. Bardeleben[1] in 1875 reported two fatal cases. The first was observed by Beclard in Angers. A charlatan attempted to remove a tonsil with a bistoury. A fatal hemorrhage ensued, which autopsy demonstrated was caused by injury to the internal carotid artery. Bardeleben also reports that Champion was called to see a case where scarification of the tonsil had been attempted, and found the patient dead when he arrived at the scene of operation. No autopsy was permitted. The cause of death was supposed to be injury to the carotid artery. Downie[2] in 1880 reported a fatality from hemorrhage following tonsillotomy. W. E. Casselberry[3] in 1893 reported a fatality following abscission of the tonsil. Damianos and Hermann[4] in 1902 reported the case of a man twenty-three years old, operated in the Vienna Clinic for hypertrophied tonsils with Fahnestock's tonsillotome, who died sixteen days later from secondary anemia. Autopsy demonstrated an eroded vessel. Digital and instrumental compression, subcutaneous injections of gelatin, and ligation of the carotid artery failed to control the hemorrhage. Johnston[5] mentions the case of a bleeder, a boy seventeen years old, who died from hemorrhage two weeks after the application of a galvanocautery to the tonsil. Hurd[6] in 1910 reported a fatal hemorrhage in a child operated with a tonsillotome. A tonsillar clamp and ligation of the carotid failed to save the patient's life, death ensuing before transfusion could be performed. Harmon Smith[7] records six additional fatalities, as follows: Two deaths from hemorrhage after tonsillotomy in cases operated upon by Broca, one in a man twenty-five years old; the other in a male child eight and one-half years of age, who had an anomalous internal carotid artery which was wounded with the tonsillotome.

Holinger's report of a death from tonsillar hemorrhage occurring in the practice of a friend. Mackellar's report of a fatal case occurring in the practice of a colleague. Barkan's case of death after removal of a tonsil with a tonsillotome. J. V. Stucky's case, a male, fifteen years of age, a bleeder, who died from a continuous venous oozing.

Here we have a record of thirteen fatalities from tonsillar hemorrhage, two of the deaths occurring in the last eight years.

Dr. J. Wright[8] in 1890, from a search of the Surgeon-General's Library at Washington, reported a series of thirty-one alarming hemorrhages following tonsillotomy. Dr. Harmon Smith[7] in December, 1903, before this section, read a paper covering the years between 1890 and 1904, in which he reported twenty-four additional cases of severe post-operative bleeding. I have continued the search of the literature to date, beginning with January, 1904, and have found forty-four cases of alarming tonsillar hemorrhage, exclusive of one case of my own. To this number should be added the seven deaths from tonsillar hemorrhage, occurring previous to 1904, and not included in the series collected by Wright and Smith. This gives us a total of one hundred and seven cases of alarming post-operative tonsillar hemorrhage with thirteen deaths.

I have tabulated the cases of hemorrhage since 1904, using the same scheme as Wright and Smith, in order to bring the subject up to date. This table will be found at the end of the paper.

Of course, instances of many grave tonsillar hemorrhages and some cases of death from hemorrhage never reach print. The reports of alarming hemorrhages from Europe are not without interest. For example, Chiari[9] states: "Among six hundred tonsillotomies performed annually for a period of nine years he did not have a single death from hemorrhage. Yet there were twenty-seven cases of alarming bleeding, usually spurting arteries in the tonsillar pillar. The bleeding was sometimes stopped by ice, sometimes by the glavanocautery, but most often by compression with the tonsil hemostat, which he never left in place longer than twelve hours."

Again, Burack[10] reports the occurrence of but three dangerous post-operative tonsillar hemorrhages in a series of over two thousand tonsil operations. These cases all recovered.

At the Manhattan Eye, Ear, andThroat Hospital between twenty-three and twenty-four hundred adenoid and tonsil operations are performed annually—an average of almost two hundred cases a month. The house surgeon of that institution who graduated at the beginning of the year told me his staff was called to the bedside to treat on an average of from eight to twelve cases of severe post-operative bleeding a month.

Many of these hemorrhages cease if a gauze pad, soaked in gallic and tannic acid solution is held on a sponge holder firmly against the tonsillar region for a few moments. In others it is necessary to insert two or three Michel sutures.

These statistics, compiled from various sources, are surely convincing proof that the tonsil operation is often attended with great danger to the health as well as the life of the patient, from the possibility of post-operative bleeding.

We shall now consider the etiological factors which tend to induce hemorrhage.

1. Age. Our statistics show that post-operative tonsillar hemorrhage is more frequent in adults than in children.

2. Sex. Alarming bleeding is more common in males than in females. Of thirty-one cases in one series where the sex was mentioned, twenty occurred in males. In Smith's report, among fifty-four cases only eight were women.

3. Anemia is a frequent cause of bleeding, and should always be looked for. The writer has noticed that flabby, pale children at the age of puberty are especially apt to bleed profusely.

4. Menstruation and pregnancy are two conditions which especially predispose to post-operative bleeding. Marschik and Otto J. Stein each report cases of alarming hemorrhage occurring in menstruating women. One of these patients also suffered from nephritis. (See table.)

5. Arteriosclerosis and nephritis naturally predispose to hemorrhage. It must be remembered, in this connection, that the former condition sometimes occurs in young adults. The writer has seen two advanced cases of arteriosclerosis in young adults in the third decade, one in a man and the other in a young woman.

6. Fibroid tonsils, if operated upon, are more likely to be followed by severe hemorrhage than the simple hypertrophied variety. Their fibroid tissue interferes with the contraction of the arterioles.

7. Acute inflammation of the tonsils is a contraindication to operation until several weeks after the

TABLE OF CASES OF SEVERE TONSILLAR HEMORRHAGE REPORTED FROM 1904 TO JAN 1, 1912.

Reported By	Patient's Age	Sex	Disease	Instruments Used	Result	References and Remarks	Methods Used for Control of Hemorrhage
L. Katz					Recovery	Monat. für Ohren. 1904, No. 11, p. 496	Compression with Miculicz clamp

Johnston	17	Male		Tonsil cauterized with galvano cautery	Fatal	Rev. Heb. de Laryngologie, 1906, p. 545.	
Gerhard H. Cocks	Adult	Male	Fibroid tonsils	Snare	Recovery	Profuse bleeding from right side 1 hr. after operation	Miculicz hemostat, under extremely unfavorable surroundings, tenement house, poor light, no assistant
J. C. Henks	16	Male	Fibrous tonsils	Tonsillotome	Recovery	Ann. Otol. Rhin. & Laryng., 1908, J. C. Henks, p. 505	Secondary hemorrhage day after operation; controlled by pressure with specially devised clips
Otto J. Stein	20	Female	Diseased	Knife and scissor dissection	Recovery	Laryngoscope, 1908, p. 387. Patient was later found to be in 2d day of menstrual period. Primary bleeding, persisting for several hours.	
G. Goldschmidt	12	Female			Recovery	Semon's Cent., 1909, p. 539	Secondary hemorrhage several hours after operation. Controlled by adrenalin
O. Wilkinson	Adult	Female	Diseased tonsils	Matthieu tonsillotome	Recovery	Jour. Am. Med. Assn., Aug., 1907, p. 497	Suture of anterior and posterior pillars over a cotton pad, placed in tonsillar fossa
O. Wilkinson	Adult	Female	Diseased tonsils		Recovery	Jour. Am. Med. Assn., Aug., 1907, p. 497	Severe secondary hemorrhage, adrenalin, styptics, styp. collodion, bleeding finally ceased spontaneously.
Bor[illegible]					Recovery	Semon's Cent., 1908, p. 539	Very profuse arterial hemorrhage from inner surface of anterior pillar, which finally ceased spontaneously when patient fainted.
L. Cohen	23	Female	Hypertrophy	Tonsils dissected out with knife and forceps	Recovery	Arch. f. Laryn. u. Rhin., 1909, p. 481. Local Anesthesia. Secondary hemorrhage, attributed to slough caused by Monsel's solution	Profuse bleeding, both sides at conclusion of operation, left side controlled with Monsel solution, right side with Boetcher's hemostat, secondary hemorrhage, right side on 9th, 10th, 12th days, finally controlled by suturing tonsillar pillars. Saline infusions
L. Cohen	36	Male		Tonsils and capsules dissected out with knife	Recovery	Arch. f. Laryn. u. Rhin., 1909, p. 481	Secondary hemorrhage from spurting vessel deep in right fossa, controlled by clamp and ligature, small vessels in supratonsillar fossa ligated
Hurd (Operated by Colleague)	Child			Tonsillotome. Patient almost dead when seen by Dr. Hurd.	Fatal	Laryngoscope, 1910, p. 674. Reported by Hurd	Clamp on tonsil, bleeding persisted, patient dying before transfusion could be given.
Waterman	20	Female		Tonsillotome	Recovery	Laryngoscope, 1910, p. 761. Reported by Waterman	Primary hemorrhage, also secondary hemorrhage 12 days after operation due to small spurting artery in tonsillar fossa, controlled by pressure with cotton applicator.
Lederman	Adult	Male	Hypertrophy	Galvanocautery snare	Recovery	Laryngoscope, 1910, p. 762, Lederman	Astringent saturated alum solution
Coffin					Recovery	Laryngoscope, 1910, p. 762, Coffin	Clamps to tonsil, bleeding several days suture of anterior and posterior pillars, ligation of carotid
Delavan	8	Female		Tonsillotome	Recovery	Laryngoscope, 1910, p. 766	Primary capillary oozing, recurring later with con. severity after swallowing; controlled by rectal feeding
Delavan	Middle aged	Male	Hypertrophy	Matthieu tonsillotome	Recovery	Laryngoscope, 1910, p. 766. Venous plexus outside of tonsil wounded	Primary bleeding, checked by holding ice in cavity
Delavan	25	Male		Mackenzie tonsillotome	Recovery	Laryngoscope, 1910, p. 766. Patient completely exsanguinated; secondary hemorrhage of several weeks duration	Cold, pressure, cautery, hemostatics. Patient finally fainted, and hemorrhage ceased
James E. Newcomb		Male		Mackenzie tonsillotome. Separation of pillars	Recovery	Personal experience with tonsillar hemorrhage, paper before Section on Laryngology, N. Y. Acad. Medicine, Jan., 1910	Secondary hemorrhage 4 hrs. after operation. Pressure over tonsil, fossa and adrenalin

TABLE OF CASES OF SEVERE TONSILLAR HEMORRHAGE REPORTED FROM 1904 TO 1910 — CONCLUDED

Reported By	Patient's Age.	Sex.	Disease	Incidents Used	Result	Reference and Remarks	Methods Used for Control of Hemorrhage
James E. Newcomb....	55	Male		Malignant tonsillotome; Pillars separated	Recovery	Personal experience with tonsillar hemorrhage; paper before section on Laryngology, N. Y. Acad. Medicine, Jan., 1910.	Adrenalin; local pressure
James E. Newcomb	Young adult	Male		Malignant tonsillotome; Pillars separated	Recovery	Personal experience with tonsillar hemorrhage; paper before section on Laryngology, N. Y. Acad. Medicine, Jan., 1910.	Secondary hemorrhage; quiet by patient vomiting
James E. Newcomb...	8	Male	Hypertrophy	Malignant tonsillotome; Pillars separated	Recovery	Personal experience with tonsillar hemorrhage; paper before section on Laryngology, N. Y. Acad. Medicine, Jan., 1910.	Adrenalin and local pressure sa line intravenously into leg
James E. Newcomb....	Child	Female		Malignant tonsillotome; Pillars separated	Recovery	Personal experience with tonsillar hemorrhage; paper before section on Laryngology, N. Y. Acad. Medicine, Jan., 1910.	Consid. primary bleeding; continued during night. Transfusion from mother's radial artery, ligation of carotid

subsidence of the inflammatory process. Moure[11] reports a case of hemorrhage after tonsillotomy, during active inflammation of the tonsils.

8. Acute infectious diseases sometimes cause tonsillar bleeding if the patient is operated upon just before the onset. F. E. Hopkins reports a case of severe bleeding on the first and second day after operation. The child developed measles on the third day.

9. Syphilis may be a cause of tonsillar bleeding. Operations on syphilitic tonsils should therefore be avoided.

10. Abnormalities in the distribution of the blood vessels supplying the tonsil are often accountable for tonsillar hemorrhage.

The normal blood supply of the tonsil is given as follows by G. Seccombe Hett,[12] whom I quote verbatim: "The vessels supplying the tonsils are the ascending palatine and tonsillar branches from the facial, the ascending pharyngeal from the external carotid, branches from the dorsalis linguæ from the lingual, the descending palatine from the internal maxillary. The branches from the facial are the largest, and enter the capsule after piercing the superior constrictor. They reach the capsule in its lower part, and running upwards, ramify on its outer surface. They then divide into branches which pass into the tonsil along the connective tissue septa, with the exception of some which pierce the capsule of the tonsil at once to supply the lower portion of the tonsil. The branch from the descending palatine pierces the upper part of the capsule and supplies the imbedded pars palatina and the posterior pillar. One or two branches of the dorsalis linguæ reach the lingual surface of the tonsil, and supply the anterior pillar, the plica triangularis, and the lingual prolongation."

E. Henking[13] states that the facial artery often has an abnormal position, and is therefore injured when operating. In Demme's[14] experience the lingual artery often occupies an abnormal position, and is consequently injured. Leffert[15] holds the same view in regard to the ascending pharyngeal artery. The wounding of the large venous plexus at the lower and outer border of the tonsil has been a cause of hemorrhage (Harmon Smith). We have already seen that an abnormally placed internal carotid artery may be the cause of injury and hemorrhage (Beclard's and Broca's cases).

11. Traumatism, especially injury of the tonsillar pillars and extratonsillar tissue (particularly the superior constrictor muscle), is naturally a prolific source of hemorrhage. This can only be remedied by care on the part of the operator. It seems to the writer that this factor is largely responsible for the increased proportion of hemorrhages after tonsillectomy as contrasted with the old-fashioned tonsillotomy.

12. The hemorrhagic diathesis and hemophilia are a much-discussed cause of post-operative bleeding. Damianos and Hermann[16] in 1902 wrote that they found in the literature of the last sixty years one hundred and fifty cases of severe tonsillar hemorrhage. They stated that the hemorrhagic diathesis could be considered the cause of the excessive bleeding in but seven of these one hundred and fifty patients. On the contrary, a careful inspection of the wound cavity in the majority of instances showed a spurting artery to be the cause of the hemorrhage.

While it is true that many hemorrhages, which depend upon purely local conditions, are wrongfully attributed to hemophilia, yet hemophilia is a subject which demands our earnest consideration.

For several years it has been customary to give lactate of calcium to prevent post-operative tonsillar hemorrhage, by some operators as a routine measure in all cases preceding operation; by others, both before operation and during active hemorrhage, by rectal or hypodermic injection. This procedure followed the published experiments of Sir A. E. Wright on the coagulability of the blood and the influence upon the same of the soluble salts of calcium.

Wright and Paramore[17] in 1905 published a series of experiments showing that the coagulability of the blood was markedly increased by the administration by mouth of sixty grains of calcium lactate: In observation 1, from 1 minute 50 seconds to 30 seconds; in observation 2, from 2 minutes to 40 seconds; in observation 3, from 1 minute 50 seconds to 22 seconds, etc. They also determined that the dosage necessary to be employed where it was desired to maintain a permanently high level of blood coagulability was fifteen grains of calcium lactate three times a day.

On the other hand, Dr. J. Addis,[18] after a most exhaustive series of experiments, says, "While the amount of ionizable calcium in the blood may be increased by dosing with calcium salts and lessened by giving citric acid, yet the increase or decrease so induced, even when large doses are given, is considerably less than that required to alter the blood's coagulability." He says the erroneous statements

formerly published are due to faulty technique. In the first place, in Wright's coagulometer, the arrangements for maintaining a constant temperature are not satisfactory. Addis found that slight variations in temperature caused considerable variation in the rate of coagulation. Wright's second error, to quote Addis, "is in taking the first appearance of fibrin, on blowing the blood from Wright's capillary tube, as an indication of coagulation. The appearance of fibrin is a phenomenon which is due to the chance concomitance of external physical conditions, and one which bears no relation to the coagulation of the blood as a whole." Addis found that the average coagulation time is seven and one-half minutes in a healthy man. A case where the coagulation time was recently tested for me by Dr. Strong, pathologist of the Manhattan Eye, Ear, and Throat Hospital, showed coagulability four and one-half minutes to five minutes before injection of calcium lactate; five minutes to five and one-half minutes after taking fifteen grains t.i.d. for two days.

At any rate, the administration of calcium lactate does no harm, and may perfectly well be employed, if so desired, in doses of fifteen grains t.i.d. for twenty-four hours preceding operation for adults, and in five to ten-grain doses for children. Although we can no longer expect to increase the coagulability of the blood by giving the soluble salts of calcium, fortunately another remedy has come to us which offers much more both in preventing hemorrhage and in the treatment of active bleeding. I allude to fresh blood serum and transfusion. Weil (quoted by Moss and Gelien[19]) states "that the hereditary and spontaneous forms of hemophilia can be differentiated in origin, severity of clinical observations, character of the blood, and the mode of coagulation. The faulty coagulation in the hereditary form is referred to the presence in the blood of anticoagulants; in the sporadic form, to the absence of substances normally present and essential to coagulation."

Weil recommends as a cure for the sporadic type of hemophilia, and as the best agent for treating hereditary hemophilia, subcutaneous injections of 30 c.c. or intravenous injections of 15 c.c. of fresh human or animal serum. Moss and Gelien[19] have collected a series of cases of hemophilia and the hemorrhagic diathesis successfully treated by serum and transfusion. A few of these are here reported.

1. Thrombur's case of hemophilia successfully treated by injections of sheep and rabbit serum.

2. Welsh cured two cases of hemorrhage in the new-born by fresh human serum. He used 10 c.c. doses, averaging about 80 c.c. in four days.

3. Schwartz and Ottenberg transfused a child eleven days old suffering from melena.

4. Mosenthal cured a case of melena neonatorum by transfusion.

5. Moss and Gelien stopped severe intestinal hemorrhages in a case of typhoid fever by normal horse serum injected intravenously.

6. Clement F. Theisen[20] reports several cases of hemorrhage treated with serum in conjunction with local measures: (*a*) Boy six years old, post-operative tonsillar hemorrhage, treated by pressure and serum (diphtheria antitoxin); (*b*) man, forty-four years old, streptococcus infection of throat; excessive bleeding following incision of edematous tissue relieved by 20 c.c. antistreptoccus serum; (*c*) nasal hemorrhage in a woman fifty years of age relieved by injection of 10 c.c. normal horse serum.

7. At the present time the writer has under observation at the Manhattan Hospital, in Dr. Chappell's service, a case of hemophilia which he has treated by injections of blood serum and transfusion. This case will be reported in detail elsewhere by Dr. W. F. Chappell.

Moss and Gelien prefer fresh rabbit serum, and consider it slightly, if at all, toxic for the human being. They point out that if horse serum is used one should first make sure that the patient has not been previously sensitized by an injection of diphtheria antitoxin on some former occasion. They prefer the intravenous method to the subcutaneous, and state that none but fresh serum, prepared immediately before use, should be used.

What may we do to prevent hemorrhage in our tonsil operations?

In the first place, the tonsil operation is essentially a hospital operation. The patient should be regularly admitted to a hospital (unless the same facilities, including the services of a trained nurse) are obtainable at the patient's home. The heart, lungs, kidneys and arteries should be examined before operation. If indicated, the blood pressure should be estimated. The temperature is taken just beforehand, and operation deferred if it registers over 101° F. in the rectum. A history of hemophilia should naturally be inquired for, and the surgeon should take care not to operate during early pregnancy or during the menstrual period. If hemophilia is suspected, and the operation imperative, the coagulation time of the blood should be raised to the normal by injecting blood serum before operation. Of course, in a large clinic where many of the patients do not speak English, we are obliged to take our chances in regard to hemophilia. Barnes[21] says "Three places in the sinus tonsillaris are especially prone to bleed after tonsillectomy, viz., the anterior and posterior pillars at their lower halves and the base between the pillars." Barnes says "The reason for this is that the larger vessels from the surrounding tissues enter the tonsil at its lower segment." These structures should be handled carefully.

The sucking of ice directly after operation, as well as gargling with ice water or other liquids, increases the bleeding and should be prohibited.

The application of ice cloths to the face at the conclusion of adenoid and tonsil operations does much to arrest the ordinary bleeding attendant upon these operations. The face is slapped vigorously with a towel wrung out in ice water. This method was first introduced a number of years ago by Dr. W. F. Chappell, and is now used as a routine measure in the Manhattan Hospital operating room. I think it does much to promote clotting and prevent post-operative hemorrhage.

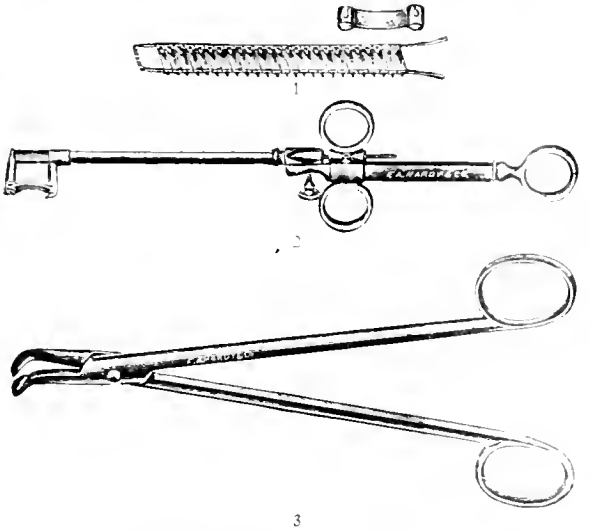
In considering the local treatment of post-operative tonsillar hemorrhage I shall mention only those methods I believe most useful.

When called to see a patient bleeding after a tonsil operation, under good illumination the tongue is depressed and the anterior pillar pulled aside so as to expose the whole raw area. If a bleeding spot or vessel can be made out it should be clamped with a long artery clamp and ligated, if possible. If we are called to a house or flat where there is very little light or assistance the best we can do is to insert a Mikuliez or Hurd tonsillar hemostat, an instrument which once played me a good turn under exactly these conditions. The tonsillar hemostat should not be left in place longer than a few

hours, at most twelve, as a slough may result, leaving an opening from the skin through into the pharynx.

In the hospital, if no bleeding vessel can be seen, pressure with a sponge on a sponge-holder saturated with gallic and tannic acid for a few minutes, may stop the hemorrhage. If this measure fails the tonsillar pillars should immediately be sutured with Michel's metal clamps. These clamps have proven very satisfactory in my hands. I believe they will replace all other local measures for the control of severe post-operative tonsillar bleeding. Before the sutures are inserted a small gauze pad, saturated with gallic and tannic acid, or covered with powdered thrombokinase (Strong[22]) should first be placed in the tonsillar fossa. If the metal sutures are used they should be removed in twelve hours.

If the hemorrhage persists after the proper application of the metal sutures we are probably dealing with a hemophile, and blood serum should be promptly used, or transfusion carried out, and the carotid artery ligated. Either the external carotid may be ligated, or, if there is urgent need of haste, the common carotid may be tied. Jackson[24] ligates



3

Wagener-Michel Metal Tonsillar Clamps.
1. Clamps for suturing.
2. Suture clamping instrument.
3. Clamp remover

the external carotid, and has performed this operation to arrest tonsillar hemorrhage seven times.

Henking[25] in 1905 stated that ligation of the common carotid on account of uncontrollable hemorrhage from tonsillotomy has been practised seven times by Guntner, Hada Siden, Sands, Fuller, Arbuthnot, Lane, Walker J. Downie and Mosetig-Moorhof. In the first five cases cited the hemorrhage definitely ceased after ligation, and the patients recovered, although two were apparently hemophiles (Guntner's and Fuller's cases). One of the two cases that died (Mosetig-Moorhof's) died of sepsis, sixteen days after the operation. In the other case that died (Downie's), Henking could not ascertain the cause of death, as he did not have access to the original reference.

In all these cases the common carotid was tied, apparently because it is more easily and quickly reached than the external carotid. In none of these seven cases did the ligation of the common carotid have any unfavorable influence upon the brain function.

ON THE IDENTITY OF TYPHUS FEVER AND BRILL'S DISEASE.*

By N. E. BRILL, A.M., M.D.,

NEW YORK,

PROFESSOR OF CLINICAL MEDICINE IN THE COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA UNIVERSITY OF NEW YORK.

The widely adopted conclusions of Drs. Anderson and Goldberger[1] that their experimental work has proven the identity of the disease which was described by me as "an acute infectious disease of unknown origin" with typhus fever has induced me to present what seems to me to be serious objections to these conclusions. I do this with the view of directing the attention of medical men to the fact that these conclusions may have been too hastily adopted.

Perhaps it will be wise to recapitulate the experimental facts which induced these well-known and exceptionally able investigators to arrive at their judgment. Briefly they are as follows: Monkeys when inoculated with the blood of a human typhus fever patient develop after a few days a type of temperature quite similar in its course and decline with the fever of the human patient. Blood from a monkey thus inoculated will produce, when introduced into a second monkey, a similar type of fever and so on through successive serial inoculations.

A monkey thus successfully inoculated is immune to subsequent inoculations with typhus blood.

Monkeys inoculated with virulent blood from a patient with Brill's disease develop in a few days

*May I be pardoned for using the name which has been so generally given to this infectious disease? I prefer to speak of this syndrome as an acute infectious disease of unknown origin until its causative agent and identity are conclusively established, and have here not consulted my preference in order to save labor to the writer and printer.

a fever similar in course to that in monkeys inoculated with *Mexican* typhus fever. The blood of such monkeys when drawn at the height of the fever and inoculated into other monkeys will produce a similar type of temperature and so on through successive generations. Such inoculated monkeys are immune to subsequent inoculations with virulent blood from a case of Brill's disease.

Monkeys inoculated with blood of Brill's disease are immune to inoculation with Mexican typhus blood and, *vice versa*, monkeys inoculated with Mexican typhus are immune to subsequent inoculation with Brill's disease.

The natural conclusions of Drs. Anderson and Goldberger from these premises is: First, that there is an immunity conferred by each disease against the other; second, therefore the two diseases are identical. It is the second part of this conclusion which, I think, we are, in the present state of knowledge, not justified in accepting. If Drs. Anderson and Goldberger had gone no further than to say that they had proved a definite relationship between these diseases to be established, no issue could have been taken with their conclusions. But there is a great difference between kinship and identity of disease.

We are justified in saying that there is a relationship between typhoid fever and paratyphoid fever. Nobody claims that they are identical, because they differ clinically and the organisms which are the respective etiological factors productive of the respective diseases, while related organisms, show biological and cultural differences sufficient to differentiate them.

The clinical pictures due to infection with these related organisms, the course of the diseases induced by them, and the epidemiological factors, have very much in common, yet differ in many respects. In fact, before we had any knowledge of the history of the organisms which produced these diseases, typhoid and paratyphoid fever were not differentiated but existed in the minds of medical men only as typhoid fever. We all accept them now as separate, *related but not identical* infections.

I have selected these related diseases because the recent work of Metchnikoff and Besredka[2] in their studies of vaccination against typhoid fever have discomfited our attitude toward the question of specificity of immunity. It has previously been held that immunity against a disease could be established by such specific disease and by no other. Naturally with this in view, Drs. Anderson and Goldberger were within the realm of logical defense in concluding as to the identity of Brill's disease and Mexican typhus fever, because they had established that an immunity exists between Mexican typhus fever and Brill's disease, therefore on account of this immunity they affirmed that the two diseases were identical.

Metchnikoff and Besredka[3] have proved, however, that chimpanzees immunized against paratyphoid fever are immune to typhoid fever inoculation. In the light of the masterful experimental results of these brilliant investigations, are we justified in concluding that on account of the immunity of chimpanzees so inoculated typhoid fever and paratyphoid fever are identical? The same reasoning will apply with equal force to Brill's disease and Mexican typhus fever. In fact, the clinical and epidemiological differences, often referred to in my previous contributions to the subject,[4] are even greater between Brill's disease and Mexican typhus than between typhoid and paratyphoid fever and would in themselves cause a hesitancy in concluding that these two diseases were identical. In view therefore of this recent work of Metchnikoff, I think it would be wise to reserve judgment, and not hastily conclude that Brill's disease and Mexican typhus fever are *identical* diseases.

Clinically and empirically we have an analogous condition in vaccinia and variola, as they occur in man. While it is possible that vaccinia is a variola modified by bovine transmission, or what is even more remote if possible, that variola is a vaccinia modified by human transmission, nobody believes that these two infections are identical. Yet inoculation with vaccinia immunizes the individual against variola.

Further, no conclusive proof has yet been offered which proves the *identity* of *European* typhus and Brill's disease.

Personally I believe that European typhus fever, Mexican typhus fever, and Brill's disease are related fevers which subsequent development along the line of acquisition of knowledge as to their infective agents will alone clear up. It is premature to speak conclusively about the identity of diseases with such marked differences as typhus fever and Brill's disease before anything is definitely known about their causative agents.

THE DIAGNOSTIC USE OF GONOCOCCUS VACCINE FOR GONORRHEAL INFECTIONS.

By EUGENE H. EISING, M.D.,

NEW YORK,

ADJUNCT SURGEON, MOUNT SINAI HOSPITAL; CHIEF OF CLINIC, GENITO-URINARY OUT-PATIENT DEPARTMENT, MOUNT SINAI HOSPITAL.

The recent publication of "A Cutaneous Reaction in Gonococcal Infections" by Dr. Ernest E. Irons of Chicago (*Journ. Am. Med. Assoc.*, March 30, 1912) has, no doubt, stimulated many others to explore this diagnostic field. As Irons mentions, Bruck (*Deutsche med. Woch.*, 1909 xxxv, 470), and Reiter (*Zeit. f. Geburt. u. Kind.*, 1911, lxviii, 471), besides himself, have noted a cutaneous reaction following the injection of gonococcus vaccine in individuals suffering from a gonorrheal infection. Bruck noted this reaction in epididymitis and Reiter in pelvic infections in women.

Much credit is due to Irons in attempting to generalize from these observations and to employ these facts for diagnostic purposes. Unfortunately in Irons' short article he fails to describe in detail the method he employs. Irons says, "I have found that a well-defined cutaneous reaction, similar to the cutaneous tubercular reaction, occurs in cases of gonococcal infection, when the extract is introduced into the skin by the method of von Pirquet." The method of von Pirquet is a method of scarification

and is epidermal. Notwithstanding this fact Irons speaks of the control showing "only the point of needle puncture." It is, therefore, difficult to understand just what method Irons has employed. Neither is it stated what "extract" he has used in his work.

The appearance of Irons' article suggested to me to try out the value of gonococcus vaccine as a diagnostic measure, using it epidermally, intradermally, and subdermally. My first cases were all done in the genitourinary department of the Dispensary of Mount Sinai Hospital in which I used a vaccine of the strength 1 c.c. = 100,000,000, prepared by Dr. Bernstein of the Pathological Department. It soon became apparent that the intradermal injection was followed by a much more pronounced reaction than either the epidermal or the subdermal. In fact the epidermal inoculation was followed by no reaction whatsoever, except the marks of scarification, and the subdermal usually by a diffuse redness. The intradermal on the other hand, with great regularity, was followed by a distinct red papule at the site of injection often surrounded by a diffuse red areola. The papule measures about 3 to 5 mm. in diameter and is slightly tender. The areola when it appears measures from 5 to 10 mm. Using normal salt solution as a control, no reaction occurs, demonstrating that the reaction is not due to mechanical effects. The injection is made within the skin layers and a small bleb should appear immediately. The observations of the papule were all made from 12 to 24 hours after inoculation. The papule endures for a variable period and vanishes within a week.

Through the courtesy of Dr. Frauenthal, a small series of cases was tried at the Hospital for Deformities and Joint Diseases upon a number of cases of chronic inflammatory joint conditions. In this series Mulford's mixed polyvalent gonococcus vaccine was employed. The tests upon these cases were of no value owing to the fact that large erythematous and edematous areas followed the use of this mixed vaccine, and the papule was less characteristic. Subsequently Mulford's pure gonococcus vaccine was used in the cases at the end of my series with the result that the characteristic papule appeared.

The series herewith appended, including 30 cases, has agreed strikingly with the clinical and bacteriological findings.

30	Prostatitis	Not found	Doubtful	"

Although three cases out of a series of 19 which are clinically gonorrheal, react doubtfully to the intradermal injection, the test as a whole is more than significant and warrants further study. It is likely that the reactions stated as doubtful should be read as positive, and that their less characteristic papule is due to a non homologous strain of organism.

Cases 1 and 3, which both act positively to the cutaneous reaction, were also tested by means of the complement fixation test for gonorrhea, through the kindness of Dr. Kaliski and react positively also to that test. These two cases are of special interest, the one being an arthritis and the other an epididymitis in individuals who denied all possible gonorrheal contagion.

If further study bears out the value of this reaction, it will place in the hands of the practitioner a ready means of determining the nature of many an obscure lesion.

THE ABUSE OF THE EDGE.

By DOUGLAS H. STEWART, M.D.,

NEW YORK.

As a type of edged tools let us take the surgeon's scalpel. This is a fine instrument only adapted for subdermic and soft tissues. But it is often used upon leathery skin, tough periosteum, or hard bone; not to mention such acts of vandalism as sharpening lead pencils, erasing ink spots, or cutting string.

Now if an edge is dull or broken it is simply unfitted for the purpose for which it was devised, and an expensive tool is, more or less, completely ruined. I have had made for me by the Betz Co. some knives which are termed generally "scalpel savers," because their sphere is the one which is inappropriate, and consequently damaging, to the delicate cutting edge of the "scalpel."

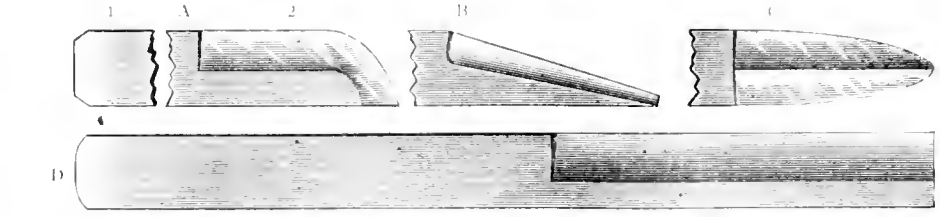
They are inexpensive and very durable. They are bigger, stronger, and heavier than the scalpel and will take a razor edge. They may be of any desired shape, but two models out of many will show the principle. They are strip steel; and if an edge is nicked or broken grind a new one. The most useful edges are straight lines, since these may be easily sharpened by a nurse, an orderly, or a boy. Take a piece of wood 9 inches long, 3/4 in. wide, and 3/16 in. thick. Now with a knife shape any kind of knife you choose. Imagine the wood to be well tempered strip steel; then, for instance, let us make a bone and periosteum knife, or a skin knife, as shown in the illustration. By blunting the point of the skin knife on an ordinary stone, e.g. a window sill, an excellent cervix knife is made. Much handier to use than a scalpel. The edge is made at such an angle that the hand of the operator is raised from the skin or does not come in contact with the vaginal wall. You can thus have the field in sight at all times as you can look under or over the hand, and the absence of shadow on one's work is desirable.

One may do anything with a scalpel saver (peel potatoes, open bundles) and with a few minutes and a good oil stone restore the edge to a first-class condition. I have one on my desk shaped like a double ink-eraser (see illustration C) at one end and with a hole through the other. It has been much and roughly used but appears quite right. This shape was planned for the operating room of

a hospital and it is always handy hanging on the wall. Far be it from me to accuse any nurse of anything, especially if she be very efficient and capable, with red hair and temper to match; but I cannot understand how it is that scissors and knives are all in so much sharper condition since that scalpel saver hung on the wall. It must be just a "happen so."

The point that I wish to emphasize is that you can have your "scalpels" sharp and can keep them so with little trouble if you use them with ordinary care and for grosser purposes employ a "scalpel saver."

78 West Eighty-sixth Street.



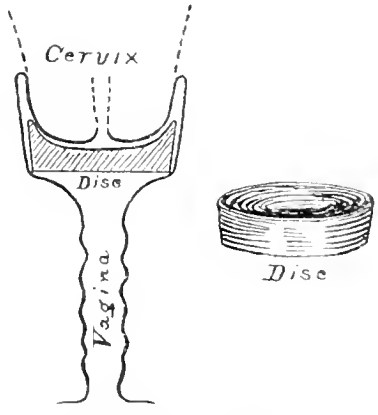
A, all around knife, bone, skin, etc. B, skin or cervix; C, desk or operating room knife; D, Thiersch's razor knife.

THE USE OF MEDICATED SUPPOSITORIES FOR VAGINAL APPLICATION.

By GEO. W. KOSMAK, M.D.,

NEW YORK.

The employment of various drugs to influence vaginal or pelvic inflammatory conditions constitutes an important part of gynecological office practice. The usual measures include the application of ichthyol and its derivatives combined with glycerin, in the forms of saturated tampons which are introduced with the aid of a bivalve speculum. There is no doubt that the depleting effect of the glycerin, particularly on various types of pelvic inflammation, is a very beneficial one, but particularly where this agent is combined with ichthyol the patients are very apt to complain of the usually profuse and annoying discharges that ordinarily accompany this form of treatment. With the idea of overcoming these objections, so-called vaginal suppositories have been devised of which the basis consists of boroglyceride, impregnated with a variety of astringent, sedative, or antiseptic substances. These are usually made in the form of a cylinder with rounded ends, or occasionally as flat disks. The shortcomings of these types of suppository must be evident to any one who has tried to use them, as it is a very difficult matter to apply them to the vaginal vault, even where they are partially retained in position by cotton tampons. One of the most ridiculous features in connection with the employment of these suppositories is their application by the patient herself, who is often directed by her physician to introduce one just within the ostium vaginæ on retiring, and as a consequence the supposedly beneficial effects are exerted in the perineal portion of the posterior vaginal wall. In order to be effective such suppositories ought to be kept in contact with the vaginal vault for a period of at least four or five hours, and this can only be done by adapting their shape to the region in question and by making them of such a size and consistence that they will dissolve slowly. If prepared in the form of a disk about three-eighths of an inch in thickness, slightly concave on one surface to admit the cervix, they can be readily enough introduced with the aid of a speculum, and after being placed against the cervix may be held there by one or two non-absorbent cotton tampons. If they melt slowly their medicinal effect is properly exerted in the region where it is required, and if the patient is directed to remove the tampons at the expiration of say, twenty-four hours, this will not be as disagreeable as with the use of the ordinary glycerin and ichthyol tampons. The accompanying sketch will aid in explaining the writer's suggestions, and it is to be hoped that some manufacturer will take up the matter and produce these articles for a practical trial by the profession.



Vaginal disc in position; it should be retained with a cotton tampon in the vagina.

The Preponderating Rôle of Perversions of Instinct in Mental Maladies.—M. Berillon divides all human instincts into four orders: instincts of nutrition, of conservation, of sociability, and of reproduction. All mental maladies result from derangements of these instincts. If one of these instincts is disarranged there results a loss of mental equilibrium. An obstacle to the satisfaction of an instinct causes a profound effect on the intelligence and sensibility. In any psychopath one should endeavor to find out the most marked imperfection in the realization of the instincts. The abnormal way in which he goes about the satisfaction of the instincts shows the psychopathic predisposition of an individual. There is an exaggeration or a lessening of these instincts; changes in nutritional instincts cause anorexia and sitophobia, gluttony, voracity and bulimia. Abnormalities of conservation cause impulsion to suicide, or anxiety and hypochondriasis. They may also cause parsimoniousness or prodigality. The social instinct when perverted causes sanguinary brutality or absurd sentimentalism. That of reproduction causes erotomania, heterosexual jealousy, or homosexual degradation. Among neuropaths, however serious be their functional troubles, the instinctive dispositions preserve their normal tendencies. There are no alterations or perversions of instincts. This is the means of differential diagnosis between psychopathies and neuropathies.—*Gazette des Hôpitaux.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

New York, June 1, 1912.

VITAL RESISTANCE OF PATIENTS.

With the great strides made in the technique of surgery in the last two decades there has developed an unfortunate tendency among many surgeons to look upon the surgical condition they are called upon to treat as something quite apart from the individual to be treated. Such surgeons examine the region of the appendix in a case of appendicitis, for instance, but do not look over the lungs or heart of the individual before advising immediate operation; still others are always ready to urge operation for a simple inguinal hernia, for a varicocele, for a chronic gastric ulcer, without considering whether the operation may not be a much graver source of danger than the morbid condition itself. However, there has recently developed the opposite tendency, which strives to counteract the unbounded enthusiasm of the technician for an immediate surgical interference, a tendency to study the patient as well as his disease, to consider the factors of safety present in the individual under consideration, and to take all possible means of increasing the chance of recovery from the operation itself as well as from the disease.

In a paper by Dr. Joseph C. Bloodgood, which embodies this tendency to a striking degree, in the May number of *Annals of Surgery*, the author insists upon the necessity of estimating the vital resistance of each patient, with the exception of those, of course, in whom no choice can be made because of the urgency of symptoms. He thinks that in the pre-operative interval physical rest must be obtained, the function of the kidneys ascertained, blood pressure recorded, and food and stimulants modified in kind and quantity to suit the individual's needs. Of equal importance is mental tranquillity and this must be obtained by natural allusions to the operation as simply a part of the general therapeutic procedure; in some cases the knowledge of its urgency should even be kept from such patients as may be thought to become too much frightened by the coming ordeal. Rest, then, physical and mental, fresh air, restricted diet, moderate catharsis, increased water, restriction or complete elimination of alcohol and tobacco are the pre-operative measures that conserve or increase the vital resistance of the operation.

During operation, anesthesia is the main item. Bloodgood speaks against trusting anesthesia to anybody but a physician; he thinks that the anesthesist should be a senior, not a junior, member of the resident staff and should be skilful in the latest anesthetic technique. In the author's experience nitrous oxide and oxygen anesthesia is the best for all purposes, while the additional use of a local anesthetic to "block" the nerves adds a great deal to the prevention of postoperative shock. Blood pressure estimations during the operation tell the condition of the patient and approach of danger better and earlier than the pulse and respiration, and a rapid and marked drop in pressure is to Bloodgood a sign that saline infusion is immediately needed. Such infusion, too, should be administered to a patient *before* he leaves the operating room if collapse in the early hours after operation is apprehended. In postoperative treatment, Bloodgood advocates salt solution by the continuous method of Murphy in all cases, so that the kidney functions may be started early; morphine in small doses to allay restlessness and pain; careful watch and early treatment of any complications, such as dilatation of the stomach, excessive distention of the abdomen, acidosis, etc. Recovery from the operation and the condition operated for should be followed by watching the patient for the development of any nervous complications, and in this the family physician and the surgeon should cooperate.

Bloodgood's paper, cursorily sketched above, is a welcome one, for it is evidence of progress in the attitude of the surgeon toward the patient, of progress that cannot but reflect further credit upon the well deserving art of surgery as practised in America.

THE POLYMORPHIC CHARACTER OF PAROTITIS.

As long ago as 1817 the close relationship between pancreatitis and mumps was pointed out by Schmackpeffer. This association has been readily explained on the basis of the histological and functional similarities between the salivary glands and the pancreas. During epidemics of mumps there have been recognized cases in which the infection of the pancreas was the initial and even the sole manifestation of the constitutional invasion. In fact some observers have regarded this invasion of the pancreas as the efficient cause of epidemic jaundice, in this case the swollen head of the pancreas producing icterus by pressing upon or excluding the common bile duct. According to Egdahl, in the etiology of pancreatitis mumps comes next in frequency to gallstones and duodenitis, and accounts for at least 10 per cent. of the cases of the former condition.

One year ago during an epidemic of parotitis in the city of Vienna, E. Freund (*Wiener medizinische Wochenschrift*, 1911, No. 49) observed eight cases presenting the following clinical picture: On the third or fourth day of the attack, after the swelling in the parotid had reached its maximum, there occurred severe abdominal pain accompanied by vomiting, constipation, and anorexia. The temperature remained normal or was slightly elevated. There was tenderness in the epigastrium about midway between the umbilicus and the ensiform cartilage.

and extending toward the left hypochondrium. In one case there was noticed a distinct tumefaction in this region. These manifestations continued for from three to eight days. In one case the epigastric pain preceded by two days the appearance of the parotid swelling. In none of the eight cases were there any evidences of disturbed pancreatic function, as revealed by examination of the urine and feces; nevertheless the localization of symptoms in the upper abdomen, occurring during an attack of parotitis, apparently justified the diagnosis of pancreatitis. The absence of any indications of pancreatic insufficiency was attributed to the fact that the affection of the pancreas was a transitory one and did not necessarily involve the entire organ.

It has been recognized for a long time that parotitis may be preceded, accompanied, or followed by manifestations in many other organs of the body, which manifestations have been regarded either as metastases or as complications. Of these the chief one is orchitis, which occurs almost exclusively in the adult, and which according to statistics gathered by Comby was present in 30 per cent. of 690 cases of parotitis in the French army. Less frequently parotitis in the female is accompanied by inflammation of an ovary. Other glands occasionally, though rarely affected, are the lacrymal, thyroid, and thymus. Among the numerous complications that have been observed during the course of parotitis are urethritis, otitis, inflammations of various parts of the visual apparatus, nephritis, endocarditis, pericarditis, peritonitis, arthritis, and, not least important, inflammatory lesions of the brain and meninges. These lesions are largely of the nature of a meningoencephalitis and give rise to restlessness, delirium, mania, and convulsions, or to various forms of ataxia. According to Cautley a mild type of meningoencephalitis is not a rare complication of parotitis.

The meningeal complications of parotitis are discussed in a comprehensive paper on this subject by H. Zade (*Archiv für Kinderheilkunde*, March 19, 1912). According to this observer one is not warranted in assigning a casual connection between parotitis and a secondary meningitis; nor in the absence of any knowledge as to the nature of the infective organism, is one warranted in comparing this meningitis to that which complicates typhoid fever, pneumonia, etc. He believes that parotitis at least acts as a predisposing cause exposing the meninges to secondary infection. The text of the author's remarks was furnished by the case of a twelve-year-old boy whose illness was ushered in with pain in the right iliac region, vomiting, chills, and sore throat. On the second day there were a relatively slow pulse and symptoms of ileus. Two days later the development of a parotid swelling suggested that the earlier symptoms were all intestinal manifestations of the mumps infection. But upon the subsidence of the glandular swelling the bradycardia continued, the headache became more intense, and other symptoms of increased intracranial pressure developed. In ten days these symptoms disappeared and complete recovery ensued. It is impossible from the history of this case to decide whether the condition was one of meningitis or of meningismus. Lumbar puncture was not performed and this omission made the diagnosis all the more obscure. According to Schottmüller a postparotitic meningitis should be regarded as a serous meningitis, with more or less of an accompanying encephalitis. In 1904 Chauffard and Boidin demonstrated at autopsy the presence of a meningoencephalitis in cases that had presented during life and following a parotitis the characteristic syndrome of bradycardia, fever, headache, and Kernig's sign, accompanied by an excess of lymphocytes in the blood and cerebrospinal fluid.

Within the past decade no work has been reported in confirmation of the results obtained by earlier investigators into the bacteriology of parotitis. In 1893 Laveran and Catrin described characteristic diplococci which they obtained from the parotid, from the edematous tissues of the face, from joint transudates, and from the blood, in cases of this disease. Bein and Michaelis in 1897 and Pick in 1902 reported a similar finding. Although these results await further confirmation there can be no doubt that parotitis is a sharply defined local infection by a specific organism which may, however, cause the most diverse and generalized manifestations, and which in extremely rare instances may even lead to a fatal outcome.

HOSPITAL SHIPS.

In the Spanish-American War hospital ships specially constructed or transformed for the purpose of receiving for care and treatment the sick and wounded of the navy and army were used for the first time. Their utility was practically demonstrated. Afterwards, in the Boer War and in the Russo-Japanese War the need of hospital ships was still further emphasized. At the present time it is freely acknowledged by naval authorities that hospital ships form an essential component part of a modern navy. As yet the ideal hospital ship has not been evolved, but as pointed out editorially in the *United States Naval Medical Bulletin* for April the utilization of vessels of this class is receiving increased attention abroad. British and German naval medical writers have been discussing the matter recently while the Italian Government has been putting the question to practical test in the war now proceeding between that country and Turkey.

Fleet Surg. D. I. P. McNabb, R. N., writing in the *Journal of the Royal Army Medical Corps*, Vol. 18, No. 2, on the functions of hospital ships, says that the ideal hospital ship should be a vessel of 3,000 to 4,000 tons with a speed of about 12 knots per hour and accommodation for some 240 patients in peace and 340 in war. It seems that in the main the views of McNabb are indorsed by the British Admiralty, as it is reported that a hospital ship is to be built and completed by June, 1913. The ship it is said will be of 5,000 tons displacement with accommodation for some 260 to 330 patients, and carrying specially equipped motor boats for their transfer. Turbines will be used and the speed will be limited to 12 or 14 knots to avoid vibration. A captain and crew will be drawn from the merchant service. Marine Oberstabsarzt Dr. zur Verth, writ-

ing in the *Marine-Rundschau*, July, 1911, says that the ideal hospital ship should be a vessel of 5,000 tons displacement, 124 meters long, 15.8 meters beam, with a coal capacity of 000 tons; such a vessel should be designed to accommodate 250 patients, with the addition of 20 beds for contagious cases. Verth is of the opinion that two vessels of approximately 250 beds each would be of greater value than a single ship of double the size. The plan pursued by the Japanese Government in so supervising the construction of certain merchant vessels as to render them well adapted to conversion into hospital transports is commended by the German writer. At the outbreak of hostilities between Italy and Turkey, the Italian Naval Department fitted up two emigrant steamers, the *Re d'Italia*, 3,802 tons, and the *Regina d'Italia*, 3,308 tons, as ambulance ships. In addition the Italian Red Cross Society equipped the merchant steamer *Memfi*. The Knights of Malta fitted up the *Regina Margherita*, 1,081 tons, under the same conditions as the Red Cross ship. The time required to transform the two first named ships into ships suitable for the reception of sick and wounded was about five days, the task being greatly facilitated by the utilization of the permanent beds already installed for emigrants. It was therefore only necessary to disinfect the ships, knock down some few bulkheads, and get the stores and personnel aboard. These vessels, however, are purely ambulance ships, used for transporting the sick and wounded from Tripolitania and Cyrenaica, to some of the large hospitals in southern Italy and Sicily, and were only intended to care for patients during the short time required to make the trip, that is from two to five days. In the *Revista Nautica*, February, 1912, Lieut. Commander N. Leonardi, Royal Italian Naval Reserve, gave an account of the operations of these vessels. The most interesting part of the description is that which states that with the arrangements followed it was found possible to take on board the wounded at the rate of one man per minute through each hatch. The Italian ships, however, are merely ambulance ships, and owing to the fact that Turkey possesses practically no navy there has been no need for hospital ships in the war. It appears likely that all the countries possessing navies will follow the example of Great Britain and build hospital ships.

Pathogenesis of Gonorrheal Rheumatism.

The pathogenesis of gonorrheal rheumatism was for long a subject for discussion. Finally, it was recognized that it was a morbid entity entirely distinct from ordinary rheumatism. Fournier was the first to formulate the proposition that gonorrhea was the necessary originating cause of this form of rheumatism. In *La Clinique*, Feb. 9, 1912, Georges Luys points out that age and sex have no great influence on the development of gonorrheal rheumatism, though men are somewhat more frequently attacked than women, and it is met with in about 2 per cent of rheumatic cases. The conclusion arrived at as a result of very numerous researches is that the gonococcus passes into the blood from the urethral mucosa, and once in the circulation, in tempestuous or cold weather localizes itself in one or in several articulations. The problem is to find out what the conditions are which favor the passage of the gonococcus into the circulatory system. Assuredly, gonorrheal rheumatism can develop as a sequence of any form of gonorrheal manifestations. Weiss and Klingelhoffer have reported a case of gonorrheal rheumatism in which the patient had never suffered from urethritis, and cases have been noted in which it followed a gonorrheal ophthalmia innocently acquired. But instances of this nature are, in the opinion of Luys, very rare, and in the vast majority of cases, gonorrheal rheumatism is developed in the course of urethritis caused by the gonococcus, and more especially when the inflammatory phenomena are located in the posterior part of the urethra.

Prevention of "Inevitable" Digital Gangrene.

Within a comparatively short time it has been shown in practice that almost inevitable gangrene of the fingers or toes may be averted by making an incision in the pulp of the digit to allow the escape of venous blood, and then applying aspiration with a suitable dry cup. Our recollection is that this resource was first practised in a nearly severed finger, which of course must have been accurately splinted to render the treatment available. At a recent meeting of the Kiel Medical Society (*Münchener medizinische Wochenschrift*, April 30) Koehler announced that the same plan of treatment had proved highly satisfactory in warding off gangrene from frozen toes. The patient had nominally frozen both his feet, but the two great toes and adjoinnig portions of the metatarsus were alone menaced by gangrene. These members showed every evidence of a freeze of the third degree. The skin was blue black, sensation was gone, needle puncture was not followed by bleeding. It had been decided to let the line of demarcation form, when the advice of Noesske to test the treatment already successful in the severed finger for all cases of threatened digital gangrene was recalled and at once carried out, with the result already stated above. Recovery was perfect from every viewpoint.

News of the Week.

Public Bath League.—As a result of the conference held recently in the City Hall, New York, the American Association for Hygiene and Public Baths has been organized with Dr. Simon Baruch of New York as president. The officers desire to enlist the interest of all concerned with hygiene and sanitation, including besides members of the medical profession, educators, lawyers, sanitary engineers, and city officials, with the object of providing a sufficiency of free sanitary baths for cleansing purposes. The formation of this association is more especially timely in New York because of the refusal of the Health Department to approve of the five sites for municipal floating baths in the Hudson River selected by the Commissioner of Public Works, since tests of the flow of the current of the river at the suggested sites had shown that the water discharged from the sewers flowed closely along the shore and would contaminate the baths. Whether any safe sites can be selected is doubtful, since as Dr. Baruch has aptly said: "Manhattan Island is a body of land entirely surrounded by sewage." Dr. George E. Soper, president of

the Metropolitan Sewage Commission, has also stated his strong objections to the floating baths as a menace to health. The questions of providing inland baths has thus been prominently brought forward and is at present under discussion by the city authorities. Dr. William H. Hale, secretary of the newly formed organization, and superintendent of public baths in Brooklyn, will probably represent New York at the International Conference on Public Baths to be held at Scheveningen, Holland, next August.

Graduates in Medicine.—Forty graduates received their medical degrees from the Medical Department of the University of Georgia at Augusta on May 16. The diplomas were bestowed by the Chancellor of the State University and the address to the graduates delivered by ex-Governor Slaton. The Medical Department of the Texas Christian University at Fort Worth gave diplomas to seventeen graduates in medicine on May 12.

New Hospital Cornerstone.—The cornerstone of the new German Hospital on Hudson Boulevard, Jersey City, N. J., was laid on May 19 by Mayor Wittpen in the presence of the Governor of the State and other distinguished persons. The hospital building will, it is estimated, cost about $18,000, exclusive of the $6,400 paid for the land.

Eclectics Protest.—The Arkansas Eclectic Medical Association, at the thirty-second annual convention in Little Rock, adopted a resolution protesting against the action of the Federal Registration Board of the United States reservation at Hot Springs, in excluding graduates of the eclectic schools of medicine from practice on the reservation.

To Fight Plague.—In submitting to Congress a special report on bubonic plague conditions on the Pacific Coast, the Secretary of the Treasury has appealed for an additional appropriation of $500,000 to be used in a crusade against the disease. The Public Health and Marine Hospital Service is expending its funds at the rate of $14,000 a month. Provided there are no new outbreaks, it is estimated that it will take four or five years to complete the task of eradicating the disease. No new cases have been found in Californian cities for some time, but the disease has been prevalent among the underground squirrels in the country and human cases have occurred in the rural districts each year. The eradication of the disease from these country districts is the problem at present confronting the Service. Money will also be needed to prevent yellow fever which now exists in several South American ports from making its appearance in the Southern States.

Swallowed 1,097 Articles.—An official report filed with the State Board of Control of California recently states that during an operation performed recently on a young woman of San Rafael, 1,097 articles, mostly metal, were removed from the patient's stomach. Among them were 108 wire hairpins, 55 open safety pins, 21 broken pins, 425 broken pieces of hairpins, 13 nails, and 40 tacks. The woman was said to be on the road to recovery.

American Hospital in Paris.—The United States Senate on May 21 passed a bill incorporating in the District of Columbia the American Hospital of Paris, the purpose of the corporation being to erect in or near Paris a hospital for the treatment of Americans traveling abroad

City Death Rate.—For the fifteenth consecutive week the death rate in New York this year has remained below that of 1911. For the week ending May 18 the rate was 14.75 with a total of 1,463 deaths, as compared with a rate of 16.27 and a total of 1,553 deaths for the same period of last year. For the first twenty weeks of this year the death rate has averaged 15.08 as compared with 17.04 for the same length of time in 1911.

Overdose of Elixir.—"Too much of a good thing" should be the epitaph of a Mr. Neumann of London, described as an herbalist, who, firm in the belief that he had discovered the elixir of life, died recently from the effects of an overdose. The elixir was based, it is said, on diluted phosphoric acid.

New York Police Surgeons.—Following an investigation, conducted during the last few weeks by Commissioner of Accounts Fosdick, of the surgeons of the New York Police Department, it is rumored that the Police Commissioner may order that hereafter the police surgeons abandon their private practices and devote themselves exclusively to their police practice. The surgeons now receive a salary of $3,500 a year, but one of their number, who considers his experience typical of all, declares that the police work nets him an average of seventy-three cents a call, and that without private practice it would be impossible to live. Mr. Fosdick's report intimated that he had found some of the surgeons rather derelict in their duties and made the more serious charge that the facts elicited led to the opinion that there had existed an organized effort to graft upon pension applications upon the part of unknown persons who seemed to have access to the records of the surgical bureau. In no case, however, was any such "grafting" traced, even by implication, to a police surgeon.

University of Pennsylvania.—Dr. David Riesman and Dr. Joseph Sailer have been elected professors of clinical medicine in the Medical Department of the University of Pennsylvania, in succession to the late Dr. John H. Musser. They will be in charge of the extramural teaching in the Philadelphia General Hospital, and will be aided by a number of associates. Under the new arrangement Dr. Alfred Stengel will be the head of the medical division, and Dr. J. Harold Austin and Dr. O. H. Perry Pepper, who will devote almost their entire time to hospital work, teaching, and medical research, will be his assistants. Dr. Richard M. Pearce occupies the John Herr Musser professorship of medical research.

German Poliklinik.—On May 17 the twenty-ninth anniversary of the German Poliklinik, New York, was celebrated at a dinner given by the Board of Trustees to the attending staff at the Café Boulevard. The president, Dr. Ludwig Weiss, acted as toastmaster, and discussed the past growth of the institution, while other speakers pointed out lines for future development. A vote of thanks was tendered to the Ladies' Auxiliary to whose able work much of the success of the institution was due.

Gifts to Charities.—By the will of the late Mrs. Cornelia Storrs of North Salem, N. Y., the New York Skin and Cancer Hospital receives a bequest of one-half of the residuary estate, which it is estimated will amount to about $25,000.

By the will of the late Mr. Frank J. Ransom of New York, the Roosevelt, St. Luke's, and New York hospitals share equally in the residuary estate, the amount of which is not given, while a trust fund of $50,000 created for the benefit of two of

the legatees, is to go on their deaths to the Society for the Relief of Crippled Children of New York.

By the will of the late Miss Lilla Gaitos of New York, the Lying-In Hospital receives $5,000, St. Rose's Home, $3,750, and the Home for Crippled Children in Philadelphia, $2,500.

Dr. George Dock has resigned the office of Dean in the Medical Department of Washington University, St. Louis, Mo. Dr. Dock will continue as professor of medicine in the school and will be able to devote more time to research work.

Harvard Medical Alumni.—The triennial meeting of the Harvard Medical Alumni Association was held in the Medical School on May 22, when an interesting series of papers and demonstrations arranged by Dr. H. C. Ernst and Dr. M. J. Rosenau was presented. The meeting was followed by the triennial dinner at the Hotel Somerset.

Dr. Harry T. Summersgill has been appointed superintendent of the New York Post-Graduate Medical School and Hospital, to succeed Dr. Frederic Brush, who resigned to take up the work of the new Burke Foundation. Dr. Summersgill has been in the employ of the Federal Government in the Panama Canal Zone, working under Col. William C. Gorgas.

Dr. Benjamin F. Beardsley of Hartford, Conn., has received the nomination for Governor of Connecticut by the Prohibition party.

Dr. Walter B. Jennings, for twelve years an attending physician at the Wilkes Dispensary of St. Mary's Free Hospital for Children, has resigned as chief of staff in that institution.

To Deport Insane Aliens.—At a conference held in New York recently by the representatives of the New York State Hospitals for the Insane and of the steamship lines, it was decided to return to their homes in Europe during the coming year some two thousand insane aliens now in the State hospitals, who would otherwise remain a burden on the State, costing annually $3,500 apiece, it is estimated. As these persons had been in the country over the prescribed time limit when they became public charges the State could not legally demand that the steamship companies deport them, and the present plan for returning them to their homes is the result of an amicable agreement by which the State will pay only the ordinary steerage rates on each passenger. It is estimated that the patients can be sent away at the rate of thirty or forty a week.

Congress on Hygiene.—Twenty-six of the larger colleges and universities in the United States have already accepted invitations to send delegates to the Fifteenth International Congress on Hygiene and Demography to be held in Washington next September. Among those which have named their delegates are Columbia University, which will be represented by Dr. Philip Hanson Hiss, professor of bacteriology; New York University, by Chancellor Brown and Dr. Hermann M. Biggs; Lehigh University, by Dr. Henry Sturgis Drinker and Dr. W. L. Estes; and the University of Pittsburgh, by Chancellor McCormack and Dr. Thomas Shaw Arbuthnot.

New York Filtration Plant.—Pure water for New York City is at last a probability and will soon be an accomplished fact if the plans prepared by Water Commissioner Thompson are approved by the Board of Estimate. The plans provide for the building in Jerome Park of a large filtration plant for the Croton water of the type known as the mechanical filter or American system. If the plans are approved ground will be broken this summer and the plant will be completed in three years. The estimated cost is $7,500,000.

Pellagra Commission.—Equipped with a complete field laboratory from the Post-Graduate Medical School of New York, the Thompson-McFadden Pellagra Commission left New York on May 27 for Spartanburg, S. C., where it will spend the next five or six months in the study of pellagra. An arrangement has been made by which patients will be brought to the Post-Graduate Hospital during the summer for treatment and further study. The commission consists of Captain Joseph F. Siler, Medical Corps, U. S. A.; Dr. Philip E. Garrison, Passed Assistant Surgeon, U. S. N., and Dr. Ward J. MacNeal, Assistant Director, Department of Laboratories, New York Post-Graduate Medical School. These will be joined in Spartanburg by two entomologists from the Department of Agriculture. The work will be done under the direction of the Division of Tropical Diseases of the Post-Graduate, to which the money for the investigation was donated.

Raid on Spitters.—The Health Squad of the Police Department turned their attention to the nuisances at the approaches to the Brooklyn Bridge one afternoon recently and during the rush hours arrested thirty-six men whom they charged with spitting, in violation of the Sanitary Code. Sixteen of them were arraigned and fined $1 each, while the cases of the others were postponed.

Dr. H. Bert Ellis of Los Angeles, Cal., was the guest of honor at a dinner given by his colleagues on April 22 at the University Club, as a testimonial of their appreciation of his able and successful management of the entertainment of the American Medical Association at the meeting held in Los Angeles last June.

Frisco System Medical Association.—At the eleventh annual meeting held in Springfield, Mo., on May 13 and 14, the following officers were elected: *President*, Dr. W. S. McDonald, Fort Scott, Kan.; *Vice-Presidents*, Dr. J. R. Dawson, Birmingham, Ala., and Dr. B. C. L. Schwab, Sapulpa, Okla.; *Treasurer*, Dr. Walter A. Camp, Springfield, Mo.

Rhode Island Medical Society.—The 100th anniversary of the Rhode Island Medical Society will be celebrated at a meeting held in Providence on June 12 and 13.

North Dakota State Medical Association.—At the annual meeting held in Valley City on May 14 and 15, the following officers were elected for the ensuing year: *President*, Dr. A. J. McCannel, Minot; *Vice-Presidents*, Dr. Murdock MacGregor, Fargo; Dr. R. Hudson Beek, Lakota, and Dr. Eric P. Quain, Bismarck; *Secretary*, Dr. H. J. Rowe, Casselton; *Treasurer*, Dr. Frank J. King, St. Thomas. The 1913 meeting will be held in Minot.

Ninth Councilor District (Ind.) Medical Association.—The annual meeting was held in Frankfort on May 16, when the following officers were elected: *President*, Dr. William R. Moffit, West Lafayette; *Secretary-Treasurer*, Dr. W. H. Dinsmore, Kramer. The next meeting will be held in Lafayette.

Bristol (Rhode Island) South District Medical Society.—At the annual meeting held recently the following officers were elected: *President*, Dr. Michael Kelly; *Vice-President*, Dr. A. B. Cushman; *Secretary-Treasurer*, Dr. A. J. Albe.

Essex South District (Massachusetts) Medical Society.—The following officers were elected at the annual meeting in Nahant on May 9: *President*, Dr. H. E. Sears, Beverly; *Vice-President*, Dr. Philip Mooney, Gloucester; *Secretary*, Dr. H. B. Bennett, Lynn; *Treasurer*, Dr. George Z. Goodell, Salem.

Hampshire (Massachusetts) Medical Society.—The annual meeting was held in Northampton on May 10, officers being elected as follows: *President*, Dr. M. W. Pearson, Ware; *Vice-President*, Dr. A. M. Beldon, Northampton; *Secretary*, Dr. J. P. Collins, Northampton; *Treasurer*, Dr. J. G. Hanson, Northampton.

Middlesex East District (Massachusetts) Medical Society.—At the annual meeting on May 8, held in North Reading, officers for the ensuing year were elected: *President*, Dr. Daniel C. Dennett, Winchester; *Vice-President*, Dr. William H. Keleher, Woburn; *Secretary*, Dr. F. Robertson Sims, Melrose; *Treasurer*, Dr. Charles Dutton, Wakefield.

Essex North District (Massachusetts) Medical Society.—The following officers were elected at the annual meeting held in Lawrence on May 8: *President*, Dr. W. H. Merrill, Lawrence; *Vice-President*, Dr. F. W. Anthony, Haverhill; *Secretary-Treasurer*, Dr. J. F. Burnham, Lawrence; *Corresponding Secretary*, Dr. G. B. Sargent, Lawrence.

Cascade County (Montana) Medical Society.—The annual meeting was held in Great Falls, Mont., on May 7, officers being elected as follows: *President*, Dr. J. H. Irwin; *Vice-President*, Dr. E. J. Greer; *Secretary-Treasurer*, Dr. P. F. Carney.

Linton District (Missouri)Medical Society.—At a meeting held in Mexico on May 7, the following officers were elected: *President*, Dr. A. W. Kampschmidt, Columbia; *Vice-Presidents*, Dr. F. J. Taintor, Warrenton, and Dr. J. E. Thornton, Columbia; *Secretary*, Dr. W. A. Norris, Columbia; *Treasurer*, Dr. C. A. Rothwell, Mexico.

Oklahoma State Medical Association.—The annual meeting was held in Shawnee on May 8 and 9, closing with the election of the following officers: *President*, Dr. J. S. Schuler, Durant; *Vice-Presidents*, Dr. J. S. Walker, Shawnee; Dr. J. M. Byron, Shawnee, and Dr. Barnes, Enid; *Secretary*, Dr. Claude Thompson, Muskogee. The next meeting will be held in Enid.

Montana State Medical Society.—The thirty-fourth annual meeting of the association held in Helena, closed on May 9 with the election of officers which resulted as follows: *President*, Dr. J. M. Scanland, Warm Springs; *Vice-President*, Dr. McGrath, Hamilton; *Treasurer*, Dr. C. T. Pigott, Roundup; *Secretary*, Dr. H. D. Kistler, Butte.

Arizona State Medical Association.—At the annual meeting held at Bisbee on May 8, the following officers were elected: *President*, Dr. John E. Bacon, Miami; *Vice-Presidents*, Dr. I. E. Huffman, Tucson; Dr. E. W. Adamson, Douglas, and Dr. Roy Thomas, Phoenix; *Secretary*, Dr Warren Watkins, Phoenix. The next meeting will be held at Globe on May 6, 1913.

Iowa State Medical Society.—The following officers were elected at the annual meeting held in Burlington: *President*, Dr. Vernon L. Treynor, Council Bluffs; *Vice-Presidents*, Dr. C. P. Frantz, Burlington, and Dr. E. E. Dorr, Des Moines; *Secretary*, Dr. J. W. Osborn, Des Moines; *Treasurer*, Dr. W. B. Small, Waterloo.

New Jersey Homeopathic Medical Association.—The annual meeting was held recently at Atlantic City, when the following officers were elected: *President*, Dr. Frank P. Ekings, Paterson; *Vice-Presidents*, Dr. A. W. Westney, Atlantic City; Dr. C. Herbert Church, Newark, and Dr. C. Winfield Perkins, Princeton; *Corresponding Secretary*, Dr. Charles F. Hadley, Camden; *Treasurer*, Dr. C. F. Adams, Hackensack.

Southwest Missouri Medical Association.—The following officers were elected at the annual meeting in Springfield recently: *President*, Dr. T. A. Coffelt, Springfield; *Vice-Presidents*, Dr. A. H. Madry, Aurora, and Dr. W. R. Beattie, Marshfield; *Secretary*, Dr. H. S. Hill, Springfield; *Treasurer*, Dr. Lee Cox, St. Louis.

Texas State Medical Society.—The annual meeting held at Waco closed on May 9 with the election of the following officers: *President*, Dr. John S. Turner, Dallas; *Vice-Presidents*, Dr. J. W. Overton, Sweetwater; Dr. O. L. Norsworthy, Houston; Dr. J. B. McKnight, Dallas. The 1913 meeting will be held in San Antonio.

Nebraska State Medical Association.—At the annual meeting in Lincoln the following officers were elected: *President*, Dr. I. N. Pickett, O'Dell; *Vice-Presidents*, Dr. W. B. Kern, Ingleside, and Dr. O. A. Quigley, North Platte; *Secretary*, Dr. Joseph M. Aikin, Omaha; *Treasurer*, Dr. A. S. Von Mansfelde, Ashland.

Obituary Notes.—Dr. John Wesley Howard of Irondale, Ala., a graduate of the Atlanta Medical College, Georgia, in 1891, and a member of the American Medical Association and the Alabama State and Jefferson County Medical Societies, died at his home of paralysis on May 16, aged 53 years.

Dr. John W. Johnston of Claysburg, Pa., a graduate of the Albany, N. Y., Medical College in 1866, and a veteran of the Civil War, died at his home of Bright's disease on May 8, aged 69 years.

Dr. Leroy S. Groves of Creston, Iowa, a graduate of the Medical College of Ohio, medical department of the University of Cincinnati, in 1859, a surgeon in the Twenty-eighth Iowa Regiment during the Civil War, and physician of Union County, died at the home of his daughter in Shannon City, Iowa, after a long illness, on May 4, aged 78 years.

Dr. R. T. Rolph, formerly of Dunkirk, N. Y., a graduate of the University of Buffalo, Medical Department, in 1873, and a member of the American Medical Association, died at Chula Vista, Cal., where he had gone in the hope of regaining his health, on May 15, aged 64 years.

Dr. Alden B. Farnham, formerly of Milwaukee, Wis., a graduate of the Bellevue Hospital Medical College, New York, in 1876, for some years a trustee of the Milwaukee Emergency Hospital, at one time president of the Milwaukee Medical Society, and secretary of the Bartlett Clinical Club, died at his home in Citronelle, Ala., on May 6, aged 67 years.

Dr. Ferdinand von Herff of San Antonio, Tex., a graduate of the University of Giessen, Germany, in 1849, and a member of the American Medical Association and the Texas State and Bexar County Medical Society, died at his home on May 18, aged 92 years.

Dr. Stephen C. Henderson of Brewton, Ala., a graduate of the Medical College of Alabama, Mobile, in 1887, and a member of the American Medical Association, and the Alabama State and Escambia County Medical Societies, died at his home on May 10, aged 51 years.

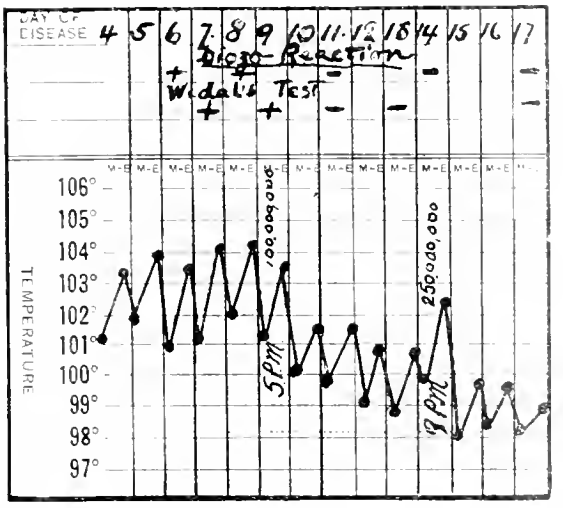
Correspondence.

AN EARLY INOCULATION OF TYPHOID BACTERINS.

To the Editor of the Medical Record:

Sir: My attention has been called to the fact that the case here reported is perhaps one of the earliest cases to receive typhoid vaccine as a treatment for typhoid fever. I have been urged to make this report, which is done merely to give the data.

On August 25, 1907, I was called to see a patient who gave the following history: Miss M. H. M., assistant superintendent of public schools in one of our large cities in the east. Family history, good. Personal history: With the exception of the children's diseases she had always been well. About a month previous a brother died of typhoid fever. During his illness the patient had assisted in various ways to care for him and thus been exposed to the infection. She came to Mt. Clemens to recuperate, which accounts for the fact that the patient came under my observation. Typical symptoms of typhoid were very apparent at my first visit. Dr. Geo. Wheeler of Madison, Wis., who at that time



was a patient at the springs, was requested to examine this case. As a result he gave typhoid fever as his diagnosis. On August 27 examination of the urine gave the diazo reaction; on the following day the Widal test was made and proved positive. With these facts before us a positive diagnosis of typhoid was made.

This patient was familiar, to a certain extent at least with the general application of bacterial vaccines in the treatment of infectious diseases. It was practically due to her own suggestion that vaccine was used in this case and while we realized that the practice was entirely within the limits of the theory of opsonins, yet we had no similar precedent to guide us, which may explain a certain hesitancy on our part in using vaccine in this instance. On August 29 a typhoid bacterin was prepared and two inoculations were given, the first on August 30, which was the ninth day of the disease, and the second on September 4, which was the fourteenth day of the disease. The initial dose consisted of 100,000,000, and the second dose of 250,000,000 dead bacteria. The diazo reaction was positive before the first inoculation and found to be negative 48 hours later.

The accompanying chart explains itself. There is nothing unusual to call attention to in this case, and as stated above it has been reported only to give the data. It is hoped that similar cases, of earlier date will be reported which will prove very interesting from a historical point of view, as it enables us to fix a definite time when the first inoculation of typhoid bacterins was made in the treatment of typhoid fever.

G. A. Persson.

Mt. Clemens, Mich.

AN APPENDICITIS OPERATION BY DR. WEIR.

To the Editor of the Medical Record:

Sir:—Your readers will no doubt be interested in the following surgical case: Dr. Robert F. Weir, famous as a surgeon for nearly a generation, but practically retired nearly a decade ago, is a cottage resident at Nassau, Bahama Islands, during the winter months. The writer (who was suffering from a protracted severe gout) visited Nassau in search of relief this last winter, and put up at the Colonial Hotel; but in spite of all medical treatment he became steadily worse. Dr. Weir, as a friend, and at the request of the writer's son, visited the writer several times and diagnosed the case as one of severe acute appendicitis. Three other surgeons, two local and one a hotel guest, confirmed this view, and it was decided at the consultation that an immediate operation was necessary to save the patient. Within an hour he was on the operating table in his rooms at the hotel, and Dr. Weir in disregard of his 74 years, his stiff fingers, and long absence from practice, operated with such skill as to excite the admiration of the three attending surgeons, the physician, and three trained nurses. The appendix was removed and found to be in such an advanced state of decomposition as to admit of no delay in its removal. The operation took place on March 17.

The feature of the case is that a retired and partially invalided practitioner over 74 years of age, operated on a man over 75 years old crippled by two years of acute gout (which disappeared after the removal of the appendix), and with such success that in eighteen days after the operation he arrived in a private car in New York and in forty-five days after March 17 was at work in his office. Certainly Dr. Weir has not forgotten his former skill and he has the satisfaction of having saved the life of the writer.

Robert V. Chesebrough.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

ROYAL SOCIETY OF MEDICINE—NODULAR LEUCEMIA—ANESTHESIA; TOXIC AFTER EFFECTS; VITAL PHENOMENA—OBITUARY.

London, May 10, 1912.

The new house of the Royal Society of Medicine is practically finished and will be opened by the King on the 21st inst. The building is in the Renaissance style and covers an area of some 10,000 square feet. In the basement, besides some offices and dressing rooms, there will be storage room for 250,000 volumes above those in the library. Opening out of a tiled vestibule on the ground floor are two meeting halls, one accommodating 500, the other 150 persons. The library is on the first floor, with space for 100,000 volumes, is 110 feet long, 28 feet wide, and 10 feet high. An annex will serve for journals.

etc. The council room, committee rooms, and tea room are on the second floor. The third floor will contain the museum, histological room, smoking and conversation rooms, etc. As you are aware, the R. S. M. is really an amalgamation of other societies and its charter, therefore, only dates from 1907, when the old Royal Med.-Chi resigned its charter to form the new society, in conjunction with such others as became its sections.

Nodular leucemia is a term proposed by Dr. G. R. Ward at the Medical Society of London as a clinical expression, to include all cases of leucemia in which nodules have been observed during life in various parts of the body. This would group together mycosis fungoides, chloroma, Kaposi's disease, sarcomatosis, and other cases, but Dr. Ward did not suggest a necessary connection between them. Names applied to conditions which resemble each other are often of little consequence, and perhaps are so in this instance, but one point mentioned deserves consideration, viz., that if the conception of nodular leucemia should obtain general acceptance it might lead to the avoidance of operations which later on have proved unjustifiable. New facts have come to light, showing connecting links between diseases in which nodules are developed, and often these cannot be distinguished from those of mycosis fungoides. Such nodules have been reported, too, in chloroma, and we have learned that the green color of this last is not so constant as had been supposed. The word leucemia to many indicates a definite morbid process, to others only a symptom of several such. The condition of the blood had to be considered to determine the variety to which a case must be assigned. Leucocytosis might be differentiated by the number of cells, their nature, and the presence or absence of mitosis. It was only the mitosis which could be considered absolute, or nearly so. The most common sites for the nodules are the bones (especially the skull), the skin, and subcutaneous tissue, and wherever lymphoid tissue is found in appreciable amount in the healthy body. The distribution and clinical characteristics of the nodules in the several tissues were examined at length and presented such differences that Dr. Ward was half inclined to think "infiltrating" might have been a better adjective than "nodular" to have adopted, for the nodules are by no means always so circumscribed as the term might imply. In fact, they vary from a diffuse edematous condition to an almost bony hardness.

Dr. H. D. Rolleston preferred the term "infiltrating," but he thought the infiltration of the skin rare in leucemia and likely to be confused with lymphadenoma, which was so much more common. Pruritus was so frequent in the latter as to almost distinguish it, for it was seldom seen in the former, if ever. Dr. P. Weber referred to cases reported as showing the leonine face. Dr. Langmead mentioned one with nodules on the buccal musosa and one under the tongue. He added that acute leucemia was not so rare as supposed, for there were nine cases admitted to the Children's Hospital within three to four years, constituting 0.75 per cent. of 1,200 p.m's. Dr. Beddoes hoped this important paper would not be indexed under nodular, or it would be overlooked. D. F. Taylor, president, asked if Dr. Ward would include in his term every case in which leucemic infiltration was observed in any part of the body. Dr. Ward, in reply, said he only used the word clinically. He had met with two in a short period with the skin affected, but he agreed that experts found it difficult to differentiate it from lymphadenoma. He had references to two cases with pruritus present. Kaposi's disease had been confused frequently with leucemia. He had not seen a case in which lymphocytoma had occurred; nor had he met with nodules under the tongue, though they were frequent in the buccal mucosa.

Postanesthetic poisoning is a subject of ominous interest to every practitioner, for although considered a rarity, it may occur to any one who has to produce general anesthesia. It is more likely to occur in children, and is probably more common in its nonfatal manifestations than is generally supposed. In children's hospitals it is often regarded as a scourge, so that a paper by Dr. E. M. Corner, read at the Medical Society of London, was of special interest, as it was based on an inquiry at the Hospital for Sick Children, although that is not complete, and so we may regard the paper as a preliminary one. So far as can be ascertained, there seems no constant predisposing condition in the patient or the method of administration or the anesthetic used. Nor has anything in respect to the operation seemed to contribute to these after effects. It has been thought that acetonuria was related in some way to the toxic symptoms, but probably that is only one of several causes.

The safest way of anesthetizing children, Dr. Corner considered, was the open method with ether. Moreover, he held, the child should be carefully prepared, when time permits, by the addition of glucose to the diet for a few days before operation. Further, he advised an injection of morphia and atropine three-quarters of an hour before administering the anesthetic.

At the same meeting a paper was read which touched on the subject of toxic effects, though referring to other points more particularly. This was by Dr. Dudley Buxton, who discussed the vital phenomena—nervous, respiratory, circulatory, and metabolic—occurring under anesthesia. In modern surgery a deeper and more prolonged anesthesia is often called for than was formerly necessary. Consequently effects are met with which, if not serious at the time, may produce grave results later. Therapeutic dosage, *i. e.* what suffices for adequate narcosis, must be differentiated from toxic dosage. Besides effects on tissues, it must be remembered that the drug may inhibit the functions of organs. Patients with functional disorders may suffer a maximum effect from a minimum degree of narcotism. To minimize deleterious action the strength or amount of the anesthetic should be lessened at once when the needed narcosis is produced, and decreased further as the time passes. It is necessary to watch for intercurrent results that may be dangerous, whether due to the anesthetic or the operation, as fall of blood pressure or temperature, loss of blood, shock. It is desirable that the dangers of prolonged narcotism or excessive dosage should be more generally considered. Careful preparation of the patient and selection of the anesthetic, as well as method and management of the narcosis, would go far to minimize immediate dangers and prevent later toxic manifestations.

Surgeon-General M. W. Kerin, C.B., R.A.M.C., was returning home on furlough when, during the cross-channel passage last week, he was taken ill and on arrival of the boat at Dover was taken to a local hotel, where he died. Surgeon-General

Kerin served in the Burmese Expedition, 1885-6. He took part in the defence of Ladysmith during the South African campaign, was mentioned in dispatches on more than one occasion, and received the Queen's Medal with two clasps. He was principal medical officer during the operations, 1908, on the Indian northwestern frontier, when he was again mentioned in dispatches and received the medal with clasp. In 1910 he was made a C.B.

OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

REPORT OF THE ARMY BOARD FOR THE STUDY OF TROPICAL DISEASES—VARIOLOID — MEASLES—DYSENTERY AT BAGUIO—BERIBERI AND RICE—SANITARY LEGISLATION—DR. WOODBURY, TREASURER OF THE MANILA MEDICAL SOCIETY.

MANILA, P. I., March 30, 1912.

THE Manila Medical Society held its regular monthly meeting on March 4 in one of the amphitheaters of the College of Medicine and Surgery of the University of the Philippines, at 8:30 P. M. A preliminary report on sprue was read by Major Percy M. Ashburn, Chairman of the United States Army Board for the Study of Tropical Diseases. Major Ashburn stated that nothing definite had yet been developed. The work had only just begun, and the matter was being reported to the Society more for the purpose of obtaining the co-operation of members through the islands with the view of bringing cases to the attention of the Board than for the purpose of presenting a scientific report upon the disease. He stated that an investigation of the past few weeks had shown that the disease prevailed at least to a limited extent in Manila and throughout the provinces, and that the employment of a milk diet had resulted in a number of cures among persons who had not left the islands.

Varioloid still continues to prevail very extensively in Manila, and to a more limited extent throughout the provinces. So far, no cases of smallpox have been encountered, nor have there been any deaths from smallpox or varioloid. The large number of cases which have occurred this year have been attributed to the unusually long dry season which has prevailed. For a period of over five months there has been no rainfall in some portions of the islands, and in others, only a very limited amount has fallen. Experience in the past in the Philippines, extending over many years, shows that smallpox or varioloid is reduced to very small proportions two weeks after the rains begin. This fact, observed over a period of so many years, furnishes excellent additional evidence that one of the principal means of transmitting this disease is through the air.

The epidemic of measles which started in October still continues to spread. The disease has now spread as far south as the province of Batangas, and as far north as Zambales. It is estimated that in Manila and nearby provinces there are an average of at least 500 cases constantly ill with this disease. It is generally believed that the type of the disease that is now prevailing is one that is not common to the Philippines, and that it was introduced by persons who came from the United States on United States Army transports. The medical history of these shows that every transport that left San Francisco for Manila, from December, 1910, until December, 1911, had cases of measles aboard. That the type of the disease is more severe than that which ordinarily prevails in the Philippines is shown by the fact that a number of deaths have already occurred. The eruption, in the present outbreak, is very well marked, whereas, in the ordinary, so-called Philippine measles, the eruption is very slight, and the symptoms are so mild that it is difficult to recognize the disease as measles.

During the early part of March the Insular Government transferred the seat of government from Manila to the mountain capital in Baguio. A few days after the employees arrived an outbreak of diarrhea or dysentery occurred. Approximately 10 per cent. of the persons in Baguio were affected. Several competent laboratory workers from the Bureau of Science were detailed to make a study of the outbreak. The report is nearly completed, and it is apparent that at least some of the deaths were due to bacillary dysentery. This was introduced among the wild tribes before the transfer of the employees to Baguio, and the latter probably became infected either by the hands of the Igorrote servants in handling their food, or by means of the flies which prevailed so extensively at Baguio. Most energetic measures have been taken to suppress the latter. A special fund of $5,000 was appropriated; 300 men were employed for the purpose of collecting manure and garbage and burning it, and eleven American sanitary inspectors put on duty. These measures have now been enforced during the past two weeks, and it is yet too early to judge of the result. After the first ten days of the dysentery outbreak, however, the disease rapidly declined, and practically all of the cases now are confined to the Igorrotes.

Recently additional evidence has become available that beriberi is concerned with the consumption of polished rice. It may, perhaps, be remembered that several months after the use of unpolished rice was begun at the Culion Leper Colony, no further cases of this disease appeared for nearly two years. During last November, owing to the great rice shortage in the Orient, and the fact that the market had been "cornered," the Philippine Government found it necessary to engage on a large scale in the rice business in order to bring it to the normal level. In doing so, large quantities of polished rice had necessarily to be purchased. This was then distributed to Government institutions for use, and among others, to the Culion Leper Colony. The use of this rice was begun in the latter part of November and in December, and beriberi began to prevail very extensively at the Culion Leper Colony during the latter part of February and the early weeks in March. There are not yet sufficient facts available to make a report upon this matter beyond that which is stated above, but it is interesting also to observe that the light houses, where there has been no beriberi in the past two years, or since the use of unpolished rice was begun, are now beginning to send cases to the Philippine General Hospital, and it is believed that an investigation will show that these persons have been using polished rice.

A marked advance in sanitation was made in the Philippine Islands by an act that was passed by the last legislature. This law provides for the establishment of municipal sanitary divisions, the officials of which are directly under the control of the Insular Bureau of Health. The expenses are to be borne jointly by the municipalities and provinces concerned. The municipality is obliged to appropriate at least five per cent. of its revenues and the

province must provide an amount equal to that supplied by the municipality. The salaries of physicians cannot be less than $600 or more than $1,500 per annum, with the understanding that they may engage in private practice. The law is very similar to that passed in Cuba after the second American intervention, and which was found to be so necessary on account of the pernicious influences brought to bear upon local health officers when they had to depend upon local councils for their salaries.

Dr. W. E. Woodbury was elected business manager and treasurer of the Manila Medical Society, vice Dr. H. D. Kneedler, resigned.

2. **Gonorrheal Arthritis.**—J. W. Sever presents a short resume of some of the more recent literature on the vaccine treatment of gonorrheal arthritis. This review seems to indicate that the results vary considerably. Apparently in the early and acute and subacute cases, results may be good, relief from pain quick, and early function obtained in some cases. In others, relief from pain alone seems to be the one result obtained. This in itself, however, is of value. It would seem that in the early cases before a general infection has taken place, the mixed bacterins would be of the greatest value as compared to the antigonococcic serum. Apparently, however, the sera have given the best percentage of results, indicating probably that the infection had become a general one and a lack of individual resistance had become established. The matter, however, has not been studied long enough apparently for observers to have come to any definite conclusions as yet in regard to the value of these procedures, and there will probably always exist more or less uncertainty as to the value of the method so long as individual susceptibility and resistance varies. One or both methods should be used as a routine in all early cases in the hope of producing an effect. In the old chronic cases, in which the joints have lost their integrity and become partially ankylosed, orthopedic measures are indicated. The opening of the joint, and the insertion of muscle strips after the fashion of Murphy, or of fascia, or distention of the joint by oil and iodoform as advocated by Brackett, seem to offer methods of restoring some function. Stiff and tender spines are to be protected by plaster jackets until the acute irritation has subsided. The author reports a case of gonorrheal arthritis that teaches the following important things, namely, the liability of old foci to cause symptoms; the necessity of joint protection and treatment; and rapid and marked improvement following prostatic and vesicular massage.

4. **Hemoptysis.**—J. B. Hawes, 2d, states that at the Out Patient Department of the Massachusetts General Hospital, from July 1, 1903, to January 1, 1912, 114 patients came to the hospital because of hemoptysis. Of these 9 were children fifteen years old or less. In 6 of these pulmonary tuberculosis was considered to be the cause of the bleeding. Seventy-eight patients, or 68.3 per cent of the total number, were either strongly suspected or proven to have pulmonary tuberculosis. Of these 78 patients, 11 were at once admitted into the hospital on account of active hemorrhage while in the out-patient department. Twenty-eight of these patients, or 35.8 per cent. of the total number diagnosed as cases of pulmonary tuberculosis or strongly suspected of having it, never returned and thus received no adequate treatment for their condition. In order to properly handle patients with pulmonary tuberculosis, or patients suspected of having it, in large out-patient clinics or dispensaries, there should be a special department devoted to this work. The general practitioner should bear in mind that unless there is definite evidence to the contrary and a source for the bleeding found in the gums, throat, nose or elsewhere, a hemorrhage from the mouth means pulmonary tuberculosis and should be treated accordingly.

6. **Salvarsan and Measles.**—L. L. Williams reports the case of a male aged 22 years suffering from secondary syphilis with slight glandular enlargement and syphilitic orchitis. He was given 0.9 gram of salvarsan intravenously. Two days later a typical measles eruption developed. The attack of measles pursued a mild but typical course. The injection was evidently given a few hours only before the onset of measles and seems to afford some evidence that salvarsan does not affect the development and course of the latter disease. In view of the antagonism of salvarsan to some of the pathogenic protozoa, the coincidence noted above may have some bearing upon the question of the nature of the organism concerned in the causation of measles.

9. Catching Cold. W. Brady.

1. **Treatment of Prolapsus of the Uterus.**—By J. Riddle Goffe. (See MEDICAL RECORD, March 23, 1912.)

2. **Apophysitis of the Os Calcis.**—J. W. Sever concludes that apophysitis of the os calcis is not an unusual condition. It may occur from muscle strain in rapidly growing children. It may occur less frequently from direct trauma, but presents then the same clinical picture. It never occurs after puberty. The treatment is rest and protection. The cure in all cases may be arrived at eventually.

3. **Eye Training for the Cure of Functional Myopia.**—By W. H. Bates. (See MEDICAL RECORD, February 10, 1912, page 288.)

4. **Mechanotherapeutics of Muscular Torticollis.**—E. F. Cyriax and A. Kellgren-Cyriax state that the following are the chief exercises, active and passive, that can be employed in the treatment of chronic muscular torticollis. (1) Resisted exercises for the weakened muscles; (2) manual stimulation for their nerves of supply; (3) purely active movements for the weakened muscles; (4) pétrissage, friction, etc., of the weakened muscles; (5) passive stretching of the contracted muscles.

6. **Conditions Resulting from Ritual Circumcision.**—F. Bierhof states that accidents and infections are not uncommon in the performance of this rite. One of these accidents is the amputation of a small slice of tissue at the tip of the glans penis, and results from failure to employ the circumcision shield. A more serious injury is complete severing of the corpus spongiosum and urethra and partial severing of the corpora cavernosa. Another

condition not infrequently met with is the persistent and organization of preputial adhesions.

8. X-Ray Diagnosis of Abdominal Conditions.—G. F. Pfahler states that practically all pathological conditions in the chest which may cause pain in the right upper quadrant of the abdomen can be demonstrated by the Rontgen rays. Subdiaphragmatic abscess can usually be demonstrated. Biliary calculi can be shown in some cases. Duodenal gastric, and colonic adhesions can practically always be demonstrated by their effects on the position and movements of these organs. Gastric ulcer can be shown only when it has perforated, and can be suspected by spasmodic contractions, which may be present in the stomach. Duodenal ulcer may be suspected if spasmodic constrictions are present in the duodenum. Gastric carcinoma can be almost always demonstrated. Renal calculus can be demonstrated in at least ninety-eight per cent. of cases with good technique. Renal abscess can often be demonstrated by combined cystoscopic and rontgenoscopic examinations. Perinephric abscess can be demonstrated when it is large enough to produce a palpable tumor, or when it displaces neighboring organs. Colonic kinks and constrictions can be demonstrated. Each of the foregoing conditions requires careful technique and careful study in the sequence of the various steps during the examination, and usually requires not only a fluoroscopic examination, but a number of plates.

1. Division of Anterolateral Column of the Spinal Cord.—W. G. Spiller and E. Martin report a case of section of both anterolateral columns of the cord for the relief of excessive pain due to a large malignant growth. The work of Petren and Spiller's studies lead to the conclusion that fibers for the conduction of pain are located in the anterolateral columns. Spiller therefore referred this patient, who was suffering intolerable pain, to Martin for division of the anterolateral column on each side. The pain was greatly relieved and the condition in other respects was not any worse than it was before.

3. Blood Picture of Autoinoculation Due to Chronic Colonic Stasis.—G. H. Hoxie notes that the blood picture in this conditions is as follows: The hemoglobin is high, with a normal red-cell count. The leucocytes also run usually under or about 9,000. The number of polymorphonuclears is low, usually below 70 per cent. The lymphocytes are correspondingly increased. Of these the larger forms with angular nuclei and wide unstained borders are in the great majority. The mast cells are infrequent. The ripe eosinophiles are about normal. In some specimens one finds many polymorphonuclears with oxyphilic granules. The platelets seem reduced in number. When studied with Wright's stain, the polynuclears show an increase in the proportion of cells, showing large ambophilic granules, so much so that the observer is struck with the "dark" appearance of the protoplasm. That is, the granules are large and purplish and seem to lie in a mauve cytoplasm. The proportion of these heavily staining cells decreases as the patient gets rid of the toxins. Hence, one can estimate rather closely how intoxicated the patient is by the proportion of these dark cells to the total number of polynuclears.

4. The Vacuum Bottle in Infant Feeding.—F. O. Tonney and H. H. Pillsbury have undertaken a series of experiments to determine the bacteriological content of milk kept in vacuum bottles for various periods. The use of the apparatus may or may not be safe, according as the milk is kept at a germicidal or an incubating temperature. In the first series of experiments two samples were used at an initial temperature of 150°. The milk was first warmed to that point and placed in a vacuum bottle, which had been previously warmed by immersion in hot water. The bottles were kept at room temperature and opened at intervals for temperature readings and bacterial tests. It was found that the temperature of the surrounding atmosphere influenced materially the rate of heat loss. The count, which was exceedingly low at first, remained so for from six to ten hours, depending on the outside temperature. After that time, and as the temperature fell below 115° F., the bacteria began to multiply rapidly and soon reached enormous numbers. It was concluded that in using this method the bottles should be kept in a warm place if the milk is to be used more than five hours after the warming. Improperly or carelessly used, the vacuum bottle becomes a potent factor for harm. The nurse may easily fall into the error of underheating the milk to only incubating temperature. In a second series of experiments made to emphasize this danger, the authors experimented with milk heated to the ordinary temperature for infant-feeding, and found that raw and pasteurized milk became dangerous in two hours. The directions given by the authors are as follows: "Warm the milk, properly modified, until a thermometer immersed in it registers 150° F., and pour it into a vacuum bottle previously warmed by hot water. Stopper the bottle tightly and put it in a warm place. At feeding time remove the stopper and take the temperature with a thermometer. For this purpose a short thermometer which can be kept inside the bottle is preferable, as the danger of bacterial contamination from this source is thus reduced to a minimum. If the reading is above 115° F., fill the nursing bottle, allow the milk to cool for a few minutes and proceed with the feeding. Replace the cork of the vacuum bottle quickly, and set it aside for the next feeding. Do not use the milk, under any circumstances, if the temperature has fallen below 115° F.

11. Hematoporphyrinuria.—A. W. Rogers reports a case of the excessive use of trional and sulphonal by a man aged 39, suffering from neurasthenia and insomnia. The symptoms were profound exhaustion of body and mind, obstinate constipation, tympanites, nausea, occasional vomiting, and much abdominal pain, localized around the navel. The urine was scanty and presented the appearance of free blood, but failed to react to blood-tests. These symptoms grew worse and the patient died from exhaustion about twenty-five days after the symptoms were noticed by the physician. The patient had been taking daily about 12 grains of sulphonal for four or five weeks with an occasional dose of 15 grains of trional. But comparatively few cases of this poisoning have been reported and the treatment is purely empirical: large doses of sodium bicarbonate and stimulation of intestinal elimination.

6 The Heating of Schoolrooms by Closed Slow Combustion Stoves Burning Coke. H. W. Sinclair and A. H. Kirkham.

1 **Treatment of Acute Appendicitis.**—Sir G. T. Beatson maintains that operative measures should be undertaken at the right time, and that that time is when the case has been brought to the conditions that constitute an "interval operation." Then, and then only, will one have complete success in the surgical treatment of appendicitis. In antiseptic surgery and its aseptic form, the author is a firm believer, but he is not satisfied that it can successfully combat infection in dealing with localized intraperitoneal suppuration or infection, and it is not fair to ask it to accomplish what is beyond its powers. Until one has a vaccine that will neutralize the virulence of intraperitoneal pus in connection with acute localized suppurative appendicitis, the author believes the wisest course is to wait and allow its virulence to subside, as it will do through the agency of the local leucocytosis that is present. In short, what one must aim at in the treatment of acute appendicitis is to bring the conditions at operation as near as possible to those that mark the "interval stage," when one can operate with comparative safety.

2. **Intravenous Injection of Hedonal as a General Anesthetic.**—C. M. Page presents a report based upon the use of this drug as a general anesthetic in 75 cases. Hedonal, or methyl-propyl-carbinol-urethane, produces general anesthesia when injected intravenously in a 0.75 per cent. solution in normal saline solution. Administration of the solution by continuous infusion gives good results. The anesthesia is steady and complete; is associated with great relaxation of the muscles, and has a wide margin of safety. During anesthesia the respiration remains steady and the pulse good; the blood-pressure usually falls slightly. The induction of anesthesia is subjectively very pleasant to the patient; little if any excitement occurs during this stage. Anesthesia is established in from 5 to 10 minutes; the rate of inflow of the fluid should be from 50 to 150 c. c. to the minute; a slower rate greatly delays the induction of anesthesia; a more rapid one may produce signs of cyanosis. The comparatively slow rate at which the drug is excreted makes it possible to maintain anesthesia for prolonged periods without infusing a very large volume of fluid. The anesthetic stage usually merges into one of deep sleep, which lasts from 6 to 12 hours. Vomiting or headache at the postoperative period is uncommon. Pulmonary complications are rare. The dangers which may arise during anesthesia are respiratory depression from an overdose of the drug and respiratory obstruction from falling back of the tongue and jaw. The method is very suitable for operations about the head and neck; the muscular relaxation and quietness of the respiratory movements also make it a valuable anesthetic for operations in the upper part of the abdomen.

3. **Vicious Circles in Disorders of the Nose, Throat, and Ear.**—J. B. Hurry states that nasal obstruction, by preventing or interfering with the expulsive force of the expiratory current, prevents the removal of the usually abnormal amount of secretion, either by blowing the nose or otherwise; its accumulation is in its turn an efficient factor in producing obstruction and a vicious circle is thus established. Inflammatory and hypertrophic affections of the nasal mucosa, and postnasal growths such as adenoids, tend to increase when stenosis is present and thus a vicious circle is maintained. Deflection of the nasal septum and nasal obstruction act on each other. Abnormal patency of the nasal fossæ by diminishing the velocity of the air stream and thereby favoring the retention of secretion, has much to do with the circle that complicates atrophic rhinitis or ozena. Reciprocal relations are frequently established in connection with sinusitis. A polypus by exciting or maintaining irritation of adjacent structures, stimulates the source of its own formation. Acute rhinitis diminishes the resistance of the nasal mucosa and so predisposes to successive attacks. Some dangerous circles are associated with stenosis of the larynx and trachea. In congestion of the aryteno-epiglottidean folds the resulting dyspnea causes the edematous masses to be brought closer together, which increases the dyspnea.

4. **Anesthesia and the Safety of the Patient.**—D. W. Buxton states that very little of any anesthetic is needed to keep up any level of narcosis when the level is once established, and that so long as the tissues are not over-narcotized the cells will by their inherent vitality part with the anesthetic, reverse the aggregation, and so regain their normal physiological state. Even in artificially produced acidosis the cells of the hepatic lobules which have undergone necrosis have been shown to recuperate, but this can only occur when the general vitality of the organism has not been excessively depressed. Indeed, this has been shown experimentally to be true of other, mainly epithelial, tissues; so that there is every presumption in favor of the belief that when a narcosis is maintained without excessive interaction between the narcotizing agent and the tissues of the body, such tissues even if temporarily damaged will rapidly recover, provided their requirements—*e.g.* adequate blood supply and so on—are safeguarded and physiological conditions are promptly reinstated.

5. **Syphilis in the South African Native.**—B. G. Brock states that 35 per cent. of natives have a fibroid condition of the lungs and 68 per cent. have induration enlargement of the epitrochlear gland. Both conditions result from syphilis, and nearly 80 per cent. of natives have one or both conditions present. Syphilis prepares the way for tuberculosis, and is, in all probability, the chief cause for the great prevalence of, and high mortality from, the latter disease in the natives engaged in mine work on the Rand. Syphilis plays a rôle in the production of lung disease in the youth and adult, the great importance of which has not been recognized.

6. The Mechanism and Treatment of Shock. H. T. Gray and L. Parsons.

1. **Sanity and Insanity.**—F. W. Mott states that the question is frequently asked whether insanity is not greatly on the increase. Before answering such a question, it is as well to know exactly what constitutes insanity at the present time. It is often difficult to draw the line between sanity and insanity. It may, however, be asserted that a person is insane who by virtue of mental defect or mental disorder no longer feels, thinks, or acts in conformity with the usages and customs of the society in which he lives. The great increase in insanity is more apparent than real for the following three reasons: (1) The standard of sanity has been raised; a great number of harmless idiots and weak-minded persons who formerly were allowed to roam at large are now gathered into asylums. (2) The death-rate having diminished in recent years, there is a tendency to fill the asylums with chronic incurable cases. (3) Many aged persons suffering from dementia who were formerly treated in infirmaries are now sent to the asylums, where they can be better cared for.

2. **Coma.**—D. Forsyth arranges the six important

causes of coma in the following order according to their frequency: Vascular derangement of the brain (hemorrhage, thrombosis, embolism); injuries to the head; epilepsy; diabetes; poisons; and Adams-Stokes disease. The less common causes are meningitis, encephalitis, cerebral abscess, cerebral tumor, fevers, eclampsia, cholerina, epidemic enteritis, general paralysis, and disseminated sclerosis. The rarer causes are pernicious malaria, muscular exhaustion, and heat-stroke.

Berliner klinische Wochenschrift.

May 13, 1912.

Psychiatric Instruction as Part of General Medical Education.—Bonhoeffer emphasizes the twofold aim of medical education, viz., to develop the technical skill on a basis of certain material foundation studies and to develop the personality. The latter, no less important than the former, cannot be developed by courses of lectures. It comes about of itself after prolonged intercourse with patients. The author believes that instruction in psychiatry tends to develop the personality of the physician, since it involves constant study of the mental processes. The latter is preeminently a part of general medical training, and the insane would never have been separated from sane patients simply because of their insanity, but because their presence is a source of disturbance to work. An examination of the mental processes is or should be inseparable from medical practice in general. In addition to the objective examination we ask the patient about his sensations, etc., not necessarily to elucidate his physical state, but to determine his mental processes. Medical teaching has erred too long in minimizing this problem. The crude practitioner does not want to listen to complaints, and if he finds nothing wrong objectively takes but little interest in the subjective side of the patient and does not go beyond the diagnosis "hysterical," "neurasthenic," "hypo," and the like, which only represents the impression made upon him by the patient and does not mean that he has arrived at an actual diagnosis after due examination. Failure to appreciate a really hysterical patient by physicians has been the means of innumerable unnecessary surgical procedures. The author knows of one hysterical who has submitted eagerly to two operations on the cecum, one on the kidney, and finally a Kraske resection of the sacrum. She was actually able to simulate unconsciously the various local affections which appeared to justify the operations—for the latter were not performed for their moral effect. Hystericals naturally have accidentally associated physical lesions which are in no way correlated with the mental state. Of extreme importance are the relationships between somatic and psychic states, which must fall into one of several categories—cause, effect, of common origin, coincidental, etc.

Pancreas Alterations and Diabetes.—Von Hansemann takes issue with those who claim that there is no anatomical basis for diabetes. It is now pretty generally admitted that there is but one true diabetes, although there are many types of glycosuria. This true diabetes is always of pancreatic origin. The only differences in opinion are such as are bound up in the question "structural or functional." Some would see in diabetes a disordered function of the pancreas with or without structural changes. The opponents feel equally certain that structural alterations must be present even if these are of a kind to escape recognition. The problem has been confused by accusing the islets of Langerhans, which as the supposed source of the internal secretion of the pancreas would naturally be found affected in diabetes. It has now been demonstrated that the latter affection may exist with intact islets, while in destruction of the latter it may be absent. The opinion has gained ground that the islets are in no wise distinct in nature from the ordinary parenchyma, and it is known that the latter is the source of the former. The author believes, as already stated, that the pancreas is always the seat of structural changes in diabetes, which latter is necessarily due to derangement of the harmonic functions of that gland.

Münchener medizinische Wochenschrift.

May 7, 1912.

Immunity and Anaphylaxis.—Traube states that in Germany at present immunity is being studied as if it were a question of chemistry and to the neglect of the physical possibilities of the problem. In other countries the devotees of physics and physical chemistry are studying immunity from their particular viewpoints. The exclusively chemical hypothesis or rationale has always been unsatisfactory. It has never been entirely obvious that a toxic heterologous albumin calls forth the defensive formation of a chemical antidote, and the phenomenon of the anaphylactic shock by no means fits into a chemical explanation. Quite recently chemotropsin has, despite its name, been shown to be physical rather than chemical in character; at least to the extent that the chemical activity of a selective staining principle depends upon its physical ability to penetrate the cell envelope. If chemical substances, *i.e.* substances of a definite chemical constitution, possess certain chemical activities which bring about definite changes in the organism, we cannot understand why bodies in every way similar chemically do not exert a similar action. The study of the relationship between chemical constitution and physiological action, fruitful up to a certain point, stops far short of finality and even leads to most paradoxical finds in certain cases. It is probably *a priori* that both physical and chemical phenomena are concerned in all biological reactions, and to study one component to the exclusion of the other is not good policy.

Lacerations of the Tentorium in the Newly Born.—Bauereisen believes that this accident is of much importance in connection with still and asphyctic births. He has analyzed eleven cases in the Kiel clinic. All were born asphyctic and nine were in the deepest state of suspended animation, the persistent heart action alone showing that life still remained. None of the series could be reanimated. The remaining two were reanimated but succumbed shortly, apparently from paralysis of the respiratory center. One child developed the full clinical picture of tentorium laceration (supratentorial hemorrhage). In the entire series of eleven cases, labor had to be terminated by forced extraction. In five cases the children were premature, as gestation had to be terminated for placenta previa, eclampsia, or nephritis. The full importance of this subject is bound up in the possibility that slight lacerations of the dura, especially of the tentorium, are very common and may be wholly or in part responsible for many deaths set down to quite other causes. When the children survive this lesion may also be held responsible wholly or in part for various affections of cerebral origin. There is of course no special prophylaxis, for the obstetrician is always supposed to use a minimum of force in manipulating the skull of the newly born, but it is probable that much mortality and morbidity could be prevented by bearing in mind that the tentorium is the point of least resistance to mechanical insults to the outside of the cranium.

Deutsche medizinische Wochenschrift.

May 2 and 9, 1912.

Pseudotyphoid and Bacillus Fecalis Alkaligenes.—Hanser and Springer report the following case: A girl aged 15 years died of clinical typhoid and came to autopsy.

No history was obtainable beyond the fact that she was in the sixth day of her disease on admission. The diagnosis was based on a positive Widal and the clinical picture of "typhoid state" including the brown tongue. There had been no roseola, no enlarged spleen, no typhoid or paratyphoid bacilli in the stools. Autopsy revealed absence of typhoid enteric lesions. The blood was then examined for evidences of typhoid sepsis with negative results. The blood, bile, and mesenteric lymph nodes, however, contained the *Staphylococcus pyogenes aureus* and a bacillus recognized as the *B. fecalis alkaligenes*. The problem at first sight seemed insoluble, but could be readily solved by assuming that within a certain interval she had gone through a mild walking typhoid and still had agglutinins in her blood. The fecal bacillus serum was found to be unable to agglutinate Eberth's bacillus. Terburgh once reported that such an agglutination can occur with some strains of the latter. In order to explain the case the authors assume it to have been a staphylococcus sepsis, which began as an angina. Aside from some minute abscesses in the kidneys there were no other actual lesions. The fecal alkaligenous bacillus often coexists with Eberth's bacillus in typical typhoid, and has also been found alone in typhoid suspects, but apparently not hitherto in full-fledged victims of typhoid, whether true or spurious.

The Paronychia of Confectioners.—Strauss states that this occupational disease is not very well known in Germany. Beginning with Poncet in 1870 a series of French authors have described it, yet it receives scant or no attention in systematic German works on industrial affections. The affection is not uncommon in South France in confectioners who work month in and out on candied fruits. Workers in other confections seem to be exempt. In preparing the candied fruits the finger tips are subjected to continuous thermic irritation, now hot, now cold, together with mechanical and chemical irritations. The digits most exposed—thumb and middle finger—are the worst sufferers. To these special lesions the artisans may also add the ordinary sugar itch of confectioners, usually ascribed to the fermentative action of the sugar. The author, who practises in Nurnberg, has recently had occasion to study three cases and dissents from the French opinions as to the specific occupational character of the affection. Only one patient of the three was a worker in candied fruits. The two other cases, with precisely the same lesions, occurred in a cook and dishwasher respectively. The affection resembled the ordinary "run around" but was much less acute, and the nail did not come away *en masse*, but turned dark and was shed slowly and fragmentally as new granulations formed beneath it. A form of paronychia sometimes termed scrofulous or malignant bears considerable resemblance to the occupational malady. In this the nail is not regenerated. The affection, while chronic, is very painful and attacks young subjects chiefly.

Rhinogenous Acute Articular Rheumatism.—Apropos of the recent interest manifested in this subject Stein reports a case in a five-year-old child who presented evidences clinically of nasal diphtheria with acute inflammation of the combined joints of hands, fingers and wrists, and both ankles. The nasal symptoms soon began to subside spontaneously and bacteriologically, the secretions negative for diphtheria but positive for streptococci. The diagnosis was fibrinous rhinitis and acute articular rheumatism. The entire disease lasted less than a week's time and the only treatment was menthol oil locally and aspirin inwardly.

Status Epilepticus.—Jodicke emphasizes the exclusively empirical character of our treatment of this condition, which naturally is the consequence of our ignorance of its intimate nature. What we call status epilepticus is really a very variable affection, the different types harmonizing in a few details only, such as continued high temperature and a comatose condition. The patient is menaced by death in a number of forms. After the passing of the status he may be left in a state of mental and physical exhaustion which may last for weeks. Aside from the dangers of death from symptomatic pneumonia and cerebral hemorrhage the patient may be left with pareses in the limbs and speech disturbances. The profound shock to the organism is shown by a tendency to lose flesh. The entire organism in fact must suffer, and weak points in the economy naturally suffer most. Our knowledge of causation must undergo revision. The status must in some cases be regarded as a psychoneurosis having a distinct psychical causation acting on a predisposed individual. But status is also a cumulative equivalent of ordinary epileptic convulsions, so that evidently factors which differ markedly among themselves may set the same mechanism in action. Status as a cumulative equivalent is especially associated with withdrawal of bromides, and this aspect of the affection is one with nature fairly obvious and for which we have a rational prophylaxis. It cannot be justly claimed that bromide medication has increased the frequency of status, for everything teaches the contrary. When left to itself without any sort of general or hygienic management, epilepsy doubtless terminated in a large percentage of cases in fatal status. In the institution material controlled by the author deaths from status make up anywhere from 5 to 18 per cent., in round numbers, of all deaths, the average for the past decennium being about 11 per cent. As far as can be ascertained, this rate was originally in the neighborhood of 50 per cent., which shows how unjust would be the assertion that status is due in any way to bromide therapy. It is undeniable that when a subject makes a good recovery from status he is in a measure better off. He seems to have secured a protracted period of immunity from convulsive outbreaks.

Tubercle Bacilli in the Circulating Blood.—Hilgerman and Lossen refer to the recent claims that a diagnosis of tuberculosis other than in the acute generalized type may be made from the presence of bacilli in the blood. That a few of the latter might exceptionally be found in the blood of ordinary consumptives might readily be conceded, but this is quite another thing than assigning to such fluids diagnostic and prognostic significance. On the other hand, recent claims are to the effect that such finds should be of regular occurrence with proper technique. The authors have attempted to solve this problem, and their conclusions are that perhaps 25 per cent. of consumptives show bacilli in the blood alike in the early and last stages, just as they come to examination. When these cases are followed up those who show bacilli in the early stages appear to have a more severe type of disease than the negative controls. The find in no sense implies that acute miliary tuberculosis is to develop. On the contrary, such patients may still respond to treatment. The tedious technique and the inconstancy of the finds will probably exclude the research for routine work.

Epileptoidism.—S. de Sanctis has made a study of 70 cases of a condition which he characterizes as epileptoidism. He describes this as a state in which there is great changeability of the feelings, especially in a hostile direction; nervous hyperexcitability; rapid and explosive reactions without sufficient cause, accompanied by anger, and not followed by somnolence; amnesia; involuntary micturition; refractoriness to work either physical or mental. The patients are not helped by bromides. There are poor sleep, hypoalgesia of the skin, slight functional motor alterations, spasm, retarded right-handedness and ambidexterity, mental insufficiency, criminal tendencies, and dipsomania.—*Rivista Ospedaliera.*

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

THE PHYSICAL EXAMINATION.

Blood Pressure.—Life insurance companies are recognizing the significance of abnormal blood pressure as a danger signal and are consequently becoming strong advocates for a more extensive employment of the sphygmomanometer by their examiners, especially since the instrument has been improved and adapted to the requirements of everyday use. The mercury type of sphygmomanometer is reliable if cleanliness of the instrument is observed and the proper precautions are taken when oxidation of the mercury occurs. The apparatus is bulky, cumbersome, and easily broken and, therefore, only fitted for office work. It will continue, nevertheless, to serve the excellent purpose of acting as a standard for the correction of the diaphragm instrument which is now so widely used, and for this reason should be in the possession of every physician unless he has ready access to one in his neighborhood.

The diaphragm dial type of sphygmomanometer has the advantage of being compact, portable, and easily applied. Like the aneroid barometer, it should be compared with a good mercury apparatus every three or four weeks in order to ascertain if any changes in the mechanism have interfered with its accuracy. If the readings vary from those exhibited by the standard apparatus the examiner will then know what allowance to make when taking observations until he can secure a readjustment of the instrument.

The blood pressure should uniformly be taken while the applicant is seated, the coat having been removed and the sleeves of the underwear, if heavy, rolled up. The cuff, about five inches wide, should be placed directly over the brachial artery, and the rest of the band neatly wrapped around the arm. The inflating bulb and the sphygmomanometer having been attached, the air bag is inflated until the pulse is lost to the finger tips. The air is then allowed to escape slowly until the pulse returns to the wrist, and the reading is made at this point. The entire procedure, after a little practice, does not require more than a few minutes, and the examiner will seldom if ever meet with any objections from the applicant.

High Blood Pressure.—The high normal limit of blood pressure may be considered as lying between 150 and 160. When the family or personal history is not too unfavorable and the weight of the applicant is under the maximum, a blood pressure as high as 160 may be looked upon as normal; then, again, under other circumstances the conditions may be such as to justify a refusal to accept the risk if 150 is exceeded.

A moderately high blood pressure will often prove to be a transitory one due to nervousness, fear of the examination, recent strenuous exercise, or a heavy meal. The report is incomplete, therefore, when a high reading is observed, until subsequent examination made under more favorable conditions indicate whether or not the tension is persistently high. The several readings should then be recorded.

The question of acceptance or rejection should be referred to the home office in cases of moderately high blood pressure. When, however, the pressure persists above 165 or 170 the examiner would better urge rejection.

Persistent high blood pressure is a danger signal of great importance, its value being particularly enhanced by the diagnostic aid rendered in the *early* stages of cardiac, vascular and renal changes which are so frequently overlooked. While we may only vaguely understand the etiology of high tension, it is at least believed by practically all observers that cardiovascular-renal disease will almost surely follow if the cause of the high tension is not removed.

Dr. J. W. Fisher (Proceedings of the Association of Life Insurance Medical Directors, October 4, 1911) in a paper on this subject stated that his company had made a strong effort to follow up rejected cases with high blood pressure. In the course of his remarks he referred to 356 applicants rejected with high blood pressure (average 171.73 mm.) and one or more impairments. The impairments consisted of arteriosclerosis in 53 cases, heart murmur in 69, cardiac-hypertrophy in 17, albumin and sugar in 10, albumin in 110, sugar in 14, albumin and casts in 10, casts alone in 6, nervous symptoms in 21, prostatic disease in 5, miscellaneous, 41. Subsequent investigation in regard to these 356 cases showed a mortality of 171.93 per cent. Dr. Fisher then presented a list of 366 cases rejected for high blood pressure only (average 170.36 mm.). The data collected later showed a mortality of 138.07 per cent.; the majority of the deaths were due to diseases of the arteries, heart, and kidneys, as would be expected. These figures afford satisfactory and conclusive evidence that high blood pressure must not be ignored in the selection of risks.

I cannot resist referring to a death claim coming under my own observation recently, as it illustrates the subject so aptly. The policy holder had been passed previously by an able and experienced examiner, the applicant at that time being 58 years old. Two years later he again came up for examination by the same examiner, and was again reported as a splendid risk with the single exception of a blood pressure of 168. On request from the home office for another reading the pressure was found to be 180 a few days later. The applicant was rejected at this time, and his death occurred nine months later from acute dilatation of the heart.

Low Blood Pressure.—The lower limit of blood pressure is not so well understood, but it may safely be asserted that an applicant should be rejected if his pressure is persistently under 100. The low blood pressure may be a temporary one and should always call for subsequent readings. Unhygienic conditions, too much work, too little nourishment, and poor air will give rise to lower vitality and consequent diminished resistance; this in turn may cause a low blood pressure. Hypotension has been particularly noticed in tuberculosis. The writer was informed within a week by an official in charge of one of the divisions of dispensaries under control of the Pennsylvania State Board of Health for treating and preventing tuberculosis, that he had a record of 1200 blood pressures taken in tubercular subjects. The records showed a uniformly low pressure of from 100 to 110, a few reaching 115, in incipient cases in which only the very first indefinite signs could be detected. In the later stages the pressure ran lower, reaching 80 in advanced cases.

Book Reviews.

WE AND OUR CHILDREN. By Woods Hutchinson, A.M., M.D. Author of "Instinct and Health," "Preventable Diseases," "The Conquest of Consumption," "Exercise and Health," etc., etc. Garden City, New York: Doubleday, Page & Company, 1911.

WITHIN recent years many books have been written on the hygiene of child life. None apparently has succeeded in presenting this subject with the degree of originality and interest that characterize this latest volume from the prolific pen of Dr Hutchinson. The reader of popular literature will recognize the titles of some of the chapter headings of this book, which is made up largely of articles that have appeared in magazine literature. The scope of this book can be best indicated by a recital of the chapter headings, which are as follows: introduction; before the little one comes; babies as bulbs; the nursery age; the sweet tooth; the kindergarten age; feeding the human caterpillar; our ivory keepers of the gate; the child's self-respect; brick walls and the growing child; eyes and ears; the worship of the race stream; reluctant parentage; the American mother; the delicate child; fiction as a diet; and overworked children on the farm and in the school. The author makes an eloquent plea for the use of natural methods in the rearing of children, whose normal instincts are not to be extinguished under the blight of theory and tradition. The craving for sugar, the need of outdoor life, the instincts of play and self-activity are but a few of the natural wants that must be respected. The author does not hesitate to demolish many a popular belief that has been sanctioned by long usage. In some instances, however, he falls into the danger of sacrificing scientific exactness in order to turn out a phrase striking for its rhetorical finish and wit. Few will agree with him that cod-liver oil is a "nauseous relic of barbarism." Almost all writers of popular medical articles, in their effort to impart interest and originality to their manner of presenting the subject, are apt to fall into the error of being inaccurate and to exaggerate the importance of certain subjects. An instance of this inaccuracy may be noted on page 58 of this book, in the use of the term animal sugar as synonymous with glycocoll, and animal starch as synonymous with carbohydrate. The author treads on firmer ground when he discusses the sociological phases of medicine such as eugenics, reluctant parentage (the euphonious substitute for race suicide) and the American mother. In exposing certain popular fallacies relating to these and kindred subjects, the author writes in his happiest vein. His book represents a unique contribution to popular medical literature and will undoubtedly attain a wide circulation.

HEALTH AND MEDICAL INSPECTION OF SCHOOL CHILDREN. By Walter S. Cornell, M.D., Director of Medical Inspection of Public Schools, Philadelphia; Lecturer on Child Hygiene, University of Pennsylvania; Director of Division of Medical Research, New Jersey Training School for the Feeble-Minded, etc. Illustrated with 200 half-tone and line engravings, many of them original. Price $3.00. Philadelphia: F. A. Davis Company, 1912.

THE conservation of the health and the medical inspection of school children are subjects that within recent years have attracted considerable attention from both public health and school authorities, and it is quite natural that there should be a demand for a textbook that would present fully and in detail the modern aspect of these subjects. This demand is admirably supplied in the present volume. The experience of the author as director of medical inspection in the Philadelphia schools has enabled him to write a book that is eminently practical and that may be used as a guide by the medical inspector, the school nurse, the public health officer, and the educational authorities. Part I takes up the subject of medical inspection; its object; administrative considerations; the methods of inspection, exclusion, and keeping records; the correction of defects; the results of medical inspection; and the present status of medical inspection in the United States. Part II deals with hygiene, including the various phases of school sanitation and personal hygiene. Part III discusses in detail the various defects and diseases, under the headings of definition, cause, prevalence, evidence and diagnosis, results and treatment. There are separate sections dealing with the eye, the nose and throat, the ear, the teeth, the nervous system, mental deficiency, the skeleton, nutrition, the skin, speech, and the infectious diseases. The section on mental deficiency, including the description of the methods of diagnosis such as the Binet test, is particularly complete. The volume is illustrated with a large number of half-tone and line engravings which admirably supplement the text. The author has succeeded in writing a book that has omitted nothing in the broad field of its subject-matter, a book that should be in every teacher's library, and indeed on the shelf of every physician who is interested in the welfare of children.

THE SURGERY OF ORAL DISEASES AND MALFORMATIONS. THEIR DIAGNOSIS AND TREATMENT. By George Van Ingen Brown, D.D.S., M.D., C.M.; Oral Surgeon to St. Mary's Hospital and to the Children's Free Hospital, Milwaukee; Professor of Oral Surgery, Southern Dental College, Atlanta, Georgia; Member of the American Medical Association; Member of the National Dental Association; Chairman of the Section on Oral Surgery of the Fourth International Dental Congress, etc. Illustrated with 359 Engravings and 21 Plates. Price $6.00. Philadelphia and New York: Lea & Febiger, 1912.

"THE discussion of a field of practice with hitherto ill-defined limitations, situated like the hub of a great physiological and pathological wheel, around which center and from which radiate almost limitless possibilities for the reception and extension of disease, has required much thought in the determination of the boundaries. In this effort the difficulty of conveying a true idea of the etiological and pathological importance of the oral region in relation to other parts and to the organism as a whole, without going too far afield in the discussion, has been realized." With these happily chosen words in the preface to the volume the author sets forth its purpose and scope and states the difficulty that confronted him in accomplishing his task. He has done a pioneer's work, indeed, in presenting in one volume, available both as a textbook and as a work of reference for dentists, dental students, surgeons, practitioners of medicine, and medical students, the vast subject of oral diseases and malformations. In carrying out his plan the author has devoted relatively little space to problems connected with the teeth alone, as may be seen by glancing over the table of contents. The chapter headings are as follows: Anesthesia, hemorrhage, shock; pathological dentition; infectious diseases; diseases of the mucous membrane of the mouth; diseases of the nervous system affecting the buccal region; diseases of bone; diseases of the glands; tumors; diseases of the maxillary sinus; diseases, tumors, and malformations of the tongue; nasal deformities and diseases in relation to the maxillæ; diseases, injuries, and malformations of the lips; and harelip, cleft palate, and defects of speech. This volume is not a mere compend of diseases of the mouth and adjoining regions. It contains many original features. Thus the chapter on harelip and cleft-palate describes in great detail and with the aid of many superb illustrations the operations devised by the author in the treatment of these conditions. This is a phase of oral surgery to which the author has devoted particular attention. The neuralgias of the triennial nerve also come in for detailed consideration, all the modern operations for their relief being described. The illustrations are numerous and of a high order of artistic merit. The twenty-one colored plates can scarcely be improved upon. The author has succeeded in writing a book that will undoubtedly gain a host of friends among surgeons, dentists, and general practitioners.

PRINCIPLES OF HUMAN NUTRITION. A Study in Practical Dietetics. By Whitman H. Jordan, Director of the New York Agricultural Experiment Station; Author of "The Feeding of Animals." New York: The Macmillan Company, 1912.

THIS book is written by one who knows well whereof he writes and appears to be a very excellent practical exposition of that vital question what to eat. The work is intended rather for popular use, although one needs to possess a certain amount of scientific knowledge to appreciate it thoroughly. The author rightly lays stress on the necessity, if good health is to be attained and preserved, of adequate mastication. Bolting food, too often the custom in the hurly-burly of American cities, is undoubtedly responsible for a large number of stomach complaints. As for the fad, which is fairly common in civilized countries, of eating food in a raw state, the author is averse to it, and thinks that the proposition to eat all foods raw is not only irrational, but even absurd, when regarded in the light of well-established facts. Jordan is not quite definite in the expression of his views with regard to the use of food preservatives, but, perhaps, wisely leans in the direction of those who oppose the method as a general practice. It may be stated with decision that the book, on the whole is useful and worthy of a place in the rapidly growing library of works on dietetics.

MATERNITY PRIMER. By A. H. F. BARBOUR, M.D., LL.D., Physician to the Edinburgh Royal Maternity Hospital. Price 75 cents. New York: William Wood & Company.

THE term "primer" aptly describes this little volume which is meant for the use of nurses about to begin their obstetric training. The language is simple and strikingly free from technicalities. The subject-matter is presented in a most interesting manner by an experienced teacher. A series of questions at the end of the volume increases its value to the pupil.

DISEASES OF THE NOSE AND THROAT. Comprising Affections of the Trachea and Esophagus. A Textbook for Students and Practitioners. By ST. CLAIR THOMSON, M.D., F.R.C.P. (Lond.), F.R.C.S. (Eng), Physician for Diseases of the Throat and Professor of Laryngology in Kings College Hospital; Physician to King Edward VII. Sanatorium; formerly Physician to the Throat Hospital Golden Square; Surgeon for Diseases of the Throat and Ear to the Seamen's Hospital Greenwich; and Surgeon to the Royal Ear Hospital, London. With 18 Plates and 294 Figures in the Text.

IT is a pleasant task to review this volume from the pen of the distinguished British laryngologist. This book is without doubt one of the best textbooks on diseases of the nose and throat that have appeared in the English language. It is complete and up-to-date, serving the needs of the senior student and more particularly those of the general practitioner. The author, while keenly alert to the vast strides made in this subject within recent years, is also in sympathy with the conservative attitude of the general practitioner. For this reason the descriptions of such subjects as adenoids, acute rhinitis, "colds," diphtheria, epistaxis, syphilis of the nose, etc., are such as cannot fail to be helpful to the physician in general practice. This conservatism does not ignore the claims of the specialist who must needs be guided by the wide horizon of the experienced clinician. For instance, in discussing the subjet of adenoids the author points out and illustrates with the aid of photographs the facts that the typical adenoid facies may be due to other causes than adenoids and that on the other hand these growths may be present to a marked degree without in any way disturbing the normal physiognomy. The conditions of the nose and throat in the acute specific fevers, and in such general affections as gout, rheumatism, myxedema, angioneurotic edema, herpes, etc., are fully described. The needs of the specialist are not ignored; the various operative procedures are described in great detail, with the aid of many drawings. This is particularly manifest in the description of the classical operation for resection of the nasal septum. Little of value in the domain of the rhinolaryngology has been omitted. Possibly Pfannenstill's method of the treatment of lupus of the nose by means of nascent iodine is too new to be included. The series of eighteen colored plates admirably supplement the text in addition to the 292 drawings and photographic illustrations. There is appended to this volume a chapter giving a long list of formulæ that have been found of value in the treatment of diseases of the nose and throat. In spite of its completeness the volume is wonderfully compact, thanks to the art of the publishers.

MODERN METHODS IN NURSING. By GEORGIANA J. SANDERS, formerly assistant matron at Addenbrookes' Hospital, Cambridge, England; formerly Superintendent of Nurses at the Polyclinic Hospital, Philadelphia, and at the Massachusetts General Hospital, Boston. With 228 Illustrations. Price $2.50. Philadelphia and London: W. B. Saunders Company, 1912.

THIS is a textbook that is adapted to the curriculum of the modern training-school. In its 881 pages it contains all that, if not a good deal more than the average nurse is expected to know. The method of turning the mattress without removing the patient from the bed, and the method of staining the tubercle bacillus, though not of equal importance from the viewpoint of the practical needs of the nurse, are given equal prominence. With the growing complexities of modern medicine, the nurse is expected to know almost as much as the general practitioner, and the aim of the writers of textbooks for nurses is usually to vie with one another in trying to include as much as possible in the text. The result is that many of the subjects that pertain exclusively to the nurse and that have very little of purely medical or scientific interest, are either omitted or hurriedly passed over. Thus, in the present volume, although the various forms of coma are accurately described, scarcely any mention is made of the methods of nursing a comatose patient. The modern textbook on nursing exemplifies the conflict between the ultra-scientific aims in the training of nurses and the practical needs of the nurse in her daily work. Possibly this criticism may be unfair, since many subjects that are taught to the nurse in the training school can not be included within the limits of a single volume. In spite of this limitation, the author has accomplished the task of writing a book that is singularly complete and accurate, written in a style that is clear, elegant, and above all, interesting. The chapters on foods and on diets and dieting are exceptionally well written. The introductory chapter dealing with the personal and commercial phase of the nurse's work and with her choice of a training-school, should be carefully read and digested by every prospective nurse. The volume represents one of the best that has been written on this subject and will undoubtedly attain a wide circulation.

ÜBER DAS KONDITIONALE DENKEN IN DER MEDIZIN UND SEINE BEDEUTUNG FÜR DIE PRAXIS. VON D. V. HANSEMANN. Price 5 Marks. Berlin: Verlag von August Hirschwald, 1912.

THIS monograph grapples with the philosophical problem of cause and effect in relation to disease and injury, as distinguished from the conditions that underlie the production of disease and injury. It is shown that the conception of efficient causes is being gradually replaced by that of conditional factors, a conception that is after all the more useful one in practical medicine.

MODERN MICROSCOPY. A Handbook for Beginners and Students. By M. I. CROSS and MARTIN J. COLE, Lecturer in Histology at Cooke's School of Anatomy. Fourth Edition. Revised and Enlarged. With Chapters on Special subjects by various writers. Price $2.00. Chicago: Chicago Medical Book Company, 1912.

THIS well-known work needs no introduction. The appearance of an enlarged and devised fourth edition is a sufficient guarantee of its popularity. This volume takes up the subject of the technology and technique of microscopy and the methods of preparing specimens for study under the miscroscope. There have been added new chapters written by specialists, on subjects that interest the amateur microscopist. These subjects are the use of the petrological microscope; rotifera; the collection, examination, and preservation of mites found in fresh water; collecting and preparing foraminifera; mosses and liverworts; the microscope and nature study; and the microscopy of foods. This last subject is illustrated with a series of six excellent plates showing the microscopic appearance of a large variety of foods. The volume is written in a style whose meaning can be readily grasped by the beginning student. It is at the same time a complete exposition of a most difficult subject.

THE OCULAR MUSCLES. A Practical Handbook of the Muscular Anomalies of the Eye. By HOWARD F. HANSELL, A.M., M.D., Professor of Ophthalmology in the Jefferson Medical College; Emeritus Professor of Diseases of the Eye, Philadelphia Polyclinic and College for Graduates in Medicine; Ophthalmologist to the Philadelphia General Hospital; Member American Ophthalmological Society; Fellow College of Physicians of Philadelphia, etc., and WENDELL REBER, M.D., Professor Ophthalmology in the Medical Department of the Temple University; Professor of Diseases of the Eye, Philadelphia Polyclinic and College for Graduates in Medicine; Ophthalmologist to the Philadelphia General Hospital; Consulting Ophthalmologist to the Rush Hospital for Consumptives; Member Oxford Ophthalmological Congress; Past President American Academy of Ophthalmology and Oto-Laryngology. With three plates and eighty-two other illustrations. Second Edition, Rewritten. Enlarged. Price, $2.50 net. Philadelphia: P. Blakiston's Son & Co., 1912.

THE second edition of this work constitutes a volume of 223 pages. The authors have "sought to avoid discussions and speculations, to emphasize methods that have stood the test of their own experience, and to omit no important data that have been recognized as trustworthy." The anatomy and physiology of the ocular muscles forms Part I; structural anomalies, Part II; functional anomalies, Part III. Part IV is devoted to the consideration of operations. The work is fairly well illustrated. There is much of value to the practical ophthalmologist in this volume. There are some omissions (as, for instance, failure to mention retraction movements of the eyeballs), but they are few. The descriptions are lucid and sufficintly full. The teaching of this excellent work can be heartily recommended

Society Reports.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held April 22, 1912.

THE PRESIDENT, DR. CHARLES GILMORE KERLEY, IN THE CHAIR.

Garbage Removal.—DR. LINSLY R. WILLIAMS, Chairman of the Public Health Committee, presented the following resolutions: *Whereas*, The present method of gathering garbage and ashes is unsanitary and obsolete, be it *Resolved*, That the Medical Society of the County of New York do hereby recommend to the proper municipal authorities that a study be made by them to ascertain a more sanitary method for the removal of ashes and garbage, and be it further, *Resolved*, That a copy of this resolution be sent by the Secretary of the Society, the Commissioner of Street Cleaning, and the Secretary of the Board of Estimate and Apportionment.

Results of Bone Transplantation.—DR. A. A. BERG read this paper, demonstrated the principles of bone formation by means of lantern slides, exhibited a number of cases in which bone transplantations had been successfully done, and showed *x*-ray pictures of the transplants in various stages of growth and adaptation in their new locations. He said that transplantation of bone constituted one of the most important branches of reparative and conservative surgery, as by this means the presence and function of limbs could be preserved, deformity could be done away with, and important structures could be protected from external violence and injury. Dr. Berg reviewed the normal construction and development of bone. In respect to the development of bone it was very commonly assumed that ossification commenced in the center of the primary cartilage or membrane, that was the so-called ossification center, and proceeded from there outward to the periphery where it was joined by a very limited subperiosteal bone formation. Such a view was erroneous. A study of the development of bone showed that a preliminary calcification of the cartilage that was to be replaced by bone commenced at the ossification center, but that the real bone formation started in the osteogenetic layer, the osteoblastic cells of the periosteum, and proceeded from there inward by means of ostogenetic buds made up of vascular canals lined by osteoblastic cells. The facts in the histogenesis of young bone ought to effectually dispose of the entirely erroneous views that had been recently expressed by MacEwen, namely, that the bone cells of the fully developed bone could reproduce new osteoblasts, and so form new bone. The bone cells of the fully developed bone originated from the osteoblasts of the periosteum. It was a rule that in regeneration of parts the development proceeded along the lines and in the manner that was followed in the fetal state. Thus, in bones the ossification proceeded from the periphery inward and in the regeneration of bone it ought to proceed in the same way. The writer reviewed the history of bone transplantation from the time of Ollier, who, in 1867, formulated his views on the subject. Ollier found that where one wished to restore bony continuity after the removal or destruction of bone one must make use of living autogenous periosteum-covered bone grafts, as there was a marked difference between these and every other kind of bone transplants. Every other kind of a transplant died if it was not already dead at the time of its implantation. Radimowsky, in 1881, and Bonome, in 1885, found, in contradistinction to Ollier, that every piece of bone died, even when it was autogenous and covered with living periosteum. Radzimowsky showed that bony union between fragments and adjacent bony tissue easily took place whether the periosteum was preserved or not over such fragments, but that this was no evidence of enduring life in the fragments of bone and that the presence of blood-vessels was no evidence of life therein, inasmuch as dead bone might be permeated by blood-vessels from the vicinity. Microscopic examination showed that such fragments were dead. On the other hand, he demonstrated that the periosteum lived and produced new bone that was deposited on the surface of the transplanted dead bone and into its lacunæ and enlarged Haversian canals. Dr. Berg then reviewed the work of Barth, who used for purposes of transplantation periosteum-covered, or uncovered, or decalcified, or macerated bone. Even he, however, conceded later that better results were obtained when living autogenous periosteum covered bone transplants were used. Axhausen's classical work led him to the same conclusion. Dr. Berg then outlined MacEwen's work and showed where he had been led into error and that he had failed to give histological confirmation of his conclusions. MacEwen thought he had proved by heterotopic transplantation of bone the inherent reproductive power of bone. He transplanted bone shavings minus the periosteum into the soft parts and into the peritoneal cavity and found the growth of bone. This was perfectly within their previous knowledge. If the shavings contained osteoplastic cells from the bone marrow or if the periosteum was not entirely removed by scraping before the transplant was made it was reasonable to see how a small nodule of bone might be formed in the new bed. A further critical review of MacEwen's experimental work brought one to the conclusion that the fundamental principles as stated by Axhausen were still true and that they must still look upon the periosteum and marrow as the factors in the production of new bone. In discussing the details in the technique of transplantation the writer first considered the relative merits of autogenous *versus* heterogenous grafts and concluded that new bone formation was always more rapid and more extensive in autogenous grafts because the cellular nutriment was now altered. In heterogenous transplants the access of nourishment to the periosteum and marrow of the transplant was hindered and there was no tendency either in the marrow or periosteum towards the formation of new bone. The bed for the transplant should be vascular so as to allow of rich access of tissue fluids to the graft; for until new blood-vessels formed the periosteum was nourished by these fluids. Two factors affected the survival of the periosteum. 1. Grafts did badly unless entirely free from muscle fibers. 2. The grafts did well if a number of incisions were made into the periosteum, thus exposing a larger surface of the periosteum. Two factors influenced the survival of the marrow: 1. If a transplant of the entire shaft was made the marrow died; in such cases it only survived at the ends. 2. Grafts would do well if split longitudinally, thus permitting a ready access of nourishment to all parts of the marrow. In a broad way it might be stated that the indication for bone transplantation was destruction of bone either by disease or trauma.

DR. ARPAD G. GERSTER said that Dr. Berg had presented the biological process and the theories of bone formation very well. He believed that Axhausen was right, but he was by no means as absolutely sure of it as the reader of the paper; fundamentally there was much of truth, however, in his work. He had seen most of Dr. Berg's cases as they had occurred in his clinic at Mount Sinai Hospital and had followed them with interest because this branch of surgery had been neglected in this country. The fact that bone had been transplanted into an infected wound and had grown taught that one need not have a superstitious fear of infection in these cases, but of course the infection must not be of the rapid and progressive form. Many great advances in the treatment of injuries to bone had come from this country, as for instance the treatment of compound fractures, Buck's extension, and the lateral extension apparatus. These inventions were the result of opportunities furnished by the Civil War. In bone transplantation there was another opportunity to show what could be done.

DR. DELANCY CARTER said that his experience with bone transplantation did not coincide with that of Dr. Berg. He had had the opportunity of transplanting bone into soft tissue and he thought this offered a better opportunity to judge of the correctness of the theory. He had reconstructed a nose by transplanting a portion of bone tissue from the ninth rib, using hard compact bone without the periosteum. He inserted the bone graft under the nasal periosteum and it had not been absorbed, even though it had had no periosteum itself. He had done a bone transplantation in fifteen cases and had had bad results in only one instance. In this case he used bone from a patient who had just been operated upon. He also cited a case where he did a plastic operation in order to replace paraffin in a patient who had been operated on twice before. He used three pieces of bone for the sides and bridge of the nose and obtained good results.

DR. FRED H. ALBEE said that his experience with bone transplantation embraced 42 cases, the largest number of these being Pott's disease. He imbedded the bone graft into a bed of bone. He thought that lack of function was responsible for a great deal of the absorption that took place. He had done some experimenting on animals and had found that bone devoid of periosteum could be transplanted and live. It made a great difference, how-

ever, whether it was transplanted into a bed of bone or into soft tissue; the results were much better when it was transplanted into a bone bed. His grafts thickened.

Dr. BERG said that Dr. Carter had said that he transplanted bone into soft tissue and it did not become soft; this was because it became encapsulated and penetrated by blood-vessels, but morphologically it was dead bone. It might remain without being absorbed, but it was not a part of the living structure but merely a foreign body. As regarded the difference of density being accounted for by immobility, as he had shown in his a-ray plates, density increased at the periosteal layer while the bone was being replaced. Bone in soft tissue might remain for a time but it would not stay permanently.

The Results of Renal Decapsulation for Bright's Disease.—Dr. SAMUEL LLOYD read this paper. (See page 1030.)

Dr. ARTHUR F. CHACE said that, now that the first burst of enthusiasm over the operation of decapsulation for chronic Bright's disease had died out, they were in a position to look at the subject fairly and he thought that Dr Lloyd's indicatinns for the operation were most reasonable. By careful tests he had found that the clinical symptoms were a very good guide as to the degree of kidney function.

Dr. CHARLES GILMORE KERLEY cited the case of a child four years of age who had acute nephritis. She had been tapped on several occasions. After a third severe exacerbation of the trouble she was operated upon. At the time she was thoroughly water-logged. Immediately after the operation the kidneys began to act and the way in which the water was disposed of was remarkable. She lost eight pounds in a week and by the end of four weeks the condition of the kidneys was approaching normal when the child was taken with colitis and died.

Dr. Samuel Lloyd said that they quite frequently saw as remarkable results as those that Dr. Kerley had just related. He cited the case of a boy who was so disfigured by nephritis that he did not look like a human being. After decapsulation he lived for four years; then a second operation became necessary, but he did not survive this. They could not depend on a progressive and continuous improvement in these cases after operation. Often there would be relapse after relapse. The most careful medical, dietetic, and hygienic attention was needed. The cure did not come quickly, usually not until about three years after the operation.

Report of a Case of Amputation of Thigh, Upper Third, for Gangrene, Complicated by Aneurysm of the Femoral and Popliteal Arteries, with Presentation of the Patient, Aged 70 Years.—Dr. JOHN H. BRANTH reported this case. He said that on January 5, 1911, when called into consultation to see the patient, he found the left leg and foot cold and the pulsation in the leg not discernible. There was a faint bluish coloration on the second and third toe. The pain was severe, radial pulse rapid and intermittent, and the temperature 101° F. A diagnosis was made of occlusion of the vessels approaching gangrene. Frost bite was thought of and the patient admitted having played cards in a summer cottage where he chilled his feet and then immersed the foot in a vessel of hot water. The sudden change of temperature from below freezing to 120° F. was too much and coagulation of the blood in the vessels followed. Had he rubbed his limb with snow or cold water no injury would have resulted. Dr. Branth cited a case from the literature showing how in the Arctic region an Esquimau with a leg frozen until it was apparently lifeless was treated. He was placed in a snow house with the temperature 20° below zero and the leg bathed in ice cold water for two hours, and then enveloped in furs for three or four hours; friction with snow and then with the feathered side of bird skin was used, alternated with wrapping the limb with furs for nearly twenty-four hours, together with a gradually raising the temperature of the snow house. On the third day, he was walking and had only a small frost bite on his toes. As it was too late for such treatment Dr. Branth's patient was stimulated and given opiates sufficient to control pain and they awaited Nature's signal to make out the line between the living and dead tissue. This line was not precisely demonstrated. The entire foot became black, and also the tibial region and the peroneal side of the leg. The soft tissues near the tibia and fibula were liquefying. The proximity of the knee joint, which if inflamed would end in a fatal result, suggested amputation of the thigh. Femoral myelitis and aneurysm of the femoral and popliteal arteries were not suspected and on finding these conditions a second amputation several inches higher had to be made with the purpose of getting above the infected marrow. A coagulated blood cast of about five inches in length was removed from the femoral artery. The femoral aneurysm was the size of a hen's egg and contained a clot like brown putty, while the aneurysm of the popliteal artery was fusiform; each had a channel for the blood current. The amputated limb was black, withered in the foot, and the muscular tissue was putrid and of gelatinous consistency. After the operation the patient suffered from shock, which was met by the usual remedies and by the end of a week he was on full diet. He was operated upon on February 20 and on March 5, when the dressings were removed, the wound was dry, aseptic, and without even a stitch abscess. These results spoke well for the asepsis during the operation but were due also to the cooling of the saw by a stream of water so that the heat of friction could not injure the bone. The wound was flushed by a pitcher of hot water to remove bone dust and any loose particles before stitching the flaps together. At the first dressing two drainage tubes and one-half the stitches were removed and three days later the remaining stitches and drainage tubes were taken out. The stump could be moved without pain. In some instances there were painful spasms of the stump after this operation. The writer thought this was due to neuroma caused by a blood clot around the nerve's end; this blood clot organized into connective and scar tissue and by contractions caused pain and spasm. In this patient the small arteries of the nerve sheath were ligated about an inch above the cut end of the sciatic nerve.

Dr. WILLIAM STEVENS said that he had watched the progress of this case with interest. He thought that the employment of the hot water to cleanse the surface of the wound after the arteries were ligated was a very important factor in preventing the appearance of pus. The marrow of the bone above the line of amputation was infected and this was cleaned out, relying on the matrix to reproduce it. This reproduction of the marrow would take place just as when two long bones were placed in apposition and a marrow was formed by absorption. Dr. Branth had been very careful and punctilious and after looking over the records of similar cases he thought that this was a remarkably good result.

Dr. J. MILTON MABBOTT said that within the last two weeks he had seen a Civil War veteran who still suffered from spasms of the stump and he was glad there was a way of leaving a stump so that this disagreeable effect of amputation might be avoided.

Dr. Branth said that the termination of the stump was a factor in causing spasm. The muscles and nerves must not be brought too far forward or too far back as that made a conical stump. The action of the hot water was partially to congeal the lymph which glued together the well fitted opposing flaps; this promoted immediate union.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

GESAMMELTE WERKE VON ROBERT KOCH. Vol. I. By Prof. Dr. G. GAFFKY, Prof. Dr. E. PFUHL and Prof. Dr. J. SCHWALBE. 700 pages; illustrated; paper; price 40 M. Georg Thieme, Publisher, Leipzig.

GESAMMELTE WERKE VON ROBERT KOCH. Vol. 2. Part I. By Prof. Dr. G. GAFFKY, Prof. Dr. E. PFUHL and Prof. Dr. J. SCHWALBE. 680 pages. Part II, 530 pages; illustrated; paper; price 40 M. Georg Thieme, Publisher, Leipzig.

A COMPEND OF HUMAN PHYSIOLOGY. By ALBERT P. BRUBAKER, A.M., M.D. 248 pages; illustrated; cloth; price $1.25 net. P. Blakiston's Son & Co., Publishers, Philadelphia.

PROCEEDINGS OF THE ROYAL SOCIETY OF MEDICINE. Vol. V, No. 5. 132 pages; paper; illustrated; price 7 shillings and sixpence net. Longmans, Green & Co., Publishers, London, New York, Calcutta, Bombay.

BRONCHIAL ASTHMA. ITS PATHOLOGY AND TREATMENT. By J. B. BERKART, M.D. Revised and Abridged Third Edition. 150 pages; illustrated; cloth; price $2.00 net. Oxford University Press, Publishers, London, Edinburgh, New York, Toronto and Melbourne.

REPORT RELATING TO THE REGISTRATION OF BIRTHS, MARRIAGES AND DEATHS IN THE PROVINCE OF ONTARIO FOR THE YEAR ENDING 31ST DECEMBER, 1910 (Being the 41st Annual Report). Printed by order of the Legislative Assembly of Ontario. 281 pages; paper.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Illinois State Board of Health Physicians' Examination.

January 17-19, 1912.

ANATOMY.

1. Give the articulations of the inferior turbinate bone.
2. Where are the medulla oblongata, the pons Varolii and the cerebellum located, and how are they separated from the cerebral hemispheres?
3. Name the nerves that supply the muscles of the forearm and hand.
4. Where does the internal carotid artery commence? Where does it terminate and into what does it divide?
5. In tapping the pericardium, where should the puncture be made in order to avoid the pleura?
6. What bones form the articular surface of the knee-joint? Name the ligaments of the knee-joint.
7. Name the tunics, or coats, of the eye, from without inward; also the refracting media, or humors, of the eye.
8. Name the branches of (*a*) the ascending aorta; (*b*) arch of the aorta.
9. Give origin, insertion, action and nerve supply of the brachialis anticus muscle.
10. Where does the right lymphatic duct empty its contents? What prevents regurgitation of blood into these ducts?

PHYSIOLOGY.

1. Name the structures entering into the formation of a joint. What is meant by diarthrosis, amphiarthrosis, and synarthrosis? Give example of each.
2. What is meant by Wallerian degeneration?
3. State the estimated quantity of the secretion of the following body juices and fluids in twenty-four hours: saliva, gastric juice, pancreatic juice, bile, and urine. State chemical reaction of each.
4. State the various changes which a fat and carbohydrate food undergoes after being taken into the mouth until reaching the circulation. Where do they enter the circulation?
5. State the rate of respiration per minute in a child one year old. Give the vital capacity of the adult lung.
6. Define eupnea, hyperpnea, apnea, dyspnea and asphyxia.
7. Name and describe the three orders of levers found in the human body. Give example of each.

NEUROLOGY.

1. Define pachymeningitis, leptomeningitis and syringomyelia.
2. Give diagnostic difference between catalepsy and epilepsy.
3. Give diagnostic difference between paralysis agitans and locomotor ataxia.

CHEMISTRY.

1. What important compound does carbon form with nitrogen and oxygen? Give formula of compound.
2. Give the formula of chlorate, bromate and iodide of sodium.
3. What do the following symbols represent: NH_3, NH_4Cl, N_2O, $NaHSO_4$?
4. Name the principal oxygen derivatives of the hydrocarbons.
5. How would you proceed to examine substances for arsenic?

ETIOLOGY AND HYGIENE.

1. What is the etiology of bronchopneumonia?
2. Give the etiology of chronic endocarditis.
3. What is the etiology of diabetes insipidus?
4. How may milk become a factor in the causation of disease or become a disease carrier? What means would you recommend to prevent the transmission of disease by milk?
5. What hygienic measures would you recommend to prevent or diminish the severity of cholera infantum?

MATERIA MEDICA AND THERAPEUTICS.

1. Name several of the solvents commonly used in the preparation of drugs, and give advantage of each. What are the objections, if any, to mixing alcoholic with aqueous solutions? Give examples.
2. Give names and general physiological actions of one or more of the convulsant series of drugs, with dose and use.
3. Name five alkaloids. What are some advantages of the employment of alkaloids? Give doses of three and the action and use of one.
4. Give dose, action, and use (local and internal) of atropin sulph. Why is atropin combined with morphine in hypodermic tablets?
5. Give classification, action, dose, dangers, and indications for use of pilocarpin.
6. Give physiological action, contraindications, dose, and use of preparations of thyroid gland.
7. Give dose, action, uses, and dangers of phenyl salicylate.
8. Name two general anesthetics. Give action, uses, and dangers of one of them.
9. Give the action, dose, dangers, uses, and contraindications of digitalis.
10. Give the action and use of one of the preparations of calcium used in medicine.

PATHOLOGY.

1. Give the pathology of ophthalmia neonatorum.
2. Define cyanosis, and give the pathological cause.
3. What is an atheromatous degeneration? Give pathology.
4. What are the pathological changes in a chronic enteritis?
5. Describe metastatic abscess formation.

BACTERIOLOGY.

1. Give methods of staining gonococci. Describe their appearance.
2. What is tuberculin? Describe the general reaction following the use of tuberculin.
3. What are the bacterial findings in puerperal septicemia?
4. Name and describe the microorganism of Asiatic cholera.
5. What microorganisms are most frequently related etiologically to the development of surgical septicemia?

PRACTICE OF MEDICINE.

1. Given a moderate regurgitation at the aortic orifice of two years' duration, this being the only valvular lesion present, describe the necessary concurrent physical signs and give the treatment.
2. Differentiate between reflex, gastric, and cerebral vomiting, and outline the treatment of gastric vomiting.
3. Name the principal complications of diabetes, and give the treatment of each.
4. Differentiate encephalic tumor from abscess of the brain.
5. Describe (a) circulatory, (b) urinary findings in a case of chronic contracting nephritis, and give prognosis and dietetic management.
6. Give the symptoms and treatment of epidemic influenza.
7. Distinguish cystitis from pyelitis, and give treatment of the latter.
8. What acute infections are liable to cause inflammation of the endocardium? How would you treat one of them?
9. Give the diagnosis of tuberculous cystitis, the treatment and prognosis.
10. What diseases are usually associated with the following: Corrigan pulse, hematemesis, hemoptysis, jaundice, dropsy of lower extremities, crepitant râles, high blood pressure, increased frequency of pulse without fever, cyanosis, vesicular breathing. (Name the disease or diseases separately for each of the above symptoms or conditions.)

OBSTETRICS.

1. What changes occur in the uterine appendages during pregnancy?
2. What are the probable signs of multiple pregnancy?
3. What are the symptoms of polyhydramnios?
4. How are abortions usually classified? What are the symptoms of inevitable abortion?
5. Discuss concealed hemorrhage.
6. Outline treatment of puerperal eclampsia.
7. Discuss the diagnosis of presentations.
8. Give treatment in case of prolapsed cord.
9. What are the symptoms of acute inversion of the uterus?
10. Discuss the methods of performing version.

SURGERY.

1. Name the surgical diseases of the mammary gland and outline treatment of the same.

2. Make a diagram of the regional anatomy of the abdomen, and name the vital organs located in the epigastric region.
3. Classify wounds, and describe the variety most commonly infected, and give manner of infection.
4. Outline the management of a case of erysipelas.
5. Give symptoms and diagnosis of cerebral concussion.
6. Describe four varieties of gastric ulcers. Give occurrence of each.
7. Give indications for aspiration of urinary bladder, and describe the operation.
8. Give the pathology of gummata, and outline surgery of same.
9. Classify the different varieties of ankylosis, and give pathology of one variety.
10. Name the congenital deformities of the spine.

PHYSICAL DIAGNOSIS.

1. Describe in detail an examination of the urinary bladder.
2. What are the physical signs of incipient pulmonary tuberculosis?
3. Differentiate regurgitation at the aortic valve and at the mitral valve.
4. What are the signs by which one recognizes fluid in the peritoneal cavity?
5. Enumerate the signs of obstruction of the portal vein.
6. What are the physical signs of lobar pneumonia?

OPHTHALMOLOGY AND OTOLOGY.

1. Give the time of appearance and diagnosis of presbyopia ophthalmia.
2. Discuss the etiology and sequelæ of otitis media.

PEDIATRICS.

1. Give symptomatology and diagnosis of marasmus.
2. What is modified milk? Give schedule for feeding from birth.

GYNECOLOGY.

1. Give the causes, physical signs and treatment of pelvic peritonitis.
2. Give the diagnosis, prognosis, and treatment of uterine fibroids.
3. Name the varieties of ovarian cysts and describe each.
4. Which route is to be selected in the operation of cystotomy in the female? Give the technique of operation.
5. Describe the operation of trachelorrhaphy.
6. What is vaginismus? Give etiology and treatment.

LARYNOLOGY.

1. Describe method of intubation of the larynx.

RHINOLOGY.

1. Mention two varieties of nasal polypi. Give symptoms and treatment.

MEDICAL JURISPRUDENCE.

1. What are the most common accidental forms of death in the new born.
2. Differentiate between burns inflicted during life and those inflicted after death.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

ILLINOIS STATE BOARD OF HEALTH PHYSICIANS' EXAMINATION.

January 17-19, 1912.

ANATOMY.

1. The *inferior turbinated bone articulates with* the ethmoid, superior maxillary, lacrymal, and palate bones.
2. The *medulla* extends from the foramen magnum to the lower border of the pons varolii.
The *pons varolii* is at the base of the brain, between the medulla and crura cerebri; in front of the cerebellum.
The *cerebellum* is behind the pons and medulla and below the hinder portion of the cerebral hemispheres.
All these structures are in the posterior cranial fossa, and they are separated from the cerebral hemispheres (which are above them) by the tentorium cerebelli.
3. The *nerves which supply the muscles of the forearm and hand* are: The median, ulnar, musculospiral, and posterior interosseous.
4. The *internal carotid artery commences* at the bifurcation of the common carotid, opposite the upper border of the thyroid cartilage; it *terminates* in the middle fossa of the cranium, near the beginning of the Sylvian fissure; it *divides into* the middle cerebral and anterior cerebral arteries.
5. In *tapping the pericardium* the puncture should be made in the fifth or sixth left intercostal space, near to the edge of the sternum. If the pericardial sac is much distended the puncture may safely be made one inch external to the border of the sternum; this will be external to the internal mammary vessels. In both cases the pleura will be avoided.
6. The *articular surface of the knee joint* is formed by the femur, tibia, and patella. The *ligaments* are: Capsular, anterior, posterior, internal lateral, two external lateral, anterior or external crucial, posterior or internal crucial, transverse, coronary, and two semilunar fibrocartilages.
7. The *tunics or coats of the eye*, from without inward, are: (1) The cornea and sclerotic; (2) choroid, ciliary body, and iris; and (3) the retina.
The *refracting media* are: The aqueous humor, the crystalline lens, and the vitreous body.
8. *Branches of the ascending aorta:* Right coronary and left coronary arteries.
Branches of the arch of the aorta: Innominate, left common carotid, and left subclavian arteries.
9. BRACHIALIS ANTICUS. *Origin:* Lower two-thirds of anterior surface of shaft of humerus, and from intermuscular septa. *Insertion:* Inferior surface of coronoid process and adjacent surface of shaft of ulna, and into anterior ligament of elbow joint. *Action:* Flexor of forearm. *Nerve supply:* Musculospiral and musculocutaneous.
10. The right lymphatic duct empties its contents into the right subclavian vein at its angle of junction with the right internal jugular vein. Regurgitation of blood into the duct is prevented by two semilunar valves which guard its orifice.

PHYSIOLOGY.

1. *Structures entering into the formation of a joint:* The articular ends of two or more bones, cartilage, fibrocartilage, ligament, and synovial membrane.
Diarthrosis is a freely movable joint, as the knee.
Amphiarthrosis is a slightly movable joint, as the inferior tibio-fibular articulation.
Synarthrosis is an immovable joint, as that between the sphenoid and vomer.
2. *Wallerian degeneration:* "When a nerve is divided the first result is a loss of its function. Inasmuch as each nerve-fiber develops from a cell which later nourishes it, if the connection between the two is severed the nerve-fiber undergoes Wallerian degeneration, and in the case of a nerve which is made up of nerve-fibers the whole nerve undergoes this change. This degeneration consists, in the case of medullated nerves, in the death of the axis-cylinder, the breaking up of the medullary sheath into drops of myelin, which are later absorbed, and the multiplication of the nuclei of the primitive sheath. In non-medullated nerves the only result is the death of the axis-cylinder. Degeneration begins very soon after the section—within a day or two—and throughout the entire severed portion of the nerve at the same time. Thus the course of a nerve, or a collection of nerves, may be traced throughout its entire extent. These changes are believed to be due to the severance of the nerve from its trophic center. If an anterior root of a spinal nerve is divided, the distal end, being separated from the gray matter of the cord, which is its center of nutrition, undergoes degeneration, while the end which remains connected with the cord retains its integrity. If a posterior root is divided between the cord and the ganglion the degeneration takes place between the cord and the ganglion; while if divided below the ganglion the degeneration takes place in that portion separated from the ganglion, showing that the ganglion is the nutritive center for the posterior root."—(Raymond's *Physiology.*)
3.

	CHEMICAL REACTION.	AMOUNT SECRETED IN 24 HOURS.
Saliva	Alkaline.	About 2½ pounds.
Gastric juice	Acid.	About 10 or 12 pounds.
Pancreatic juice	Alkaline.	About 1½ pounds.
Bile	Alkaline.	About 2½ pounds.
Urine	Acid.	About 40 to 50 ounces.

4. *Fats* are not digested in the mouth or stomach; in the small intestine they are acted upon by the steapsin of the pancreatic juice and by the bile. These two agents cause the fats to be emulsified and saponified. The fats are absorbed by the villi, and are conveyed to the circulation by means of the thoracic duct, which enters the venous circulation at the junction of the left subclavian and internal jugular veins.

Carbohydrates. The saliva (by its ptyalin) changes starches into dextrin and sugar; the stomach does not aid in the digestion of carbohydrates; in the small intestine the amylopsin of the pancreatic juice changes starches into dextrins and sugar, and the invertin of the succus entericus changes cane sugar into invert sugar. Carbohydrates are absorbed in the small intestine and converted by the portal vein to the liver, and thence by the hepatic vein to the ascending vena cava.

5. A child one year old respires about thirty times a minute. The vital capacity of the adult lung is about 230 cubic inches.

6. *Eupnea* is the condition in which respiratory action is easy or normal. *Hyperpnea* means exaggerated respiratory action. *Apnea* means cessation of respiratory action. *Dyspnea* means difficulty in breathing. *Asphyxia* is unconsciousness due to interference with the oxygenation of the blood.

7. Levers of the *first order* have the fulcrum between the weight or resistance and the power or moving force; the skull, in its movements backward and forward on the atlas, is an example. Levers of the *second order* have the weight between the fulcrum and the power; as in depression of the lower jaw. Levers of the *third order* have the power between the fulcrum and the weight; as in flexion of the forearm.

NEUROLOGY.

1. *Pachymeningitis* is inflammation of the dura mater. *Leptomeningitis* is inflammation of the arachnoid and pia mater. *Syringomyelia* is a condition characterized by the presence of cavities in the substance of the spinal cord.

2. In *catalepsy* there is loss of will, muscular rigidity, generally loss of consciousness, and it is often associated with hysteria.

Epilepsy is diagnosed by the aura, the sudden onset, the cry, the sudden loss of consciousness, the tonic convulsion, the biting of the tongue, the dilated pupils, and the urinary incontinence. In *hysteria* the patients do not generally hurt themselves.

CHEMISTRY.

1. Urea; CON_2H_4.

2. Sodium chlorate, $NaClO_3$; sodium bromate, $NaBrO_3$; sodium iodide, NaI.

3. NH_3, ammonia; NH_4Cl, ammonium chloride; N_2O, nitrous monoxide; $NaHSO_4$, monosodic sulphate.

4. Alcohols, aldehydes, acids, ethers, ketones.

5. *Test for arsenic:* Reinsch's test is as follows: To the suspected fluid add a little pure HCl; suspend in the fluid a small strip of bright copper foil, and boil. If a deposit forms on the copper, remove the copper, wash it with pure water, dry on filter paper, but be careful not to rub off the deposit. Coil up the copper, and put it into a clean dry glass tube, open at both ends, apply heat at the part where the copper is. If arsenic is present there will appear in the cold part of the tube a mirror, which will be found on microscopical examination to consist of octahedral crystals of arsenic trioxide.

ETIOLOGY AND HYGIENE.

4. The milk may come from a diseased cow; it may become contaminated by the milker, the container, the surroundings, the water used to wash the cans or to adulterate the milk; or it may become contaminated at the dealer's or purchaser's house by being left uncovered, exposed to flies, etc., or by not being kept in a cool place. The only way to prevent the transmission of disease by milk is to insist on a thorough inspection of all dairies and sources of milk supply, and to educate the public in the care of milk between the time of its purchase and its consumption. The inspection should include: the color, reaction, specific gravity, sediment, taste, odor, acidity, total quantity of solids and of water; the percentage of cream, fats, lactose, casein and ash; the presence or absence of preservatives, coloring matter, added solids, dilution, pathogenic microorganism, dirt or other foreign matter. There should also be thorough investigation as to its source, the cows and their environment, the method employed in caring for, milking, storing, and transporting the milk.

MATERIA MEDICA AND THERAPEUTICS.

1. *Solvents used in pharmacy:* Water, alcohol, glycerin, ether, chloroform, benzine, carbon disulphide, oils, and acids. *Alcohol:* Solutions in alcohol will keep almost indefinitely; gums, albumins, and starch are insoluble in alcohol. *Glycerin:* If concentrated, glycerin is antiseptic. *Ether* is a good solvent for resins, fats, oils, and some alkaloids and neutral principles. *Chloroform* is not inflammable. *Carbon disulphide* is a good solvent for rubber and phosphorus. *Oils* are used in making liniments.

2. *Strychnine* is a convulsant. *Action:* Strychnine is a bitter tonic, stimulates appetite, secretion, and digestion, increases peristalsis, stimulates the vasomotor centers, and so raises arterial tension; it stimulates both accelerator and inhibitory nerves of the heart. All the functions of the spinal cord are exalted by strychnine, reflex, motor, vasomotor, and sensory. Large doses cause dilated pupils, irregular and jerky respiration, increased reflexes. *Therapeutic uses.* For indigestion, intestinal torpor, heart disease, pneumonia, amenorrhea, dysmenorrhea, paralysis, impotence, and as a cardiac and respiratory stimulant. *Dose:* Strychnine sulphate, one-sixty-fourth of a grain; strychnine nitrate, one-sixty-fourth of a grain.

3. *Five alkaloids:* Quinine, atropine, aconitine, cocaine, and strychnine. *The alleged advantages of the employment of alkaloids* are: Prompt action, accurate dosage, no inert or foreign matter is given which may mask the action of the drug, and there are no nauseating doses for the patient to take. *Doses of three:* Aconitine, gr. 1/400; atropine sulphate, gr. 1/100; morphine sulphate, gr. 1/6. For action and use of strychnine see QUESTION 2.

4. ATROPINE: *Dose,* gr. 1/100.

Action: Anodyne, mydriatic, inhibits secretions, depressant of terminations of nerves, accelerates the heart beat, causes rise in blood pressure, but toxic doses cause the blood pressure to fall, stimulates the respiratory center, but large doses depress the same; it may cause vertigo, restlessness, excitement, delirium, or mania.

Therapeutic indications: For the relief of pain, to dilate the pupil, to check secretions, for diarrhea, for asthma, for shock and collapse, for colic of all kinds, for delirium, for epilepsy, chorea and migraine, for paralysis, for cough, in constipation, in chorea, spermatorrhea, or cystitis.

Atropine is often combined with morphine when the latter is used, for the following reasons: (1) To prevent nausea and insomnia; (2) to intensify the effect of the morphine, and so a smaller dose may suffice; (3) to neutralize the effect on the pupils.

5. PILOCARPINE is *classified* as a diaphoretic. *Action:* It causes increase of saliva and of perspiration; increased peristalsis; it increases and then diminishes blood pressure and heart action; it causes the pupil to contract and depresses the nervous system. *Dose:* gr. 1/5 of the hydrochloride. *Dangers.* Marked cardiac and respiratory depression, nausea, vomiting, and collapse. *Indications for use:* Bright's disease, uremia, eclampsia, pleural effusion, dropsy, and whenever prompt diaphoresis is required.

6. THYROID GLAND. *Action:* "It is a powerful vasomotor dilator, causing flushing of the cutaneous surface; large doses are apt to produce loss of appetite and diarrhea; it stimulates the cerebrum, and, given to excess, produces headache, restlessness, insomnia, palpitations, hot flushes, sweating, tremors, and even convulsions; it is excreted by the kidneys, and the quantity of urine is uniformly increased by it; it induces a greatly increased oxidation in the system. *Uses:* Myxedema; goiter (especially the hyperplastic follicular variety); sporadic cretinism; arteriosclerosis; delayed menstruation."—(Wilcox's *Materia Medica.*) *Dose:* 4 grains. *Contraindications:* Diabetes mellitus and in great emaciation.

7. PHENYL SALICYLATE. *Dose:* 7½ grains. *Action:* antiseptic, germicidal, anodyne, and antipyretic; it combines, in most respects, the actions of phenol and salicylic acid. *Uses:* As a disinfectant, in inflammation of the mouth and pharynx, in cystitis, as an intestinal antiseptic in typhoid fever, in muscular rheumatism, in intestinal indigestion and fermentation, in cholera. *Dangers:* In the small intestine it is decomposed into salicylic acid and carbolic acid, and symptoms of carbolic acid poisoning may develop.

9. DIGITALIS. *Physiological action:* It is a gastrointestinal irritant, it slows the rate of the heart, prolongs diastole, increases the force of the heart, it contracts the blood-vessels, and causes a rise in blood pressure, it also acts as a diuretic. *Therapeutic use:* Digitalis is indicated in diseases of the heart: (1) when the heart action is rapid and feeble, with low arterial tension; (2) in mitral lesions when compensation has begun to fail; (3) in nonvalvular cardiac affections; (4) in irritable heart, due to nerve exhaustion. Digitalis is *contraindicated* in diseases of the heart: (1) in aortic lesions when uncombined with mitral lesions; (2) when the heart action is strong, and arterial tension high. Digitalis is also a diuretic; and it is also used in some forms of nephritis, exophthalmic goiter, pneumonia, chronic bronchitis, etc. *Dangers: Overdose or constant use* will cause irregularity of the heart, headache, vomiting; and hobbling dicrotic pulse, particularly when the patient changes from the recumbent to a sitting posture. *Dose.* Of the tincture, 15 minims.

10. CALCIUM PHOSPHATE. *Action:* It is supposed to

build up the solid tissues of the body, and to give them proper consistence and solidity. *Uses.* It is given in rickets, tuberculosis, scrofula, molluscs fibrosum, anemia, syphilis, and neurasthenia.

PATHOLOGY.

2. *Cyanosis* is a bluish discoloration of the skin due to non-oxidation of the blood. It is caused by local or general circulatory disease; heart disease, emphysema, pneumonia, and asthma.

BACTERIOLOGY.

1. The *Gonococcus* is a diplococcus with a special predilection for the mucous membrane of the urethra and vagina. It is sometimes found on the conjunctiva. The appearance is that of two coffee beans; the gonococcus is found in the pus cells, stains with ordinary aniline dyes, but not by Gram's method. It is aerobic, and can be cultivated on human blood serum; it will not grow on gelatin, agar, bouillon, or potato. It was discovered by Neisser.

To demonstrate *gonococci:* On a cover-glass make a smear with the discharge as thin as possible, and let it dry in the air; cover it with a freshly made solution of anilin-oil-gentian-violet for one or two minutes; wash it in distilled water; leave it in Gram's solution for two minutes; wash it in 95 per cent. alcohol until decolorized; wash it in distilled water; counterstain with a dilute carbolfuchsin without heat, or with a saturated aqueous solution of Bismark brown; wash in distilled water, dry with filter paper, mount, and examine with an oil-immersion lens. The gonococci will appear as *diplococci within the leucocytes*, which have been *decolorized by Gram's stain*, and have taken the counterstain.

2. *Tuberculin* is a glycerin extract of cultures of the bacillus of tuberculosis. It is used as a means of diagnosis and treatment of tuberculosis. For the *reaction* see French's "Practice of Medicine" (1910), page 391.

5. *Streptococcus pyogenes, pneumococcus, Staphylococcus pyogenes*, and colon bacillus.

2. PRACTICE OF MEDICINE.

CEREBRAL VOMITING.	GASTRIC VOMITING.
Little or no nausea, vomiting continues after stomach is emptied.	Nausea relieved by vomiting, returns when food is taken.
No tenderness on pressure over the liver or stomach.	Liver and stomach are tender, pressure produces inclination to vomit.
Pulse infrequent and hard.	Pulse frequent and weak.
Tongue clean, breath sweet, conjunctivæ normal or injected, headache primary.	Tongue furred, breath offensive, conjunctivæ often yellowish, headache secondary as to time.
Constipation generally obstinate.	Griping abdominal pain, diarrhea and clay-colored stools.
No salivation	Increased salivation.

(Potter.)

Reflex vomiting is found in pregnancy, uterine or ovarian disease, worms, irritation of the fauces.

4.

TUMOR OF BRAIN.	ABSCESS OF BRAIN.
1. No primary focus of infection but often history of syphilis or malignant disease of other organs.	1. Suppurating area in ear, nose, pharynx, scalp, or lung abscess.
2. Very slow development.	2. More rapid.
3. More definite focal symptoms.	3. Focal symptoms often present, but not so definitely localized as in tumor.
4. No rigors or septic symptoms.	4. Often begins with chills, septic symptoms often continue.
5. Temperature normal or slightly and irregularly elevated.	5. Temperature subnormal, other times higher—pus temperature.
6. Pulse slow.	6. Not slow as a rule.
7. Constant headache.	7. Not a constant or prominent symptom.
8. Projectile vomiting frequently present.	8. Not often; vomiting, if present, more frequent and not projectile.
9. General symptoms of pressure progressive.	9. When present they vary greatly in intensity.
10. Choked disc constant.	10. Not constant.

(Eisendrath's *Surgical Diagnosis.*)

10. *Corrigan pulse* is usually associated with aortic regurgitation; *hematemesis*, with gastric ulcer or carcinoma, leukemia, splenomegaly, pernicious malarial fever, yellow fever, scurvy, chronic heart disease, and corrosive poisoning; *jaundice*, with yellow fever, Weil's disease, acute yellow atrophy of liver, various poisons, gastroduodenitis, and catarrh, gallstones, or parasites in the bile ducts; *dropsy of lower extremities*, with cardiac dropsy, hepatic cirrhosis, abdominal tumors, or enlarged viscera; *crepitant rales*, with lobar pneumonia and hemorrhagic infarction of lung; *high blood pressure*, with chronic intestinal nephritis, gout, arteriosclerosis, uremia, and lead poisoning; *increased frequency of pulse without fever*, with exophthalmic goiter, endocarditis with loss of compensation, acute endocarditis, and pericarditis; *cyanosis*, with congenital heart disease, asthma, emphysema, stenosis of or foreign body in glottis, trachea or bronchi, croup, pneumonia, bronchopneumonia, and pleurisy with effusion; *vesicular breathing*, with consolidated or congested lung, and in many cases of dyspnea.

SURGERY.

2. In the *epigastric region* are: Part of stomach, liver, gall-bladder, pancreas, duodenum, suprarenal capsules, and the kidneys.

7. Aspiration of the urinary bladder is indicated in retention of urine. Suprapubic puncture is performed as follows: "Having outlined the distended bladder by percussion—a curved cannula and trocar (which are better than the straight) are taken in the operator's right hand, with the convexity upward, and so held, with the index-finger upon the shaft of the instrument, that the depth to which it may enter the bladder is fixed in advance. The bladder is steadied by the surgeon's left thumb and index placed on each side of the median line. The instrument is thrust sharply but gently into the bladder, entering in the median line just above the symphysis pubis, and directed backward and downward—piercing skin, superficial fascia, passing between the inner borders of the recti and pyramidales (or through their muscular substance), prevesical space, anterior bladder-wall, and into the bladder. The trocar is then withdrawn and the cannula left *in situ* until the urine has come away, chiefly of its own accord, and partly aided by gentle pressure. Upon withdrawal of the instrument the opening is at once closed by sterilized cotton and collodion." (Bickham's *Operatic Surgery.*)

PHYSICAL DIAGNOSIS.

2. The early manifestations of pulmonary tuberculosis are: (1) *Physical signs:* Deficient chest expansion, the phthisical chest, slight dullness or impaired resonance over one apex, fine moist râles at end of inspiration, expiration prolonged or high pitched, breathing interrupted. (2) *Symptoms:* General weakness, lassitude, dyspnea on exertion, pallor, anorexia, loss of weight, slight fever, and night sweats, hemoptysis.

3.

AORTIC DISEASE.	MITRAL DISEASE.
Symptoms are mainly due to anemia, viz.:	Symptoms are mainly due to venous congestion, viz.:
1. Pallor.	1. Cyanosis.
2. Throbbing of the carotids.	2. May get pulsation in the veins of the neck.
3. Attacks of an "angina pectoris" type of pain.	3. Sudden attacks of severe dyspnea—actual acute pain is rare.
4. Breathlessness on slight exertion.	4. Breathlessness, but often present without exertion.
5. Nervous symptoms are prominent, owing to cerebral anemia. Syncopal attacks are also common.	5. Pulmonary symptoms are most prominent, *i.e.* cough in the morning, chronic bronchitis, hemoptysis, dilated right side of heart, and later symptoms due to tricuspid leakage.
7. The *left ventricle* is usually much hypertrophied.	7. The *left auricle* is somewhat hypertrophied, but the main hypertrophy is that of the *right ventricle.*

—(From Wheeler and Jack's *Handbook.*)

OPHTHALMOLOGY AND OTOLOGY.

1. *Presbyopia* generally appears between the fortieth and forty-fifth years. "The presbyope is compelled to hold reading, writing, sewing, and other forms of near work farther away than the usual distance, making such efforts

uncomfortable. With this recession of the near point beyond the usual situation, the print becomes pale and indistinct, and fine type can be read only with great difficulty. The patient is apt to use strong illumination. This produces contraction of the pupil, and thus improves the definition by diminishing the circles of diffusion. If the condition be uncorrected he suffers from asthenopic symptoms, especially pain, fatigue, lacrymation, dimness of vision, and irritation of the lids, all of these symptoms being more marked in the evening with artificial illumination. Presbyopia has no effect upon distant vision."—(May's *Diseases of the Eye.*)

2. *Otitis media* (inflammation of the middle ear, tympanum, or drum cavity) is divided into four clinical forms, viz., acute catarrhal, chronic catarrhal, acute purulent, and chronic purulent otitis media.

Acute catarrhal otitis media is frequently caused by acute coryza and the infectious fevers. There is a painless obstructed sensation in one or both ears, impairment of hearing, and tinnitus. The inflammation causes closure of the eustachian tube.

Acute purulent otitis media: Acute catarrhal otitis media, instead of undergoing resolution, may pass into acute purulent otitis media (especially in exanthemata) from the passage of pathogenic germs from the nasopharynx into the middle ear. The pain will become more intense, the hearing dull, tinnitus will become louder and more distressing, and fever usually sets in.

Chronic purulent otitis media is due to the permanent lodgment of staphylococci in the acutely inflamed middle ear. This unfortunate result is usually brought about by improper—*i.e.* excessive—treatment of acute otitis media, generally by the patient, but sometimes, regrettably, by the physician.

Chronic catarrhal otitis media results from acute catarrhal otitis media that has failed to undergo resolution. Nasopharyngeal catarrh is usually associated with this condition. The onset is gradual, and is characterized by repeated attacks of the acute form, each one increasing in severity. As the symptoms of tinnitus and deafness increase there may be attacks of ear vertigo of tympanic origin. These may be mistaken for neurasthenia, epilepsy, apoplexy, etc. Early in the case there are contraction of the tensor tympani, retraction of the chain of auditory ossicles, and consequent impaction of the stapes in the oval window. *Complications* are inflammation of the mastoid cells, caries and necrosis, phlebitis, meningitis, and brain abscess.—(From Gould and Pyle's *Cyclopedia of Medicine and Surgery.*)

PEDIATRICS.

1. MARASMUS may be congenital, due to poverty or artificial feeding, overcrowding. *Symptoms:* Loss of weight, an old look, wrinkled skin, legs like drum sticks, prominent abdomen, hollow temples, shrunken fontanels, large eyes, sharp features, anemia, hemic murmur, edema, vomiting, loss of appetite. *Diagnosis* depends on symptoms, but it may be difficult to differentiate it from malnutrition.—(From Holt.)

2. *Modified milk* is cow's (or other) milk in which the proportion of the ingredients has been changed so that the milk may resemble mother's milk as much as possible.

GYNECOLOGY.

1. ACUTE PELVIC PERITONITIS. *Etiology:* Infection. *Symptoms:* Intense and diffuse abdominal pain, tenderness, and distention; vomiting, constipation, elevation of the temperature (103°-104° F.), small, hard, rapid, and wiry pulse (120-140), and increased respiration (30-40) of a painful character are also present. The dorsal decubitus with the legs and thighs drawn up is assumed. The duration is from six to nine days and the prognosis is unfavorable. *The treatment* consists in rest in bed, the administration of opium or one of its alkaloids, and the application of hot or cold fomentations or turpentine stupes to the abdomen. If the affection is due to septic infection a saturated solution of magnesium sulphate should be given. If suppuration has occurred abdominal section should be performed with irrigation of the peritoneal cavity with normal salt solution (temperature 105°-110° F.) and the introduction of drainage.—(Gould and Pyle's *Pocket Cyclopedia.*)

2. UTERINE FIBROIDS are very common. "They are benign, but are harmful on account of the disturbance produced by them when enlarged, and also on account of the various degenerations which they are likely to undergo. Menorrhagia, metrorrhagia, and pain are the common symptoms of the growths, although in patients with large intestinal and subserous fibroids hemorrhage may be absent. In cases of the submucous tumors (fibroid polypi) bleeding may be extreme. The tumors are usually of slow growth, but sometimes they increase very rapidly in size, causing serious pressure symptoms. The diagnosis is sometimes very difficult and always impossible without physical examination. Uterine fibroma may coexist with pregnancy.

The treatment consists in removal. In cases of subserous fibroid the snare may be used when it is pediculated, and when sessile the capsule may be cut and the growth enucleated. In the subserous and interstitial variety if the patient can be kept under observation and the tumor is small operation should be postponed; otherwise a choice should be made between removal of the uterine appendages, ligation of the uterine arteries through the vagina, myomectomy, and hysteromyomectomy."—(Gould and Pyle.)

4. The *vaginal route* is to be selected in the operation of cystotomy in the female. "The patient is preferably in Sims' position, with the anterior vaginal wall exposed by Sims' speculum. A large sound is introduced through the urethra and its point pressed against the vesical mucosa in the middle of the long axis of the vesicovaginal septum. An incision is now made upon the sound through the septum with the knife or scissors. The point of the sound will then pass through into the vagina. The opening thus made is enlarged so as to extend one inch in the median line of the long axis of the vesicovaginal septum. Its upper end will be about one-half inch from the anterior wall of the cervix uteri, and its lower end the same distance from the neck of the bladder. The margins of the vesical and vaginal mucosa are then united by fine interrupted catgut sutures."—(Dudley's *Diseases of Women.*)

6. *Vaginismus* is a condition of painful and spasmodic contraction of the vaginal orifice, which renders coitus either painful or altogether impossible. The slightest touch causes painful spasms, and examination may be impossible without an anesthetic. Its *causes* are irritable hymen, ulcer, or fissure anywhere in the immediate vicinity, urethral caruncle, caruncular myrtiformes, a long perineum with vaginal orifice placed too anteriorly. The *treatment* consists in removing the cause when possible, tonics and general constitutional treatment, dilatation of the vaginal orifice; local application of a 5 per cent. solution of cocaine will relieve the hyperesthesia and allow coitus. The condition is sometimes incurable.

RHINOLOGY.

1. NASAL POLYPI. These are of two different origins: (1) Inflammatory, and (2) neoplastic.

(1) *Mucous polypi* are merely edematous granulations hanging from the surface of a diseased ethmoid bone, which is affected by rarefying osteitis or caries. They occur in young adults, and cause nasal obstruction, often bilateral. Grow from the middle and superior turbinate bones. They frequently undergo cystic degeneration from the development of cysts in the glands of the mucous membrane covering them.

Treatment: (*a*) Removal by wire snare under cocaine; (*b*) usually a thorough erasion of the lateral mass of the ethmoid or the opening of a suppurating sinus is required, so as to remove the diseased bone.

(2) *Fibrous and sarcomatous polypi:* Consist in all gradations between fibromata and sarcomata, usually beginning as the former and ending as the latter. Occur in children and adolescents most commonly. Grow from the base of the skull and occupy the nasopharynx. Cause nasal obstruction with sanious discharge. *Pressure signs* may be: (1) Pushing down the velum palati and causing asphyxia; (2) expanding the nasal cavities and producing a widening of the nasal bridge; (3) pressing the eyeballs outward; (4) extending into the base of the brain. *When they are malignant* secondary growth may occur in the lymph glands of the neck. In these cases the primary growth is probably a lymphosarcoma of the pharyngeal tonsils.

Treatment is only possible in the early stages. (1) Removal by a snare through the anterior nares; (2) removal through the mouth after splitting the soft palate; (3) removal from the face after turning up the soft parts and enlarging the anterior nares by temporary displacement of the maxillæ.—(Grove's *Synopsis of Surgery.*)

MEDICAL JURISPRUDENCE.

1. *Accidental forms of death in the new-born* include: Asphyxia, hemorrhage, atelectasis, convulsions, malnutrition, malformations, neglect.

2. In *burns* produced *before death:* There is usually a blister, with a bright, red base, and containing a serous fluid, which is albuminous; occasionally there will be no blister if there has been excessive shock; also, there will be a red line of demarcation between the injured and the uninjured parts, and this, being a vital process, is only developed during life. In *burns* produced *after death* there is no true blister, no red base, and gas only is present in place of the serous fluid.

THE BEST MEANS OF COMBATING INFANT MORTALITY.*

By ABRAHAM JACOBI, M.D.,

NEW YORK,

PRESIDENT OF THE AMERICAN MEDICAL ASSOCIATION.

My principal duty and intense pleasure is to tender my thanks to the House of Delegates which selected me for the highest honor in the gift of the medical profession of America, and to my colleagues of all the fifty States who were good enough to approve of its choice. Nor am I under less obligation for their attendance on this occasion to such citizens, men and women, as by their presence here exhibit their interest in things medical and socio-political.

My everlasting gratitude is due for the mode in which this great honor was conferred upon me. Being duly aware of the small measure of my merits, I was overjoyed to have reason to believe that I owed my election to my lack of efforts to secure it. My democratic training and the gentlemanly nature of thirty-five thousand members of the American Medical Association, like the principled citizens of all parties, resent electioneering importunities and abhor the humiliation and demoralization caused by gesticulating and shouting candidates for office and honor. I have the confidence that if there be any in this or any other cultured assembly who is looking for the highest office for the sake of power and preferment only, he will be deservedly disappointed. Whoever *sets out* to be the first, let him be the last. There is only one thing that is and must forever remain first—that is the medical profession of America, as represented in this American Medical Association, and its object, which in all its aims is only one and indivisible. That one and inseparable object is to promote the art and science of medicine, to unite into one compact organization the medical profession of the United States for the purpose of fostering the growth and the diffusion of medical knowledge, of promoting friendly intercourse among American physicians, of safeguarding the material interests of the medical profession, of elevating the standard of medical education, of securing the enactment and enforcement of just medical laws, of enlightening and directing public opinion in regard to the broad problems of hygiene, and of representing to the world the practical accomplishments of scientific medicine.

With all this, my professional friends are conversant. I want to impress it, however, upon our guests, lay friends both present and absent, for I want them to understand from the very wording of the constitution of the American Medical Association that their interests and ours are closely related.

In order to be powerful and influential, you must not only be wise but numerous. In last year's official report you were told that it was not prudent to increase our number. In fact, you are 35,000, and the largest medical association of the world. But please remember that yours is also the largest country of the world. There are 100,000 medical men besides us, with the same rights to enter and the same duties to perform. We have been told that reasons of finance are amongst those which should restrict our number. I appeal to you and to those 100,000 outside. A big bank account appeals to our treasury, but glittering gold alone never saved a country nor a soul. If you have money, it is yours to spend as you have made it. See to it that your House of Delegates spends it in increasing, and consolidating, and strengthening your Association. Our colleagues in the vast country want to be invited; then they will come in. They must learn what we are, and where their interests are—and the interests of the public—from better sources than the hordes of irregular manufacturers and the "freedomers" whose bitter attacks convey what knowledge many millions are permitted to have of the American Medical Association. Let the people understand the meaning of the American Medical Association and its doctors through *our* doings, and not through the scurrilous lies of our and the people's enemies. My hope is for an annual increase of thousands of members. Multiply and be fertile. Stand still awhile, and you invite decline.

It is by vast numbers only that our profession will ever attain its legitimate influence in politics and in society, and such beneficent power as Socrates, Descartes, Kant, and Gladstone claimed for it. The proclamation of a great principle may impress many philosophic minds, but its realization demands the labor of the enlightened democratic masses. That is why from this exalted position of mine I beg to contribute a share to the discussion of a subject which has enjoyed an important place in the best brains and the warmest hearts of our enlightened and philanthropic era. I allude to the great mortality of the infant, and the numerous efforts to combat it. You are acquainted with them all. Many fair results have been accomplished, to add to them is my ambition. Infants must not be born merely to be sick or to die.

The Committee for the Reduction of Infant Mortality of the New York Milk Committee has made an arrangement with the Russell Sage Foundation which will furnish a nurse who will look after a thousand pregnant women, with a view to enable them to bear infants with *improved resistance*. The mother will be provided for in case she is overworked. Which one of the poor is not overworked?

According to the Milk Committee, and other au-

*President's address before the American Medical Association, at the Sixty-third Annual Session, at Atlantic City, June, 1912.

thorities, 17 per cent. of infant deaths are caused by congenital troubles. One-third of all of them occur before the first month has passed. Two great remedies are recommended. One is that no midwife be allowed to handle any of these cases; the other is that after confinement rest be provided for the mothers, and that the children be referred to milk stations. Now, there is no worthier organization than that committee. What it sets out to do, it performs, but it cannot help being restricted to charity so long as one-half of us is condemned to ask and take it, and the other obliged to give and teach. The latter is probably the most valuable performance of the committee. As its activities, like those of its kind all over the country, are meant to be thoroughly altruistic, it is entitled both to praise and to criticism. I hope it will appreciate the former and mind the latter.

Look at that program: first, no midwife for any of the thousand mothers. You ask, "but who?" Second, the Milk Station for the child because the charitable people want rest provided for the mothers, *at the expense of the baby*. If that is a good program for one thousand women and one thousand babies, if that be the best that can be invented or discovered for the one thousand lucky enough to fall into the hands of charity, what is to be done with, or for, or against those millions beyond the reach of the Sage Foundation? But you suggest, these one thousand mothers and babies are to serve as object-lessons only, to be imitated by the millions. The least, then, we must hope and work for, is that the millions of women to be confined and the millions of babies to be born now and in the future, should participate in the same benefaction which is promised a few. The universal object is to save and raise babies. My program is different, inasmuch as it suggests additions and changes.

If 17 per cent. of infant deaths are caused by congenital troubles, study these congenital troubles and obviate them. The baby's life and pathology begin nine months before its birth.

If one-third occur in the first month, study and combat that first month, and the indications arriving during and after labor.

Your dealings are not with children but with infants; not with infants only but with the new-born that is just terminating its embryonal and fetal evolution and expects to be treated like a new-born human animal and not like a calf.

No midwife is to handle the case; indeed no midwife *will* handle any of your cases, for you have none, with rare exceptions. It is proper attendance, however, which society owes to the women and the newly born, as a duty to them and to itself. They are valuable assets, both of them. Unless *that* be granted, no discussion is competent.

In one of the programs to relieve the coming child and the struggling mother, I read the demands of absolute rest for at least four weeks before and six to eight weeks after confinement; nursing and feeding, both gratuitous when required; and hospitals for the illegitimate and—when needed—the legitimate confinements.

By the Milk Committee, satisfactory *rest* is wanted for the mother. That means that she did not have it in time, before or after the baby came. If rest means a long rest in bed, and milk station and no breast-feeding, you deprive her of her woman's privilege and most important office in life after child-bearing, and of the facility of getting well radically and physiologically. For without nursing the breast is liable to become atrophic and the uterus subinvoluted. And the infant? Well, the infant, to give "rest" to the mother, is deposited on the altar of a milk station.

I shall be as brief as possible, for I do not believe that the speaker should have all the fun at the expense of his audience. On the other hand, I want to say my own things in my own way—perhaps taught by Jonathan Swift, who preferred to express his opinions "for the amelioration of his hearers, more than for their entertainment."

What the *world* wants is healthy babies. What the *baby* wants is full health and weight; that means a competent mother, sufficiently fed to have a quiet night, free from excessive labor through the day, exempt from a local curable disease that may interfere with the development of the child within her and likely to undermine her well-being, her nursing qualities, and future pelvic and general health. What the *mother* wants is what she has a right to expect, as a reward for the service she renders to mankind in the shape of a healthy child: a place as healthy as the best hospital without disrupting the family. Modern society is built up on the family, the crude teachings of anarchical and a few early socialistic doctrines notwithstanding. No woman will consent to being taken to a hospital unless desperate need compels her to go. To tell a woman she may die unless she go is a cruel sentence. Society is beginning, however, to appreciate that it owes human beings a human dwelling-place, with air enough to breathe in. If you build houses unfit to breathe in, you steal air which is common property. What *society* wants is men and women citizens. But in order to be able to rely on their cooperative functions, it must see to it that in its book of ethics the term of charity is supplanted by responsibility. It is useless to call that socialism or communism. It is the substratum of every religion and every humanistic philosophy. I like to abrogate the term socialism and its alleged dangers, but only by abolishing the social causes engendering them.

Poets have told mankind that once, in the best olden times, the world was a garden, and they want it to become so again; statesmen—not politicians—have exerted themselves to disseminate prosperity and affluence; great physicians have looked for means to ward off disease and prolong an enjoyable life; jurists have endeavored to make the globe habitable by locking up or killing criminals, or the hopeless and dangerous insane. They all deal with those who are alive and, justly or wrongly, in possession of the surface of the earth. We are expected to deal with the present only, and to fight the evils which seem to be uncontrollable now and in the near future. Is there no way to prevent those who are born into this world from becoming sickly both physically and mentally? It seems almost impossible as long as the riches provided by this world are accessible to a part of the living only. The resources for prevention or cure are inaccessible to many—sometimes even to a majority. That is why it has become an indispensable suggestion that only a certain number of babies should be born into the world. As long as not infrequently even the well-to-do limit the number of their offspring, the advice to the poor—or those to whom the raising of a large family is worse than merely difficult—to limit the number of children, even the healthy ones, is perhaps more than merely excusable.

I often hear that an American family has had ten children, but only three or four survived. Before the former succumbed they were a source of expense, poverty, and morbidity to the few survivors. For the interest of the latter and the health of the community at large, they had better not have been born.

Theoretically and practically the addition of unhealthy, sickly, sick, and contagious children is a misfortune to the newcomer, to his parents, and to society. Therefore a clean bill of health should precede matrimony. The clergymen who refuse to marry couples without it are good citizens, and the health departments are bound to see to it that contagious, mainly sexual, diseases should be reported, watched, and cured. Nor is this all: Hereditary influences propagate epilepsy, idiocy, cretinism. Such persons must not be permitted to propagate their ailments.

Now we build asylums for the diseased, neuropathics, and drunkards; nurseries and schools for epileptics, cretins, and idiots; sanatoria for incipient tuberculosis, and refuges—still too few—for the dying consumptives, withal conscious of the fact that our only hope of finally exterminating tuberculosis lies in the perfect but comfortable isolation of hopelessly advanced cases. Surely we try to cure and to prevent. Do we not begin at the wrong end? Consumptives, and epileptics, and semi-idiots are permitted to propagate their own curse, both what is called legitimately and illegitimately. Human society should have pity on itself and its future. The propagation of its degenerate, and imbecile, and criminal should be prevented. We have no positive laws yet for the syphilitic and gonorrheic who ruin a woman's life, deteriorate her offspring—if she have any—and impair the human race. We have come to this: that half of us are obliged to watch, and nurse, and support the other half, most of whom should never have been born. In morals and in money the degenerate are an expensive detriment. The only protection for the nation, for mankind, is to assure a healthy, uncontaminated progeny. Strict laws are required to accomplish that; such laws as will be hated by the epileptic, the consumptive, the syphilitic, and the vicious. No law ever suited the degenerates against whom it was passed, and it is unfortunate that while disease and incompetency and vice are to a high degree hereditary and contagious, moral health and virtue are not so to the same degree. Now those for whom the responsibility of the State does not exist are exactly those who are most entitled to it—the newly born.

Altogether, babies have a strenuous time of it, not only after birth. Heredity, degeneracy, or incompetency is often caused by social influences. Financial temptations or necessity make women select not the strong and healthy men, but the old and rich. Their children are having less and less vigorous offspring. Rich and profligate boys spend their sexual powers on prostitutes and save little for possible babies. The lack of children in American families is not always due to voluntary abstinence. Thus the future of the American population has to rely on the offspring of the immigrants, and the American type of the next century will not be much influenced by those whose ancestors came on the Mayflower. Modern industry reduces the vigor and vitality of men, and woman and child labor exhausts the mothers and fathers of the future and present generations. Millions of men are prevented from contracting a marriage by pecuniary want and the impossibility of satisfying their sexual hunger except with prostitutes. That is true not only with regard to factory hands, clerks, and employees generally, but to the picked men of the people. Army and navy, the millions of soldiers and marines of all the nations of the globe, whom we are urged by our self-styled leaders to imitate, withdraw the vigorous men from natural modes of living, labor, and propagation, and prevent them from marrying in time; and wars, the cynosures of our coarse politicians who take the places that should be filled by statesmen, kill and cripple and deteriorate the best muscle of the land and tempt them into perdition. Only the "weaklings" are left—and their offspring! It is sad to contemplate the short-sightedness of our loud-mouthed leaders and their heelers, and of the people who elect them to rule over us.

The history of the newly born is pictured on their bodies. Pinard weighed numerous new-born babies. Those born in poverty were 10 per cent. less in weight than the others. Many were premature, their mothers injured and sick afterward, and without milk. Of that class, from three to four times as many die when at home as when in a well-regulated and well-fed hospital. Their subinvoluted uteri and parametritides are very common occurrences and are the sources of lifelong invalidism and treatment. Those few are fortunate who need not complain like the woman healed by Jesus, who had suffered all her life from her illness and from the physicians. I see many such. Those are not so fortunate who are treated according to the last magazines' academic discussions which demand an early day for getting up. A woman of the million, permitted or ordered out of bed to work, is the pivot of her poor household or her small farm or shop, or the live part of her lifeless factory machine. She is not like one of your first class paying hospital appendicitis cases that may safely be ordered out of bed for a half hour or a few hours daily, and will not be harmed thereby. This one will continue to convalesce when she returns home. But the woman of the middle class or the poor who is told or permitted to rise early from an appendical wound, a uterine wound, or after confinement will add to her endometritis, her phlegmon, and her adhesions. That is why even apparently simple questions of medicine will never be answered without the consideration of social questions, and medicine must more and more become the guide in the solution of social problems.

A decided physical inferiority at birth is a common occurrence. Ballantyne experienced in the Fulham Infirmary as high a percentage as 21.9. They are called unfit, when born of overworked, underfed, and neglected women. Their number is much smaller and very trifling when their mothers, when poor, are looked after long before the uterine life is terminated or when circumstances, financial or sanitary, are more favorable.

Many premature, feeble, thin babies of unpromising weight may be saved when there is ample care, such as a midwife will more readily give than a doctor. If that be absent, the baby's life is endangered. We have often been told that many of the new-born do not deserve saving for they are puny and not promising. Is salvation worth while? Who can tell, unless you try? But thus far it has been only chickens, lambs, and elephant babies that have been judged by the pound. Kant, Goethe, Helmholtz were puny waifs, whose lives were de-

spared of. But they have furnished elements of culture to the world of which we might have been deprived if they had been without the midwife's care and close attention. Lucetus is said to have been 5½ inches long. He died when 80 years old. He wrote eighty books, not many of them poor. That is an achievement, though not always pardonable and rarely laudable. There are more men 80 years old, but they are not all guilty of writing eighty books.

Hard labor up to confinement interferes with the life or the health of the fetus and new-born. The least that should be done for the mother is a reduction of working hours during pregnancy, and protracted rest after confinement. The women's worst occupation is that with metals, mainly lead. Their percentage of premature births and miscarriages was 53.6; while those with other work furnished another not quite so, but sufficiently formidable number, viz., 17.2. Lead, mercury, phosphorus, copper, iodine, aniline, and nicotine, have been found in the amniotic liquor and in the fetal organism.* The indication is clean; less work, less hours, no directly insanitary occupation, at least several months absolute rest after confinement. The result will be hardier and heavier, and more resistant babies.†

When the baby is born it wants many things, amongst others air and food—mostly food.

Maternal milk is the only safe nutriment. Its quality is not much influenced by emotions, cares, worries; occasionally, only, by medicines taken by the mother or rarely by her average food. Its quality is only temporarily altered by menstruation, which never causes a change that justifies the interposition of artificial feeding. The daily quantity is rarely less than a quart. Maternal affection, the wish to nurse, the act of sucking increases the quantity. There is no such thing as absolute absence of milk secretion. Essential alterations in the articles consumed by the nursing woman are not demanded. As her appetite is mostly increased, she is entitled to so much more than her average consumption as is required by the one or two pounds needed by her baby. She may eat and drink what she digests and was used to; she may perform her duties, attend to her labors—even some factory work—and fill her time as her station in life suggests. There is no reason why she should not spend time in shopping, concerts, theaters, lectures, and parties, except the dog parties reminding you of 1790 in France—even suffrage parades—provided she will not forget that she has a baby at home to welcome and feed. The checking of babies, with or without baby carriages, by department stores, is a convenient innovation, which improves the chances of babies, women, and merchants alike. Elections are no longer so exciting, dangerous, or murderous as they were in our large cities as late as twenty or thirty years ago—so there is no objection to woman suffrage, whether it be considered a plaything, a civic duty, or a disease. Even so, there is no danger, for infectious diseases in the mother are no contraindication to nursing, unless it be a smallpox case in an antivaccinationist; for not injurious bacteria but beneficent antibodies pass into the milk and improve the baby's power of resistance. All of these considerations prove the dangerous tendency of those of our colleagues who in their mistaken subserviency to the ignorant suggestions of fashionable and lazy ladyships fall in with their and the dairymen's teaching that cows are their proper God-sent substitutes. These accommodating colleagues of ours are, through short-sighted complacency, enemies of the race.

The mother's milk has certain protective properties not possessed by any artificial food or the milk of another animal. Experiments have proved that the latter may propagate the artificial immunity toward certain vegetable poisons—the ricin and abrin; and a wet nurse may immunize her nursling by being herself immunized through diphtheria antitoxin. So the mother who was ever thoroughly infected with scarlatina or measles will, at least for the time she is nursing her baby, protect the latter against those infections.* The infected milk of an animal will not have that effect; immunity is secured only by the milk of the same—that is, the human animal—which proves that we are superior to our animal brethren and sisters, unfortunately, only so long as we are young. Many of us when we lose our infancy lose our superiority.

The attentive doctor and the diligent midwife know that our women, poor and rich, suffer from no organic mammary degeneration. Large and small breasts can be educated into competent milkers. They can be roused into action after days and weeks of comparative inactivity, and into renewed efficiency after a recess of one or more weeks. It is quite well known, what I alluded to, that the very sucking of the baby is the best educator of the breast. That is why for the hundreds of thousands of mothers the doctor should be the oracle; the midwife of the people, with her future education and her diligence, the trainer. Both should remember, or rather, learn, that a better milk supply is guaranteed by not improperly and untimely straining the breasts' function. You do not milk a cow every two hours. A healthy new-born baby should never have the breast more than once every three hours: after the third month, he must get along with five meals in twenty-four hours, and will turn out a baby worth having.

Milk contains substances organic chemistry never discovered or measured. They are the *ferments* which circulate in the blood. Some aid in the digestion of albumin; others, of fat and starch. Besides, there are defenders in it of the circulating blood; the *alexins* (Hans Buchner) destroy bacteria; agglutinins immobilize bacteria by bunching them; antitoxins formed in the infected vigorous animal destroy the poisonous toxins of the bacteria. When they are not sufficient—for instance, in bad cases of diphtheria—we inject antitoxins formed in the blood-serum of another animal—for instance, of horses. Any mother that ever had a mild or bad case of diphtheria—or, for that matter, a certain other infectious blood disease—accumulates some antitoxins in her blood and tissues, and in her future milk, and thus protects both it and her nursling. It is possible that so long as the infant is at the breast it is for that very reason less liable to take diphtheria. The fact is that few babies of the first half year become diphtheritic. That is the period of nursing at its mother's breast—its mother's or another human female's, not, however, that of another animal. It is not chemistry alone, but also biology, which distinguishes the milk of their organic producers. Old Doctor Heim was told by a so-called "noble" mother: "I keep an ass for my

*Bluhm: In Weyl's Manual of Hygiene, vol. viii.

†Furth, Henriette: Die Mutterschaffs-Versicherung, 1911.

*Fifty years ago I could refer only to anatomical reasons which secured the very young against diphtheria.

baby. Ass's milk is as good for my baby as my own would be, is it not?" "Yes, yes," said the old man, "just as good for young asses."

Boek found that of infants who died of intestinal diseases, 61.4 per cent. had been fed on ill urs; 24.3 per cent. on cow's milk; 15.8 per cent. on a mixture of breast milk and cow's milk, and 1.4 per cent. on breast milk.

During the siege of Paris (1870-71) the women were compelled to nurse their own babes on account of the absence of cow's milk. Then infant mortality under a year fell from 53 to 7 per cent. During the cotton crisis of 1860 there was a famine. Men and women starved, and on account of no money for artificial food, the women nursed their babies. One-half of their mortality disappeared. In the poor forest districts of the Westerwald the bottle-fed babies had a mortality of 20 per cent.; the breast-fed babies, one of 8 per cent.

In Berlin half of the babies were breast fed in 1890; in 1909, only one-third of them. At the same time another German town, Barmen, nursed four-fifths of its babies, in one year 90 per cent. Of 575 starving and neglected women in a Berlin institution 83.3 per cent. could nurse their infants; why? they were better fed than before, and gave up only when the Moloch of industry reclaimed them as victims. After these poor babies had enjoyed the privileges of some of the rich—viz., health and life—they were sacrificed again on the altar of anti-social circumstances. For during the first year of life, of 1,000 breast-fed babies 70 have died; of the artificially fed, 270 up to 430. They have been counted by the statisticians, by the parents, and by the undertakers.

Wittingly or unwittingly, surely not meaning it as a grotesque joke, the Nestlé Food Company has a picture on the cover of their latest circular. It represents a woman with immense wings—I imagine angels look that way—flying off with two infants to unknown parts.

The mortality of babies below 1 year has been found—not estimated—to be, for the exclusively breast-fed, 6.98; for those brought up on a mixture of breast-milk and artificial food, 9.87; for those fed artificially, 19.75. That means that somebody or something is to be held responsible for the deaths of thirteen babies who should live in good health and with good prospects. Babies turned out to milk stations because their mothers must be told to "rest" belong to that class. It is true, not every baby can be nursed, but the exceptions are scarce. One was born of a mother who died of sepsis carried in part by a dirty midwife or by an infected or ignorant doctor. That is true, statistically, even now that other doctors boast of their asepsis. My own past life does not class me among these others, as I may plead guilty, and no one has a right to blame me for exaggerations. I am, or have been, in the same boat with some of you. Of the five hundred tracheotomies I performed before the Listerian era, of a thousand I assisted in, of thousands of cases of scarlatina, measles, erysipelas during epidemics, and even hospital gangrene during war times—too many occurred while soap and water existed without being used at the proper time and in the proper places. We did not know better, but you do. Every case of death of sepsis in the mother should burn hell into the conscience of whoever permits it nowadays; every case of death from lack of breast-milk should cause a trial for homicide against a doctor or midwife, or mother. For the latter, it is true, there are, if not excuses, many explanations. Some mothers must get up after three days to do washing and scrubbing, and do it without a sufficient quantity of food—starving women make no milk—must make a scanty living in the factory, or in a small business; others go to afternoon teas and bridge parties, or have been taught by their fashionable doctors who agree with them in their suggestions that modern science has proven that a woman's udder may be replaced by a cow's bosom, that a milk laboratory's clerk will furnish printed mathematical schedules for the modification or alteration or substitution of food adapted for every month of an orderly Fifth Avenue infant.

But after all, truth will crop out. There is rarely a woman who cannot nurse her infant.

Ignorance can be learned from and taught by doctors, by midwives, by nurses, but wisdom also. As half of our babies, in all countries, are born under the supervision of midwives, it is these who, when their education is no longer so hopelessly neglected as in our country, in their more intimate contact with the people can exert the widest influence. They will best overcome the prejudice which derives from the well-clad people the notion that breast-feeding is no longer fashionable; they will prepare the nipples, teach cleanliness and antisepsis such as they have been taught in the schools of the—I hope—near future. Edith Peiper reports an increase within five years of from 55.7 to 72.5 per cent. of women who gave exclusively breast-milk to their babies in a public institution.

In a large midwifery school of Germany (Stuttgart), the percentage of women who nursed their babies increased from year to year under proper treatment and teaching. Of one hundred women, only 22 to 25 per cent. gave their babies breast-milk to the exclusion of other foods before 1884. Exclusive breast-milk feeding was furnished by 41.1 per cent. in 1884; 61.4 in 1887; 84.3 in 1888; 100 in 1902; 99.5 in 1903. All of these women were poor or in very moderate circumstances, but they were looked after and fed before confinement and after. It takes missionary work to accomplish results of that nature.

In our country, it is calves that are looked after by our Government. The babies have no votes yet. They will wait.

I must give you a few more figures though I may bore you. I have more sympathy with the world's baby than even with you. I want every incredulous Thomas to leave this place convinced that every baby has not only the right to suckle its mother but the facility.

Dietrichs reports the mortality statistics of 628 infants of the poorest married women of Cologne. Of 100 children born alive, three of those who were nursed for nine months or more died before the end of their first year; of those nursed from three to nine months, twelve; less than three months, thirty-five; of those who were fed artificially, forty-seven. Forty-seven out of 100 born alive, in one year.

Perhaps a report by Prinzing is equally convincing in connection with the mortality of other than intestinal diseases. During the years 1895 and 1896, the mortality of Berlin babies under one year, when breast-fed, was 7.09; when fed artificially, 38.6. Of 1,000 babies, congenital debility killed fourteen of the breast-fed; 43.6 of those raised artificially.

	Breast-Fed	Artificially Fed*
Gastroenteritis killed.....	12.2	171.10
Atrophy and marasmus.....	2.0	24.0
Convulsions	11.10	42.0
Bronchitis and pneumonia.....	5.6	39.6
Pertussis and diphtheria.....	8.3	19.3
Other diseases.....	17.2	46.4

*Alfred von Lindheim, Saluti juventutis, 1908.

The illegitimate infants fared much better than the legitimate ones. That sounds paradoxical, but the mothers of the former, when controlled by the authorities, are obliged to nurse their babies; the latter are the babies of the mothers who return to domestic and factory work, and are exposed to neglect and early and improper artificial feeding, mostly by strangers. Among living infants of the second year, the proportion is reversed, for obvious reasons. The lessons to be derived from these facts are intelligible. A social improvement of the mothers, but that only, will add to the chances of the infant population.

In the *Berliner klinische Wochenschrift* (No. 28, 1911), Professor Franz publishes the report of the gynecological divisions of the Charité. One hundred per cent. of his puerperal women nursed their babies. Dr. Kahn accomplished mostly the same results.

It is true that private practice does not reach the same number. Among the well-to-do, with better surroundings, better food, more rest, but greater indolence, less sense of responsibility; and more accommodating doctors to amuse them, and with more money with which to buy inferior food, the percentage of nursing women is smaller. Their daughters will know better, provided the doctors—we and our successors—will teach them.

G. Dufort reports on conditions prevalent in four districts of Belgium. Women objected to nursing, with a mortality of from 153 to 252 per one thousand, in the first year. Then the Government and a private organization took measures to improve the percentage of breast-feeding women. Not all governments mix up with such things; some are not on the job; some are on the stump. This percentage increased in certain localities where it was lowest, within two years, from 4.3 per cent., to 17.02. That increase was due to the midwives who were taught by premiums, by the practitioners, and by clergymen. You see doctors and priests are still good for something. In other districts the percentage of breast-feeding was 56.6 per cent. in 1907; in the first half of 1908, 57.1 per cent.; in the second half of 1909, it was 74.12 per cent. That means an increase obtained by the country midwives in two years of 17.6 per cent. More, there were midwives who could report 94.0 per cent. in the first half of 1908, and at the end of 1909, 100 per cent.

The same midwives made it their business to extend the duration of breast-feeding about the same time. In 1907, there were fifty-seven babies who did not receive the breast through their first half year exclusively; this number was reduced to forty-eight at the end of 1909. Of these infants who were kept at the breast exclusively through six months, 64.7 per cent. extended this time to nine months; 75.4 per cent. in 1909. The author again and again refers to the powerful influence the midwives—after having been instructed—exerted among the population the women and the babies.*

*Dr. A. Balestre and Dr. M. d'Oelsnitz (Bericht über den III. Internationale Congress für Säuglingsfürsorge, Berlin, Sept. 11-15, 1911, p. 780) express their satisfaction with the results of the Infant Protective Society of Nice, which was founded twenty-five years previously, mainly for the encouragement of maternal breast-feeding.

What, after all, *is* a midwife, whose presence at or attendance on a confinement case, according to my esteemed Milk Committee, must be shunned? An editorial of the *Boston Medical and Surgical Journal*,* has it all. That cautious and elegant magazine gives the following definition: "The midwife may be defined as a person attempting to practice obstetrics without complete or even adequate medical education. The tolerance of such persons is an anomaly in an enlightened civilization. The midwife is a relic of medievalism, unhappily extant in the Old World, but whose persistence in our own community should not be encouraged by any form of recognition."

Meanwhile, Holland, Belgium, France, and Italy require a two years' course of schooling for their midwives; Norway, Sweden, and Denmark, one year. Germany has had its midwifery schools, mostly attached to university hospitals, for more than a century. Many countries subsidize their midwives, who live and practise in sparsely settled districts. Great Britain† established in 1902 its Central Midwives Board, to supervise and control midwives for the specified purpose of preventing the death of women in childbirth, infant mortality, blindness, and physical degeneration.

There are in England and Wales 17,790 trained and untrained midwives—too many yet of the latter class. The British Empire's 108 midwifery schools—including four in the East Indies and one in Hong Kong—have not yet afforded sufficient facilities. But the *British Medical Journal* emphasizes the fact that even in the old type of midwives there is a great improvement in cleanliness and obedience to rules, one of which is the calling in of medical aid in cases with a purulent discharge.

And we? Fifty per cent. of all the births in the United States are attended by non-medical midwives—in New York, 42; Buffalo, 50; St. Louis, 75; Chicago, 86. The patients so attended are negroes, aliens, and natives born of aliens; that means one-half of our population; that means those who during the disappearance—voluntary, wanton, or not—of the original stock and by additional immigration and multiplication will form what within two generations will be the type of the two hundred millions of Americans then living. And where are our midwives? Where are the 108 schools which little Great Britain deems—on account of their scant number—insufficient for her urgent needs? Where are the American safeguards of our fetuses and new-born? When our experienced and far-seeing president of Bellevue and Allied Hospitals established a small school of midwifery, he was applauded for his exceptional foresight and altruism. We think nowadays that the ocean is only a short bridge; but the experiences of Europe, established on a solid and constant foundation do not travel on it. That is the way of indolence by which we negligently murder our forests, lay dry our river beds, cause our freshets, and kill or cripple our newly born. I wonder in which other country we could be expected to accept what I lately read, that people cannot receive obstetrical service under the midwife, "no matter how well trained for her vocation;"—I ask why not?—or agree with a well-meaning author who sympathetically cries out: "Professors are teaching midwives, so medical students are deprived of their professors' time;" or throw up our hands when Stokel tells us that it is "a curious

*Feb. 23, 1911.

†*Brit. Med. Jour.* Dec. 17, 1910.

fact that even among people of refinement the older and dirtier the midwife, the greater seemed the confidence placed in her ability and judgment." That is as sound, perhaps, or not, as when the great English opsonin scientist publicly arraigns habitual bathing for its dangerous effect in admitting microbes through the clean skin—a desirable bedfellow, he!—or when Knott* tells us of "Lady Lawson, who died at the age of 116, never practised ablution of any kind, or hardly in any degree, because, as she averred, those persons who washed themselves were always taking cold or laying the foundation of some dreadful disorder," or the occasional preference given to an old doctor not though but because he is habitually intoxicated. There is still another line of mistaken altruism: Fenwick fears lest a midwife, scantily trained, compete with physicians. I should say, if she succeeds, it serves him right unless he owns a superior training. A pretty good doctor will not do for you or your wives or cases, any more than a pretty good egg for your breakfast.

Is there anybody here who remembers that when fifty years ago the question of the licensing of midwives was brought up before the Medical Society of the County of New York, it was voted down with all con except one pro? Ask our New York doctors at present. We know better now and feel better about it. For we feel like citizens at present. We have also been told that all countries have found "the practice of midwives unsatisfactory." That is not so. The fact is that the other countries maintain that they know their own business and constantly add to the facilities and education of midwives as we do those of doctors. Some assert also that the attendant upon a midwifery case must either be a trained obstetrician or a subordinate "like our excellent trained obstetrical nurse." "The obstetricians are the final authority to set the standard. They alone can properly educate the medical profession, the legislators, and the public." Who educated *them*, if you please, if not the professional schools, and they themselves as best they could afterward? The midwives are not even mentioned as worthy to be educated. Do our obstetricians demand all the obstetrical practice? I am prepared to bid a hearty welcome to my friend the evening-dress obstetrician—who charges $200 or $300 or $500 a job—to the confinement where the man earns $10 or $15 a week, or the woman 7 cents a dozen and the children nothing, unless they sell newspapers.

In spite of English complaints concerning the insufficiency of midwifery attendance, the reports are very promising. In 1910 there were 321 midwives in Liverpool, 198 in Birmingham, 159 in Manchester. In Liverpool, the average number of cases per midwife was seventy—one had 500 cases. Of all the births in the towns midwives attended in Liverpool, 71.9 per cent.; in Birmingham, 63.2 per cent.; in Manchester, 57.2 per cent. Still births attended by midwives were 391 in Liverpool, 212 in Birmingham, 279 in Manchester. Their honest discipline is exhibited in the following figures: Medical assistance was called for 1,015 cases in Liverpool, 674 in Birmingham, and 2,279 in Manchester. The indications for such calls, under the universal rules, are high temperatures, abortion, laceration, illness of the patient, imperfect removal of the placenta, puffiness, convulsions, large varicose veins, sores on genitalia, malposition, trauma, hemorrhage, venereal diseases.

*Medical Record, Dec. 3, 1910.

This very day the system under which they work in our country is an absolute lack of system, slovenly and shiftless—no instruction is offered, no examination demanded, no supervision enforced, and the babies swell the universal mortality.

What is it that a midwife should be taught? Common sense and the experience of other countries should tell us, for we have none. I mean experience. We are only told by our omniscient colleagues that she is dirty, ignorant, untrained, superstitious, septic, the cause of invalidism, degeneracy, and blindness. That is a list of statements exhibiting more temper than knowledge. For, indeed, in thirty-three of the fifty States and territories there is no law restraining the practice of midwifery or what is so called. In three there is no restriction whatsoever. In thirteen there is no provision for training, but there are, curiously enough, laws requiring examination and licensure. What is it, after all, that every one of our States—indeed, after a while, the Federal government—should demand on the part of a midwife who is to be the obstetric guide of fifty millions of Americans? In my opinion she must have as moral a character as you expect and officially demand in a male or female student of medicine or man generally—and, for that matter, of any American outside a penitentiary; a good common school education without Latin and Greek; a fair health so as to endure the hard work she means to undergo in future; a reputation for love of work and conscientiousness; and such knowledge of popular physiology and anatomy as the program of our future midwifery schools will designate. What they must surely teach, like the English schools, are four topics—*the care of expectant women, the conduct of normal labor, the care of babies immediately after birth, the simple principles of artificial feeding, if that become unavoidable*—and the diagnosis of abnormalities, so as to advise the calling in of medical skill. As there are many, I shall spend a few minutes on their consideration.

The fact is, that of one hundred deaths under a year, 2.2 occur by injuries during birth, ten on the first day of life, twenty-five during the first two weeks, thirty-four during the first four weeks. Most of them should be saved through perfected knowledge and art, more skilful attendance than half our population enjoys, and greater acquaintance with the dangers of the newly born. You notice that a large number die from other than the usual causes, viz., indigestion, and you are startled by the fact that one-third of all the deaths occur within the first month.

There are a number of diseases and accidents of the new-born which are as amenable to the care of the midwife as to that of the doctor. Much of what the doctor can do the midwife *cannot* accomplish. But her domain is vast. I shall mention a few of those which belong to it.

A calamity never prevented by one of us, possibly, however, by an attentive and painstaking nurse or midwife, is death by suffocation. There were in England and Wales during ten years, 10,000 overlain infants; in 1900, 1,774; in Liverpool, out of 960 inquests there were 143 on babies that had died of suffocation from the same causes, by accident or malice; in London in 1900, 615; in 1901, 511; in 1902, 588. In London they had annually 8,000 official inquests, one out of fourteen of which were on overlain infants.

A serious complication of labor is *asphyxia*. It may be caused by the mother or by the fetus. Dis-

orders of placental circulation, mostly toward the end of labor, early loss of amniotic fluid, respiratory and cardiac disorders, disruption of the placenta, compression of the cord, and cerebral pressure can mostly be prevented or moderated by appropriate aid. Asphyxiated babies may die, however, within an hour, or the first few days. Those who do not so die are apt to be worse off. They are very liable to become paralytic, idiotic, or epileptic. Little shares the opinion, the contrary assertions of others notwithstanding, that a large percentage of cases of spastic encephalitis ("Little's disease") is produced by congenital asphyxia. Hundreds of times, both in obstetrical and pediatric practice, have I, when looking for etiological factors, received the uniform answer that the baby did not cry for some time after birth, and that the attendant had to work over it minutes, or even hours. Asphyxia must not be tolerated. A few moments' delay adds to the danger which may be averted by knowledge and skill. Losing a baby is a loss and bereavement; crippling it for life is worse. Accidents of that kind can be avoided by much less than the profound knowledge of medical experts, few of whom will ever deign to attend a mere case of common confinement. The statements on a certificate that the new-born is a still birth, means a statistical fact, not an explanation, still less an excuse.

Atelectasis is more apt to be relieved, and death from it more readily prevented by a midwife than by one of us, no matter by what it is caused. Soft cartilages in the premature, feeble muscles, defective nerve centers and lungs, but mainly hepatization, early pleural effusion, struma and compression of the brain are the usual causes. Frequent changes of position, warm and cold baths, shaking, forced inspiration, occasional closure of mouth and nose, so as to fill the medulla oblongata with an extra momentary dose of irritating carbon dioxide, an interrupted momentary Faradic stimulation, and all the procedures demanded in asphyxia are advisable in atelectasis. A midwife should and can master all or most of these measures, as well as a doctor. The former is more efficient because she mostly uses more diligence and can spend more time than most of us.

The *mouth* of the newly born is exposed to injury resulting from the antediluvian tendency of not leaving well enough alone. The habit of washing and rubbing the oral cavity of the newly born, even by clean fingers and rags, hurts the very thin mucous membrane covering the posterior part of the alveoli, and the punctuated epithelial accumulations on both sides of the raphe. Doctors and nurses and midwives who do not know how to omit interference are dangerous. For the forcible removal of the epithelium leads to invasion of cocci and bacilli, and the mycelium of muguet. The latter, though easily cured by a strong solution of borax in glycerin, need not occur in the baby's mouth, for its habitat in the vagina of the mother is quite accessible, both in a private home and in obstetrical wards and in foundling institutions. A consecutive invasion of the stomach and intestines, of blood-vessels and lymph ducts, even of the kidneys and nerve-centers, may easily be avoided by a person who has been taught to prevent and to cure.

The observing obstetrician or pediatrist or midwife has an opportunity to notice all sorts of microbic infections, such as tetanus, hemorrhages, and the intense forms of syphilis. Its worst form is the pemphigus of the soles of the feet, which must be recognized within a few days. The midwife is the readiest to make the diagnosis, and to recognize the necessity of treatment. That does not mean her treatment, just as little as she will undertake the treatment of melena, sclerema, jaundice, sepsis, dermatoses, erysipelas, traumata, or umbilical defects or diseases.

Some of the septic diseases of the newly born for the cure of which the doctor is always too late, or incompetent, are those which go by the name of Buhl, of Winckel, etc. They develop before any symptom is perceptible. The poisons which cause them are probably multiple and connected with the rapid metabolism occurring during, and immediately after, labor. Many cases look like acute atrophy of the liver, or pernicious vomiting; or the main symptom is fatty degeneration, or hemorrhage, or intense jaundice. Overdoses of chloroform in predisposed women have been accused. Intense asphyxia I have seen coupled with or causing it. There are many such cases which can be prevented by appropriate and instant aid, such as I plead for. Many, I believe, will be cured by vaccine therapy, provided it can be employed in time. That is possible only when the indication for it is suggested or only suspected by a person who is on the spot and better taught than a common neighbor or nurse.

Constipation of the newly born should be recognized by the midwife. What I described nearly half a century ago as congenital constipation is the result of an excessive length of the sigmoid flexure. When the continuance for one or two days suggests it enemata should empty the bowels. Unless that be done, moderate and later on serious costiveness is an accompaniment of the dilatation of the descending colon, and autointoxication. "Hirschsprung's disease" is rarely a fully developed congenital dilatation. If a midwife be too alert she may be guilty of preventing an operative interference. I was one of the alert midwives. None of my cases ever terminated on an operating table.

Ophthalmia is the source, not only of blindness, but of death through general septicopyemia under the general symptoms of multiple abscesses and arthritis. A series of cases I, like others, have observed of vulvovaginitis, endometritis, and peritonitis. The endometritis is always of long duration, and may for anatomical reasons relapse indefinitely for many months and years, and often gives rise to contagious dissemination in families, in hospital and asylum wards, by careless nurses and by gregarious bathing.

The tissues of the newly born contain more water than those of the adult; the difference amounts to 10 per cent. Loss of water is badly tolerated, while large quantities are eliminated at once through the lungs, kidneys, and skin, and some through the intestines. Without a proper supply, the tissues deteriorate, and the physiological equilibrium is lost. That was always so—the newly born *is* conservative—and was considered normal. The baby had to be satisfied with reading in every textbook—even in the old ones from which some new ones are compiled—that he has to please the attending oracles by giving up 10 or 20 per cent. of his weight within a week or two. However, as the mother has but little milk during the first days, the least the baby should have a right to expect is water—at least teleology ordains it so—the more so as the first mammary secretion means colostrum,

which contains three or four times as much protein as the milk of later weeks—that means 3 or 4 per cent. That is mainly so—even still more so—when the baby is premature and endowed with less vitality than when born at full term. Neither you nor I shall undertake to change that, but the danger connected with it requires correction, and if artificial feeding be resorted to at all the food should be amply diluted. There is another reason for so doing. *Uric acid sediments* and renal stones are comparatively frequent in small infants. They are caused by the uric acid infarctions which, as a speedy result of the rapidly changing metabolism, are found in the diapers on and after the second day of life. Besides forming gravel and calculi, they give rise to occasional attacks of colic, to small hemorrhages, and frequent cases of nephritis, with, or mostly without, pyelitis. Neither I nor my pupils and friends have seen so many stones and inflammations since, for the last forty years, we made it our rule to feed the newly born on plenty of water. It is also demanded for the purpose of rendering the chemical and physical condition of cow's milk casein more digestible. As long as a human baby is not permitted to live on its mother, that fact is important to consider. Artificial feeding during the first days and weeks should furnish more than 75 or 85 per cent. of water, which is normal even for the adult. Altogether, our infants and children are not supplied with water in sufficient quantity at any time. In our era of equality for all sexes and colors, we should recognize the rights of all ages. When you are hungry, you want to eat; when thirsty, you drink. The baby wants its equal rights. But no matter whether it is hungry or thirsty, it is condemned to receive the same food to quench both its hunger and its thirst. When it cries with hunger, it justly receives food from the bottle or breast; when it cries with thirst, it is given the same food from the same bottle—not mere water. I have often felt like presenting a bill to the Legislature or to the professional philanthropist, enforcing, when father, mother, and physician are thirsty, beefsteak and potatoes. A German pediatrist improves the method of giving water by giving the new-born tea and saccharin. What tea is, I do not know; what saccharin is, we do know. It is found to be a poison. That should not have been, however, the reason why our magnanimous Agriculture and Treasury Departments twice postponed the execution of the law which forbids its indiscriminate sale by the manufacturers of foods.

Midwives are more fortunate than we doctors. They need not know so much as a few taskmasters ask of them—for instance, two German professors, Salge and Siegert, who are so interested in the babies as to insist upon midwives being examined on the intricate problems of metabolism. I fear, after having been a midwife sixty years ago and since, I could not pass to-day. Then, midwives need not know all the mixtures and mathematical formulas concocted by twenty of my pediatrist friends, each one of whom is sure that the other nineteen are quite wrong. Nor need they be acquainted with the fifty artificial foods which were recommended in Germany—that haven of great learning, profound research, irregular practice, advertising, patent medicines and foods—by the *Deutsche medizinische Wochenschrift* a short time ago, and again rejected in the very same year.

The teaching of midwives is not so difficult as our medical profession imagines it to be. We are defective ourselves, for there is a fact which seems to be agreed on by our college teachers, viz., that our young doctors are incompetent to conduct a normal or abnormal labor. As that is so, we, the practitioners, should try to learn some lessons by theory but more by practice. Their incompetence is the result of the insufficiency of our medical school instruction, which is acknowledged to have been scanty in spite of our four years' medical courses. The schools furnish neither systematic obstetricians nor competent general practitioners. I shall not be hard on them, however, for I was a teacher myself. That is why the number of septic infections and of still-births is liable to be large in their practice. If that occur in the green tree—viz., among the men and women with medical diplomas—what can we expect from the untutored?

We speak against midwives and their detrimental doings, and their unreliability. Teach them their duties, which are not many; furnish bedside instruction—which even for a hundred thousand physicians is scanty or none—so that they will learn the manual care of labor; let them be taught not to use medicines, not to operate, not to try, except in certain cases, even to remedy wrong fetal positions; teach them the use of soap and water, and antiseptics; enforce by law and custom the frequent change of their own clothing; forbid the simultaneous attendance on two or more cases; see that she does not attend a labor case as long as in her family or immediate neighborhood there is a case of contagious disease, and she will cause or disseminate no puerperal sepsis. She must be examined and licensed and protected, like you and me.

Registration alone, however, will not do. Nor will our complaints do. Our responsibility does not cease when we decline it. Our duty does not end by sending and collecting a bill for an individual medical service. A death not prevented, a life not saved, is a blot on our escutcheon. The people want more. We are not yet—as the British government proposes—official state employees of the people. If there were not an excess of individualism among us, the attempt to force socialistic coercion on the profession of England would not have been made. Not yet.

Less than a year ago, the New York Academy of Medicine passed, among others, the following resolution:

"Whereas, some of the results of obstetrical malpractice are unnecessary blindness, mental and physical degeneracy, and death of infants, and unnecessary suffering, invalidism, and death of mothers; and wheras both doctors and nurses in this country are given instruction in the treatment and care of child-bearing women and new-born infants, there is no existing provision for the adequate training of women who take into their keeping the lives and future well-being of this large number of both mothers and infants, be it resolved that the Section of Obstetrics and Gynecology of the New York Academy of Medicine recommends that measures be taken in this State to secure State legislation which shall provide for the training, registration, licensure, supervision, regulation, and control of women engaged in the practice of midwifery."

It is useless to attempt a comparison of a midwife with a medical man. They must be considered individually. The ignorant doctor in obstetrical

work is the inferior of a well-informed midwife, and *vice versa*. I remember only two cases of sudden death caused by atmospheric air entering a large uterine vein—in both instances resulting from the nozzle of a fountain syringe introduced into the uterus before the air had all been expelled. In both cases it was a colleague that did it. That does not prove that we doctors do not know how to clean a uterus without pumping air into a vein but I know of no midwife that could have done worse. Still, ignorance, like sinfulness, makes all mankind kin. The greater number of annual labor cases in the United States—more than a million—are attended by midwives, or alleged midwives. As long as these cases are uncomplicated, the presence of a bright trained woman should be, and is, welcome. She must have learned to distinguish the position of the fetus, and know when to call a doctor, how to do, in his absence, a version in cases of emergency; how to attend the eyes, hemorrhages depending on incomplete uterine contraction or from injuries—one of which is tearing off of the placenta, and how to recognize eclampsia, inversion of the uterus, the presence of a mechanical obstacle like fibroma or a contracted pelvis. She must know how to deal with asphyxia. More than anything, she must have been taught to appreciate two things: first, how to keep absolutely clean—that means to disinfect herself and her hands and tools; second—and therein lies a secret of success—not to leave the woman. That is, more than you or I do, or usually did.

The results of midwife practice do not always compare unfavorably with those of our professional brethren. Of 116 cases of ophthalmia neonatorum which were treated in the Massachusetts Eye and Ear Infirmary in one year, 114 were in infants attended by physicians and 2 by midwives; of 33 cases treated in the New York Eye and Ear Infirmary in one winter, 22 occurred in the practice of physicians and 11 in that of midwives. Of the 11 midwives three had used nitrate of silver; of the 22 doctors, only one. According to these reports, if it were wise and proper to generalize the doctors should be replaced by midwives.

In a period of 6 years, 1905-1910, the city of Manchester has the following to say about puerperal fever and recoveries and deaths following them in the practice of midwives and of doctors. In cases of puerperal fever in the practice of midwives, there were 210, with 41 deaths; in the practice of doctors, 275 with 80 deaths; in the cases attended by midwives and doctors, 100 with 26 deaths.

Nor are midwives' cases, those reported in 1910, inferior in results; 45 puerperal fevers were treated at home, with a mortality of 10 or 22.2 per cent.; in Monsell Hospital, 66 cases with 16 deaths or 24.2 per cent.; in other institutions, 20 cases with 5 deaths or 25 per cent.

Now, my friends, you have been kind to me and patient as hundreds of times before. That is why I shall now finish in a minute with a few conclusions for those who with me are convinced that healthy women and living vigorous infants are the best possessions of this nation. They need not be conquered with treasures and cannon and corpses of countless men; they need conservation only. What I want is that a pregnant woman should be in a condition to carry her fetus to its legitimate end in health and vigor, and able to nurse her infant. Every text-book talks to us of the *inability* of women to do so, and indicates formulæ and trade-shops and factories from which to graduate toothless young Americans. One hundred per cent. of our women, however, can be made to nurse, even the so-called "flower of fashion" of the land. From two to three times as many babies will live when breast-fed compared with the number of those who are raised on any artificial food without exception. By breast-feeding you will save 100,000 babies that now die or become invalids, from no other cause but unnatural feeding.

Dangers which now attend the process of parturition in more than one-half of the women of this country must be modified, relieved, or removed by the presence of a person instructed and trained by practice to conduct a normal labor and, when needed, to call timely aid. We want, for the benefit of the women of the country who need midwives 200 midwifery schools after English or German patterns. You are welcome to do even better. But make a beginning. We are all in debt to the country, so let us pay it. Let no legislation of any State pass without a bill or law construed in intelligible language to safeguard the newcomers and their mothers.

A town without an ample supply of good doctors and midwives and a village without one or two competent and responsible and licensed midwives, are like a tenement house without a fire-escape or a *Titanic* without life-boats.

19 East Forty-seventh Street.

HELIOTHERAPY IN SURGICAL TUBERCULOSIS.

By GERTRUDE AUSTIN,

PARIS, FRANCE.

FORMERLY HOME-SISTER AT THE CHILDREN'S HOSPITAL, GREAT ORMOND STREET, LONDON.

"La fleur humaine est, de toutes les fleurs, celle qui a le plus besoin de soleil."—Michelet.

That it should be possible to expose little children for hours daily without clothing of any kind to the sun's rays in midwinter at an altitude of 5,000 feet in the mountains, sounds quite incredible; and yet this is what is being systematically done, and with the most brilliant results, in cases of surgical tuberculosis at Leysin, Switzerland. Who would have dreamed that these frail and diseased little bodies could develop such an extraordinary degree of endurance after only a few weeks of acclimatization?

Accounts of this new treatment had reached me from different quarters, and as I am specially interested in children's diseases, and particularly in that awful scourge tuberculosis, which ravages so many homes and is the nightmare of all parents, I decided to visit Leysin, to see with my own eyes the details of the method, how it is applied, and what results it gives. From this trip I have come back an enthusiastic convert to Dr. Rollier's ideas, and feel sure that the subject is one of immense practical interest to the general public, and well worth their most serious consideration. In how many homes, alas! are little children lying ill and suffering from this terrible disease! Mothers will certainly be thankful to learn that a new era has finally dawned, and that the hitherto lamentable results obtained in this branch of surgery will soon be a thing of the past.

I reached Leysin one glorious morning early in January. Leaving the Rhône Valley below shivering in the chilly, gray clouds that clung tenaciously to the pine trees on the mountain sides, the tiny cog-train crept steadily up the steep grade. Little

Fig. 1.—Leysin village and valley, and mountains beyond.

by little the enveloping mist became less dense, and light from above began to break through in patches; finally we emerged entirely from the gloom and found ourselves transplanted into another world. Everything about us lay buried beneath a thick mantle of spotless snow, which glistened and sparkled in the dazzling sunshine, while above us the intense blue of the cloudless sky formed a marvelous contrast to the frost-bound landscape. The penetrating chill of the valley had vanished entirely, and was replaced by the pleasant warmth of the dry, still mountain air. On every side towered the su-

Fig. 2.—"Le Chalet."

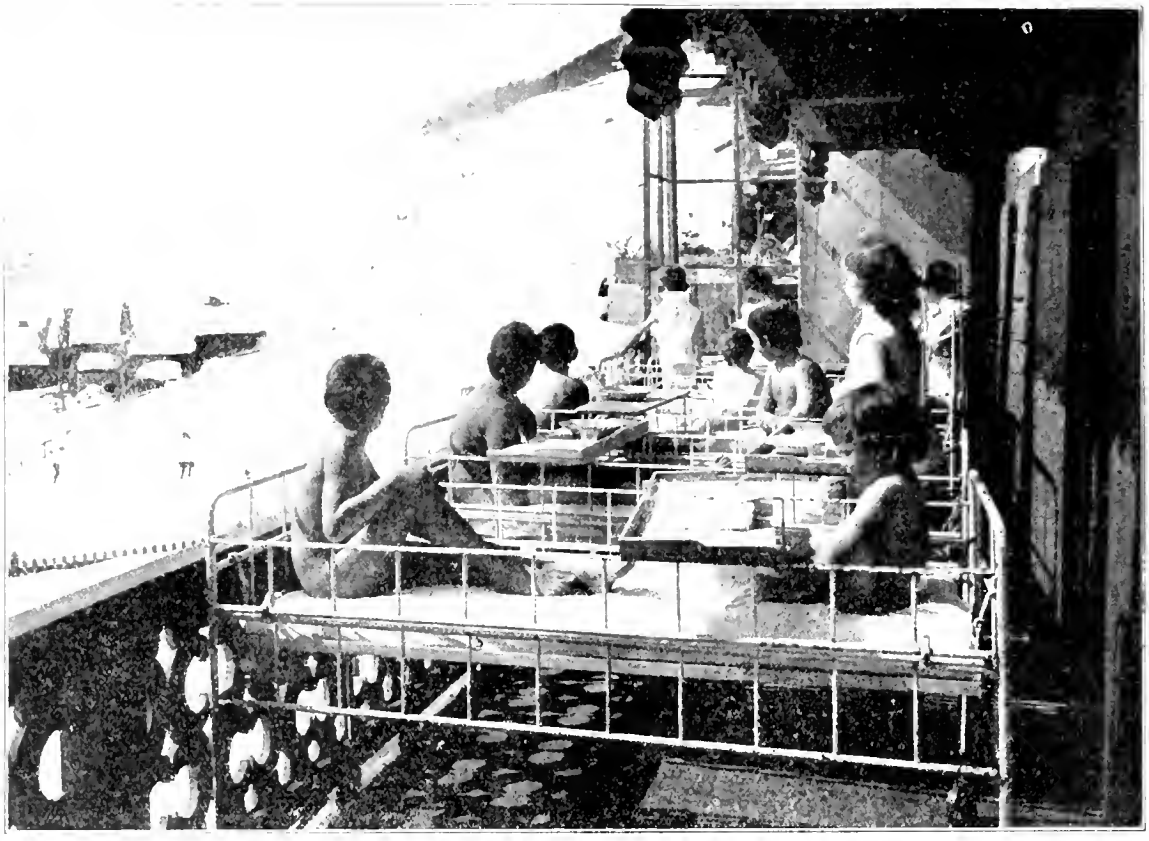

Fig. 3.—Heliotherapy in midwinter at an altitude of 5,000 ft.

perb Valaisan Alps, the nearer ridges protecting from every breath of wind the little, high lateral valley into which we were entering. Below us stretched the upper surface of the white, billowy expanse of mist through which we had risen, shutting out entirely from view the world beneath, which we had left scarcely two hours before. Such a dramatic transformation scene I had never witnessed. Could fairyland itself be more exquisitely beautiful than this?

As soon as possible after my arrival I called on Dr. Rollier at his clinic "Les Frênes," one of the

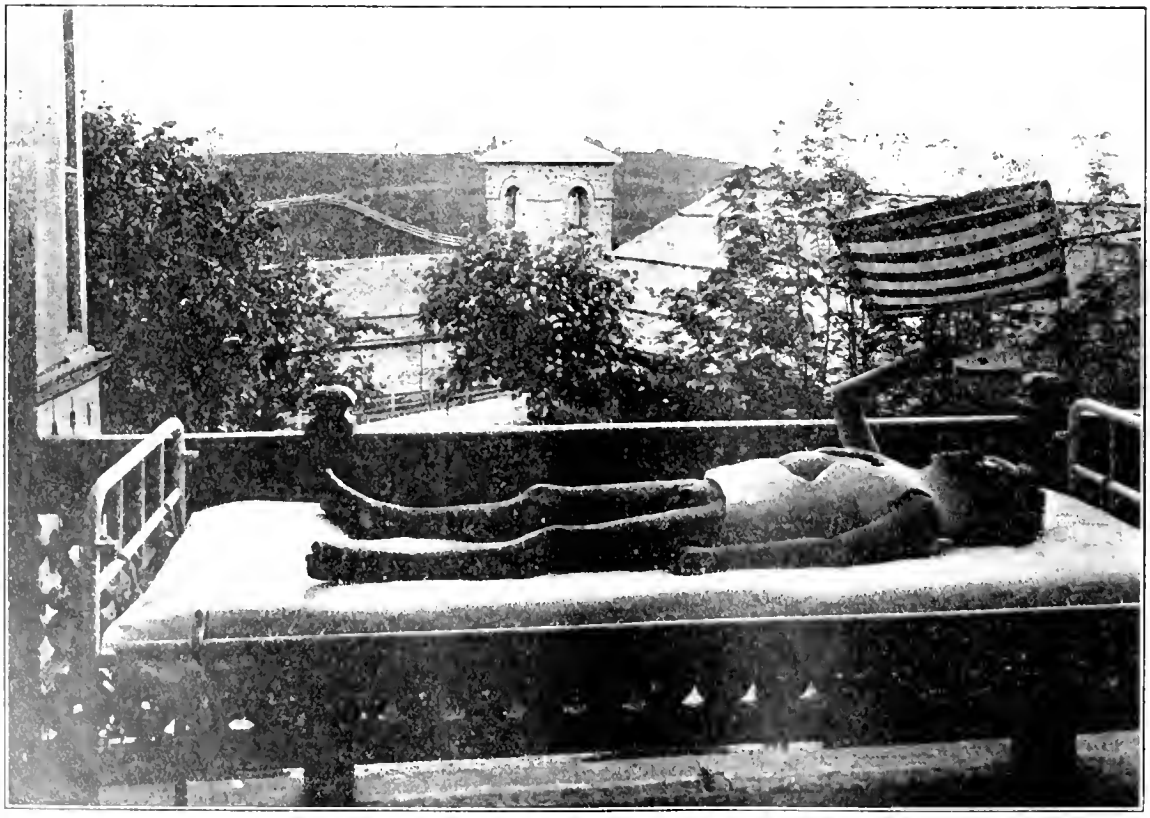

Fig. 4.—Pott's disease of the spine.

two in which adult patients are received, and [illegible] him of my errand. I shall never forget his kindness and courtesy. During my stay at Leysin he allowed me to study his cases, explained anything I wanted to know, and supplied me with his

Fig. 5.—Child X. Y., 4 years old. Pott's disease, with pronounced gibbosity.

publications on heliotherapy. Precious as his time is he gave me of it ungrudgingly, and I soon realized that the eight years he has devoted to the study

Fig. 6.—Same child as in Fig. 5, with first wardrobe [illegible]

of this question have been spent in the advancement of science and the good of humanity rather than in promoting his personal material interests. His results are now beginning to be known all over Europe, and by publishing them to the world he hopes to make converts to his method and persuade other men to open clinics in high altitudes so that children of all countries may benefit by his experience and enjoy the advantages until now confined to the favored few whom he can take in at Leysin, where unfortunately he has only 350 beds at his disposal. He is always ready to explain his treatment to competent visitors, and certainly every student of this all-important question may expect the same cordial welcome at his hands that was extended to me.

My first visit to the children is an event that I am not likely to forget. It was with no little difficulty that I walked from my hotel down the steep, winding road that leads to "Le Chalet," as every one in Leysin calls this diminutive hospital. The sun had not yet appeared above the mountain tops to soften the frozen snow, and progression was difficult, not to say dangerous. The clinic is a picturesque, wooden construction, a regular Swiss chalet, faces due south, and stands in a small garden which in summer-time is no doubt green and gay with flowers, but which on this cold January morning was carpeted like everything else with pure

Fig. 7.—Same child as in Fig. 6, one year later.

white snow. I had planned to arrive betimes, for I wished to see the exodus of the children from the wards to the galleries. But as I stood upon the doorstep waiting for admission the sun rose above the mountain-tops, and already there were sounds of merry laughter in the frosty morning air. Happy voices were féting the beneficent rays whose healing powers even the little ones appear to understand. They love this sunshine, which gives them health and takes away their pain, and it is they themselves, when able to do so, who, the moment the word is given, push down the bedclothes, and pull up and over their heads the nightdress that is obligatory at other times.

When I was taken by the matron out onto the first gallery, my surprise knew no bounds. Who would have supposed that such dark-skinned, healthy-looking little bodies could be found in a hospital, and above all who would have expected to see tiny children on a winter's day in January, basking in the sunshine as naked as when they were born, except for the quaint little white calico hats which make such a startling contrast with their brown skin. Most of them are in a recumbent posi-

tion, some even lying face downwards, which does not seem to worry them at all; the more fortunate ones are able to sit up, roll about in bed and have a good time, while all are reveling in their warm sunbath. A few are not yet fully exposed, it is true, for they are newcomers and have not completed

the necessary training which endows them with this extraordinary power of endurance. The latter have still the pale, weary faces which sickness gives, and it is easy to see that their sojourn at Leysin has been but a short one.

The morning lessons were just beginning, for the good doctor disapproves entirely of "no work and all play" for his little patients. Both from a moral and from a physical point of view he considers some mental occupation absolutely necessary; and while he allows no fatigue or overwork, he insists that all children old enough for regular education shall continue their studies, as he thinks there is an interdependent relation between the training of the mind and the development of the body. It is considered a privilege to take part in these lessons, for this means that the days of sickness and suffering are past and convalescence has begun. The teacher stands at the head of the beds lest the shadow of her body should interfere with the action of the curative rays. It was an interested and intent little audience she had on the morning of which I write. I think I can safely say that few people have seen classes of sick children doing their lessons perfectly naked in midwinter out-of-doors, all gay and happy, and looking far stronger and healthier than many of our city children who have no ailments whatever.

I returned again and again to the clinic to hear the childish prattle and watch the happy faces as the little patients pursued their studies or played with the toys that were strewn on every bed. They seemed to enjoy the excitement of seeing a visitor, and answered my questions or listened intently to the stories I had to tell of other children I had known. My thoughts flew back to these other children, lying in crowded wards in sunless cities as I had often seen them. I recalled their wasted frames, their wan faces puckered up with pain, and the tired, hopeless look in their weary eyes. What a contrast! My heart ached when I thought of the thousands who would benefit so wonderfully by this treatment, if they could but have it. And only 350 beds, half of which are given up to adult patients, who must also be thought of and provided for.

By surgical, as distinguished from medical, tuberculosis, is of course meant the forms that attack the joints, bones, lymph nodes, peritoneum, and genito-urinary organs, which until quite lately it was usual to treat by the knife, immobilization, and modifying injections. These were apt to leave the patient scarred or crippled, with stiff joints or shortened limbs; in some instances, even, amputation had to be performed. But now, when treated by this new heliotherapy process, operations become unnecessary, the sun's rays doing the work of the scalpel, but with one very important difference: the patients recover without disfigurement and leave the mountains with normal limbs and supple articulations. Dr. Rollier's *modus operandi* cannot perhaps be fully appreciated except by one who has gone through life handicapped after treatment by the old method, or by those who have had some dearly loved child, a victim to the disease, come back to them after operation more or less maimed for life. And only those who remember the former long months of immobility and the consequent weakness, depression, and wasting away of the muscles can realize the advantages enjoyed by the little folk at Leysin, their happy outdoor life and pleasant surroundings during a cure which of necessity is always a protracted one.

This new method consists in exposing the body of the patient to the sun's rays in open galleries com-

Fig. 9.—Child A. B. (shown in Fig. 8), one year later; complete recovery.

municating with the wards and facing due South. The actual seat of disease is uncovered for five minutes only, to begin with, as there must be no blistering or burning of the skin; the next day the region is treated for two periods of five minutes each,

separated by an interval of half an hour, and on the third day these exposures are lengthened to fifteen or twenty minutes. At each séance a larger area of skin is uncovered, so that by the end of a week or ten days (for each case needs individual

Fig. 10.—Dystrophic child with the physical signs of pretuberculosis: enlarged lymph nodes, gastrointestinal disturbance, skin eruption, weakness and fever. Condition on arrival.

study) the entire body, the head excepted, is lying nude in the sun. The head has to be protected for some time longer, to prevent congestion; but it too is also ultimately brought to tolerate the sunlight. The patients are wheeled out in their beds onto the galleries as soon as the sun appears in the morning, and lie there naked for hours under the influence of its healing rays, being only moved back into the house when the cool night air begins to make itself felt. The large windows of the comfortable steam-heated wards open down to the ground and are never closed, so that when the sun has disappeared behind the mountains the invigorating air continues the cure during the night hours. A carefully

Fig. 11.—Same child as in Fig. 10; condition one year later.

studied diet furthermore helps to build up and renovate the diseased bodies under treatment. No medicines are given; the stomach, enfeebled by sickness, has therefore only to digest the good, nourishing food supplied, and thus contribute without interference to the general amelioration of the patient's condition. According to the necessities of the case the invalid is partly or entirely immobilized until the actual disease is cured; and only then, and in cases where it is absolutely essential, is an apparatus

Fig. 12.—Boy, ten years of age; suppurated white swelling of the left ankle.

applied to correct deformities or straighten limbs.

In those cases where an apparatus cannot possibly be dispensed with an opening is cut as large as possible at the seat of the trouble, so that the sun's rays can continue their curative action on the diseased region all the time that the patient is in plaster. The doctor finds that he is thus able to prevent any wasting of the imprisoned tissues, such as always takes place when the body is immobilized for any length of time without this precaution. Thanks also to this method joints quickly recover their movements when the apparatus is taken off, and if somewhat stiff at first become quite limber after a few days of insolation and exercise. In Pott's disease the "window," as Dr. Rollier calls this opening, is cut in the front of the corset worn by these pa-

Fig. 13.—Same boy as in Fig. 12, eight months later; the joint is dry, manipulation no longer causes pain, and active and passive movements are free.

tients, support being necessary at the seat of the disorder; this aperture is extensive, laying bare a portion of the abdomen and of the thorax. The remainder of the body is uncovered and takes its daily sun-bath for as many hours as possible.

In all the surgical wards at Leysin the knife is held in far greater aversion than any apparatus; the latter is an absolute necessity in some cases, though its use is to be avoided whenever possible, whereas the former is considered to be almost always an agent of harm. When in spite of the insolation an abscess seems about to open, it is punctured and the pus drawn off, and it has rarely been necessary to repeat this more than two or three times in a given instance. When an abscess has already burst and is infected on arrival, it is scraped and the cavity disinfected and then exposed to the full light of the sun with its walls laid wide open, a small antiseptic dressing being applied at night. The few failures recorded have been in just such cases as these, where the abscess has been infected from without; and the doctor repeated to me over and over again, while speaking of his results, that he fears the open abscess more than any other complication with which he has to deal.

Under this treatment the patient's improvement is rapid: appetite increases, fever disappears, the natural functions become regular, the red blood corpuscles increase in number, the hemoglobin increases in quantity, and the children put on weight and become gay and happy. At the same time the local condition shows signs of amelioration: pain ceases entirely, and this is one of the earliest and most striking phenomena observed; unopened abscesses become absorbed; and swelling decreases and finally disappears. Thus slowly and surely the disease is led on to recovery.

The ultimate results obtained in the different forms of surgical tuberculosis are as follows: lymph nodes resume their normal size and leave no scar whatever, even if punctured, so long as they come to treatment before they open. Joint and bone lesions heal up without deformity, shortening or stiffness. Even lung trouble, which alas! often coexists with surgical tuberculous disorders, is cured if treated in time by this process of insolation and aëration. Finally, children deformed by rachitis become pictures of health and return to their homes in splendid condition if they follow this cure. Infected wounds, the result of accident, also heal very rapidly after cleansing and exposure to the sun's rays.

The following statistics will speak for themselves: Out of 309 cases of surgical tuberculosis treated by heliotherapy, in 284 (78 per cent.) recovery was obtained; in 48, improvement; in 21 the condition remained stationary, while 16 (4 per cent.) succumbed. These figures appear more remarkable still when we consider that in 132 cases there was open tuberculosis with secondary infection. The 61 cases of Pott's disease of the spine (19 with abscess and 10 with fistula and secondary infection) gave 45 recoveries, 10 improvements, 3 failures and 3 deaths. In coxalgia (closed form, with or without abscess) there were 32 recoveries, 5 improvements and no deaths; whereas in 22 cases with secondary infection there were only 12 recoveries, 4 improvements and 3 deaths. Closed tuberculosis of the pelvic bones also gave excellent results, 5 recoveries and 2 improvements in 7 cases; but with secondary infection the prognosis is distinctly bad: 1 recovery and 3 deaths in 5 cases. In visceral tuberculosis the results were again excellent: peritonitis and enteritis, 27 cases (5 with fistulæ) gave 17 recoveries, 3 improvements and 3 deaths; renal and visceral forms, 16 cases, with 12 recoveries and 2 improvements; genital forms, 6 cases, with recovery in all. No such results as these have ever yet been obtained in the treatment of surgical tuberculosis, and the only pity is that Dr. Rollier has not more room at his disposal for patients. He is obliged to refuse applicants every day.

What, then, is the nature of the action of heliotherapy in these cases? Sunlight, as is known, is composed of luminous rays (yellow, orange, green), heat rays (red), and chemical rays (blue, indigo, violet). These different colored rays, which make up the spectrum, each play a part in the process of healing, as well as the more recently discovered infra-red and ultra-violet ones, which are invisible to the naked eye. Some are analgesic, some have a tonic action, some penetrate deeply into the tissues, whilst the microbicidal properties of others destroy the bacteria which are the cause of the disease. The toxins are likewise influenced and modified by the sunlight, which has a marked action on nutrition. Thus a culture of bacilli covered with a red glass attenuates, and the germs begin to perish; but if the red glass is replaced by a violet one, the culture revives and resumes its virulence. Dr. Rollier does not attempt to concentrate any one ray in particular, as Finsen did, but uses diffuse white light just as it comes from the sun.

But in order to derive the maximum benefit it is a *sine quâ non* that patients be treated at a certain altitude. Experiment has shown that 25 or 30 per cent. of the sun's rays is absorbed by the atmospheric dust and moisture before they reach the level of the sea, whereas on the top of Mont Blanc (15,800 feet) only 6 per cent. of their efficacy is lost. Patients treated by heliotherapy at Nice, for instance, only become slightly browned; while those at Leysin get to be a rich walnut color. This superactivity of the pigment-cells of the epidermis plays an important rôle in the cure, and confers on the patient a remarkable power of resistance to disease. During an outbreak of chicken-pox among his children Dr. Rollier noticed that all those who were entirely naked and deeply pigmented escaped the contagion, while with children wearing an apparatus the eruption came out in its usual manner on any part of the body from which the sun's rays were shut out by the plaster, but was entirely absent on the tanned surfaces. In a general way experience has shown that cases that pigment intensely are always the ones that recover the most quickly and radically. Fair children and Venetian blonds pigment much less than dark ones, and are also much more exposed to tuberculosis than the latter. I saw one little fair-haired girl three years old, who in spite of constant and prolonged insolation had scarcely tanned at all; it had been found impossible to produce any pigmentation of her delicate white skin.

If such clinics as these could be built on the mountainsides in all countries, and the tuberculous children be transported there, we should by degrees be able to grapple with this horrible disease whose frequency is one of the greatest blots on our age. Our little ones would then grow up healthy men and women endowed with that greatest of all blessings, a perfectly sound constitution, and would be properly equipped to face the struggle for life which is ever becoming more difficult. Those countless chronic cases which now encumber the wards of city hospitals, and which come back over and over again with a new focus of disease, only to die at last exhausted by fever and suppuration, would no longer

be hopeless if treated in high altitudes and for a sufficient length of time. When these patients can one and all breathe the life-giving mountain air, and feel the sun's healing rays upon their skin, they will almost always be radically cured from the beginning, and thousands of lives will thus be saved for the countries where the steady depopulation that is going on has become the burning question of the day. We must study more carefully the statistics given by the health bureaux concerning infantile mortality in big cities if we would appreciate the absolute necessity of getting better results in the treatment of all kinds of tuberculosis in children. It is certain that if all the surgical forms of this disease could have the same enlightened care as that given to the little patients at Leysin, the ugly scars and crippled limbs so often seen, and which are such a sad hindrance in later life, would become a thing of the past, and children all the world over would be spared the endless misery and suffering which is, unfortunately, now so common that we have almost ceased to realize its enormity.

20 Rue Chaucrin.

THE RELATION OF THE CLINICAL PROFESSOR TO THE HOSPITAL, THE COMMUNITY, THE MEDICAL SCHOOL AND THE PROFESSION.*

BY JAMES BUDLEY MORGAN, A.B., M.D.,

WASHINGTON, D. C.

[ASSISTANT PHYSICIAN GARFIELD MEMORIAL HOSPITAL]

THERE is a general unrest in the medical world, extending somewhat to the administration boards of the hospitals, as to what position the clinician should occupy in reference to the hospital, the community, the medical school, and the profession. According to Dr. D. L. Edsall,† "while the importance of the subject is easy to see, the fundamental reasons for its agitation are not so readily comprehended."

A physician or surgeon in whom the administration board of a hospital has confidence should be given the most generous, solid, and complete authority in all things which directly or indirectly have to do with the management of the sick. His associates and assistants should be either his appointees, or should receive his endorsement. To be fair to the hospital, whose reputation will reflect the standing of its visiting staff, the first and best efforts of the clinician should be given. As has been stated by noted clinicians and consultants: "There is no reason why the clinician should not practise, provided it does not interfere with his teaching, which should be paramount" (Dr. J. M. T. Finney); "he should practise, but only in consultation, and never to occupy more than half his time, the other half to be given to the hospital" (Drs. W. W. Keen and R. C. Cabot).

As a teacher of medicine, the hospital and its sick are benefited by having the advice of one who is well equipped in his branch, and who is wide-awake and enthusiastic in all that appertains to the progress and advancement of medicine, and whose hypotheses, teachings, and results are constantly under the scrutiny of his associates, his assistants, and a class of eager students; "such a clinician will spread the reputation of the college" (Dr. N. S. Davis). To attain this acme at which a chief aims, the administration board should aid by giving all laboratory facilities and ample and intelligent nursing of his patients. As to the equipping and the maintenance of the laboratories in a hospital, where much teaching is done, there are many who insist that the medical school should bear a good part of the expense.

The securing and segregating of interesting and instructive cases for the students is one of the chief and most important duties of the assistants and associates, and they can be much aided by the students of the third and fourth year classes, who should attend regularly the dispensary service of the hospital and call to the associate's attention any item in the history of the case, or any feature in the appearance and actions of the patient which might seem unusual. A large dispensary service in connection with every hospital and medical school should be encouraged; it is an absolute necessity in forming a nucleus from which most valuable experience is given to the student, where he sees and examines first-hand a variety of simple and of grave cases, which in no other way could be gained except in long years of practice. The dispensary should furnish many ward cases, and much clinical material for the amphitheater; the laboratories are then called upon for reports before the professor sums up a complete and comprehensive clinical lecture on the case. "There is a general unanimity of the Committee of One Hundred on the Standard Curriculum for Medical Colleges, in the belief that in clinical lectures actual patients should furnish the text. We all realize that the medical school which actually does well all it claims in its catalogue is very uncommon" (Report of the Committee of One Hundred, American Medical Association).

Some, but not frequent opposition has been raised to the use of ward cases for teaching purposes. In the experience of the writer this repugnance or opposition of the patient to be used before a medical class is easily overcome if the situation is intelligently explained to the patient and a mien of coercion or authority is never used. Most of the sick rather seek a presentation of their case, knowing they will be benefited thereby; and others who would raise an objection, refrain if they are made to know that by having their illness especially studied and discussed they can be of help to others who may likewise suffer. It is extraordinary what community of interests the sick in a ward will have and how much they will put up with, in the way of noise and inconvenience and disagreeable sights and odors, if they are convinced that all are working to help suffering humanity about them; thus "one touch of nature makes the whole world kin."

Few outside of the medical profession realize the tremendous outlay of time, money, and endurance that is required from this generation of practitioners, if they are really to be in the front rank of their profession. Outside of the honor that one has from being a clinical professor, the time spent in the preparation for clinics and in attention to the sick poor, is shamefully remunerated at the present time by most medical schools, hospitals, and municipalities. It is expected, and now being demanded by some leading medical schools, that their professors in the practical departments, such as of medicine, surgery, and obstetrics, should bestow all their time and efforts on the hospital and the clinics; some schools not so radical would allow consultation work under certain conditions. A well-known

*Read before the Medical Society of the District of Columbia, April 17, 1912.

†*Boston M. & S. Journ.*, Feb. 29, 1912.

educator says a clinical professor should be a strict consultant and should very seldom see out-of-town patients, "as these consume a great deal of time" (Dr. George Blumer). Another holds that "on general principles, the Professor of Clinical Medicine should do only a consulting practice. In an ideally conducted institution, I don't see how he could do more and attend to his duties of teaching and study" (Dr. W. S. Thayer). "However, just *how* he practises is not the important thing; the important thing is that his teaching should have first call on his services, and practice should not encroach upon his teaching time. His time in teaching and in hospital work connected with his teaching, should not occupy less than half his time" (Dr. Henry A. Christian). "He should see patients by appointment and with strict limitations" (Dr. Beverley Robinson). It can easily be seen there are several sides to this arrangement, and some serious reasons why, perhaps, the broad contemplation of one's mind may be somewhat biased or warped by confining the efforts of a scientific and progressive medical man to the wards of a hospital. "To be a thorough clinician" (Dr. Frank Martin) and "in touch with every aspect of practice" (Dr. H. A. Hare) some from our oldest and largest universities believe that a clinical professor should practise, "otherwise the professor would be a pedagogue, and his work academic; and moreover he should practice if he wants to be free and alert in the care and solution of problems of the practitioner" (Dr. J. H. Musser).

Some strongly contend that the fame and usefulness of a medical school will be greater by having its professors practise in the community and consult with their professional brethren (Dr. Charles L. Green); are there not a great many practical and scientific points that the profession at large are capable of giving to the consultants? And finally, as the main purpose of all study of medicine is to make good doctors, in the widest sense, are we sure that the clinical professor, if his usefulness to the community is abridged, is the best to prepare the future practitioner for the public? "If students are to be taught how to care for the sick in their own homes and in general practice, a part of the instruction should be given by men who have experience acquired outside of hospitals" (Dr. William Fitch Cheney).

How is the clinical professor to "gain the experience and knowledge of the management of people except in private practice?" (Dr. J. C. Wilson). "A hospital experience alone could never make a physician a great clinician, as patients do not go to hospitals in this country, until they are in the superlative degree of their lesions, differing materially from the clinical hospitals of Europe in this particular" (Dr. J. B. Murphy). The last two objections could be very easily removed by appointing only those to clinical professorships who have had for a considerable time "the responsibility of managing patients in private practice" (Dr. F. Forchheimer).

"Great usefulness as a teacher may go together with great skill as a practitioner, but one does not imply the other. In Great Britain and America, until recently, there was no distinctive career for the clinician except as a practitioner. In Germany, which may be said to educate the world more largely than any other country, in medicine, and this is more true in clinical branches than in the non-clinical, contrary to the impression of many, the pathway to progress in clinical work is made definite and we can judge of its success by the lasting good results accomplished" (Dr. D. L. Edsall). There the clinical professor, in his wards and in his service, is as much a *head* as the admiral of his fleet in battle array. The confidence, honor, and obedience which he inspires follow as natural consequences of the training, zeal, and resourcefulness which the clinical professor shows on all occasions. His comfortable salary is augmented by the students that walk his wards, and by the demand for consultation that is made upon him from his preeminence as a clinical professor.

Time was when the medical student gained an actual knowledge of the appearance and treatment of diseases by visiting the sick with the professor, as he made his rounds of the city in his one-horse chaise; then it was that one or two courses of lectures of six months each was the standard, and the writer does not refer to those times to disparage, but simply to emulate those magnificent types of men who, with so few known facts, by close observation and logical deduction treated intelligently and successfully so many diseases. To-day is different; we no longer delve in the inexplicable, but many puzzling and serious maladies are made clear and simple from having the hospitals, the laboratories, and the teachers. A medical school without a hospital is a misnomer, and "ultimately every hospital forming part of a medical school should be endowed" (Dr. Lewellys F. Barker). "To keep a hospital up to the highest standard of efficiency, from a scientific standpoint, the hospital should be connected with a teaching institution. The more openly and candidly the work of the hospital is carried on before the public, the greater the benefit to the profession and the community. When medicine was empirical, it was a dangerous thing to give it publicity, but the more the public know of scientific medicine the greater advantages they receive from it and the greater respect they have for it" (Dr. J. B. Murphy).

Some clinical professors do consultant work and have limited office hours, never attending patients routinely outside. It may be said that it is the consensus of opinion of a very large number of the leading clinicians in the United States that the clinical professor—much more if he be also academic—should not practise (do a family practice), but his spare time from teaching and research should be given to consultation; however, "if he is a recognized teacher, and is seen to be obtaining results in his teaching, the matter of practice should be left to his own judgment" (Dr. N. P. Colwell). "No man should accept or hold a professorship in a clinical branch unless he can give the greater part of his time to his teaching" (Dr. V. C. Vaughan). "Even consultation must be *limited*, so that it will not interfere with his chief obligation, that of a teacher. If his services as clinical professor are of any value he must spend at least one-half his time (4 to 6 hours daily) in a study of the material (patients, laboratory, etc.) and in class work. He cannot do this and serve a family practice" (Dr. Frank Billings). "It is doubtful if a practitioner in the broad sense can have a place as clinical professor in the best medical schools" (Dr. Lewellys F. Barker). "In general it would not be well for the Professor of Medicine or Surgery to do a family or general practice, because this necessarily makes demands on his time, which cannot be anticipated. He must be ready to go when sent

for" (Dr. Henry A. Christian). Therefore his private practice must be for "consultations only" (Dr. W. Gilman Thompson).

The question is immediately raised, who is going to reimburse the clinician for the abandonment of a rich clientele? It might be said right here that there are two principal problems which face the medical schools in any very radical change for the present:—first, the difficulty of securing sufficient highly trained, skilled men; and, second, the lack of funds.

The foundation of this paper has been based upon answers to four questions which were sent to over thirty leading professors in medical schools and hospitals, and the following table is a digest of the opinion of each:

SUMMARY OF REPLIES.

Questions.	Affirmative	Doubtful	Negative
1st. Should a clinical professor of medicine or surgery practise medicine.....	9	4	16
2nd. Should he practise only as a consultant..	15	5	6
3rd. Should he have office hours to see patients	23	2	0
4th. Should he attend pay patients in the hospital (where he gives his clinical lectures).....	21	4	1

THE THERMO-HYDROPATHIC TREATMENT OF TYPHOID FEVER AND OTHER INFLAMMATORY CONDITIONS.

By E. S. GOODHUE, A.M., M.D.,

HOLUALOA, HAWAII.

The use of cold water baths for high temperatures in typhoid fever has undoubtedly been beneficial in a large number of cases in which such baths have been wisely and conscientiously administered, but in a few instances, at least, the results have not been satisfactory, and with most of our country practitioners the routine administration of cold baths has been entirely out of the question.

So far as I have been able to determine, in states like Illinois, Indiana, California, and Massachusetts, outside of large cities, only about 1 per cent. of cases have been subjected to the cold tub-bath treatment, and from scattered reports furnished by Southern states I find the ratio is even less. In places without well-equipped hospitals, the difficulty in administering a tub-bath is an objection to its use, no doubt, but reports show that in nearly every locality and in the practice of nearly every physician there was a time when the tub-bath was used in typhoid fever; some way was arranged by which the bath could be given, because it was considered almost a *sine qua non* in the treatment of typhoid fever with high temperatures.

In all new therapeutic ventures or measures, there is upon their recommendation by reputable men a general tendency toward their adoption by the profession at large and a trial is made by every practitioner. Even if the measure be of undoubted value, there are failures in its application, and, owing to maladministration, ineffective procedure, unintelligent observation, or partial record, some will condemn what afterwards is found to be valuable. There was a very long and doubtful stage of experimentation with diphtheria antitoxin. Many were convinced that this great therapeutic resource was a failure and did not either ameliorate or prevent diphtheria, yet in the end the value of the serum came to its high place. No one dares to question its efficacy now. The tub-bath treatment had its period of enthusiasm, and then of defervescence, but no general reaction. For some good reason it has gradually lost favor, and in several large hospitals is not made use of even in high typhoid temperatures. Had results proved that cold baths were an unqualified benefit in the hyperpyrexias of typhoid fever in a majority of cases, the treatment would have become general; it would have forced itself upon a profession in duty bound to accept all real therapeutic measures, even though offering difficulties in their administration; but cold baths have not justified the early promise.

Besides the disagreeable subjective effects of the cold bath, chilliness, and an almost unconquerable dread of the first shock, there have been in a large series of cases, results not at all favorable to the treatment; congestive and hypostatic effects, even collapse, all of which carefully observed and recorded, have forced the profession very generally to abandon the treatment and substitute cold sponge baths and local applications of cold either by irrigation or cold packs. In a series of some 300 cases of typhoid fever, some of them in hospital, some in private practice, I have found my mortality rate lower and convalescence more rapid in those cases where cold tub-baths were not administered, and I have given them up entirely in hospital practice and out of it.*

The limited local action of high degrees of cold or heat is practically the same, and both have been used to great advantage in various forms and for many different conditions of disease. Each produces a sudden contraction of the arterioles, followed (over limited surfaces) by dilatation and hyperemia, but where the application is general as by submersion in cold water, there may not be the secondary result, the dilatation and hyperemia; the patient may remain chilly, his skin pale, his fingers and toes purple, resulting in possible collapse. This is often seen in conditions of health in weak persons, children, and infants; many persons are constitutionally unable to "react" after a cold bath, and suffer therefrom. For such persons to persist in "hardening" themselves is often disastrous not only to comfort but to health, and I have seen the subsequent depression and lowering of vital force give rise to serious consequences. "Colds," bronchitis, pneumonia, have followed, because the usual resistance to germ invasion is removed and can no longer stand to safeguard the organism. I have on record a patient who went into a cold bath (bathing pool), a strong healthy man, remaining there for two hours, to come out in a state of collapse, go to bed, and not get up until convalescence from a severe bilateral lobar pneumonia. After studying the action of cold or heat upon normal tissues, on surface areas by means of water and ice bags, packs, tubbing, douches and injections I tried it in disease, particularly inflammatory conditions, where almost since the beginning of time it may have been recommended, finding that the initial effects of extreme cold and heat are identical, but in long continued applications of cold, the vitality of tissues is so affected that injury is done. An exception to this is found in applications of ice to the head whenever brain conditions indicate their use. This is because the thick intervening bony structures prevent any permanent alteration in the soft tissues beneath.

The remedial effects of heat have long been rec-

*Some Notes on the Recent Typhoid Fever Outbreak in Kona, Hawaii.—*Journal of the American Medical Association.*

ognized not only by the profession but by laymen. So we have the hot-water bag, poultices, fomentations, stupes, hot douches, injections, and enemas, and latterly the application of hot pastes and earths, the efficacy of which is due entirely to the heat they retain and convey. Any physician who refuses to recognize the value of these applications for local inflammations, has failed to observe that they certainly relieve pain, soothe the patient and, in the end, hasten recovery. Their value lies in the heat they conserve. Cloths dipped in hot water are not as good because they must be removed often, and do not supply the continuous, equable heat. For various local pains, neuritis, neuralgia, myalgia, the hot-water bag has long served, but all these means are inadequate, and mechanically inefficient. So with rectal enemata of hot water for the tenesmus of proctitis or dysentery, relieving a most distressful symptom; and douches for uterine and ovarian irritation and pain; but they are all clumsy, do not adequately supply heat to the part that needs it, and, as carried out, are only in a measure palliative, rarely curative.

For several thousands of years the Japanese have been in the habit of taking *hot* baths—not warm ones. They get into a tub of hot water, from 108° F. to 110° F. over a slow fire and are literally parboiled. Here they stay from 20 to 30 minutes, then step out and simply dry themselves without towel friction. Indeed, it is not necessary, for their skins glow, and they seem immune to subjective sensations of cold, often going about naked or in their loose kimonos without "catching cold." They are a healthy, muscularly well-developed people, free from skin diseases as a rule, and resistant to infections from without."

Bathing in warm water, that is, water at a temperature of from 90° F. to 102° F., does not have the same good effects. Such immersion seems to increase a susceptibility to "colds," and on getting out of the bath, one is apt to feel chilly if the temperature of the air is below 80° F. Indeed, I believe such baths are enervating and not better than cold ones, which leave the bather chilly. But a bath in water at a temperature of 110° F. to 115° F. has an entirely different effect. At first there is a decided shock to the body something like that caused by getting into cold water, the breath is driven out of the lungs with some involuntary exclamation, the heart beats faster, but almost instantly this passes off, a sense of warmth and extreme comfort supervenes, and the whole surface of the body flushes, remaining for some time hyperemic. A person soon becomes accustomed to these baths, and loses all dread of the first shock which is not disagreeable like that coming from sudden applications of cold to the body surface; but for those who cannot at once get into hot water, it is well to begin at a temperature of 105° F., then to turn on hot water and gradually run up to the required temperature. This can be done without any inconvenience; in fact, one hardly realizes that the temperature of the water is rising until it reaches 115° F.

A stay of ten to twenty minutes is generally sufficient; sometimes in health five minutes will do; it depends, of course, upon the requirement. I have found myself able to stay half an hour in water 110° F. by increasing from 100° F. to this temperature, and for a few minutes in water at a temperature of 118° F. At the latter temperature the pulse rate increased from 72 to 85 for three minutes, falling slowly to normal. The respirations increased four or five above normal for about the same length of time. Baths in water from 108° F. to 110° F., for a period of ten to fifteen minutes leave one feeling comfortable, stimulated, and without visible perspiration. Over that temperature and for longer periods, there is apt to be perspiration, which makes it necessary to use friction afterwards, and some precaution as to change of temperature. In taking "cold," during the coryza and sneezing period, in the beginning of bronchitis, pharyngitis, myalgias ("aching all over"), I have found the hot bath almost abortive. A stay in water at a temperature of 105° F. for ten minutes, then getting into bed taking a laxative and a diuretic are sufficient to abort these conditions. A neuritis or neuralgia, a painful "stiff neck," are relieved quickly, and in many cases with the attendant anti-rheumatic treatment.

I have found the baths efficacious in lumbago, sciatica and tonsillitis. In glandular involvements with enlarged glands of the groin, axilla, and neck, the baths are beneficial, producing an immediate softening by elimination and absorption and stimulation of the lymphatics generally. Of course in severe tonsillitis, pharyngitis, and laryngitis, hot local applications, preferably hot packs, are valuable. Local infections of the hands or feet I treat by placing in very hot boracic acid solutions, but where there is general infection or in localities not easily treated in this way the hot tub-bath is efficacious. The tense and painful tissues are relieved in most cases. In acute nephritis following infectious diseases, I have had most satisfactory results, relieving the condition in a few days. I have just had under treatment a girl aged 14 years with severe nephritis as secondary to measles. In this patient there was general anasarca, great distention of the abdomen, and swelling of the face, with excessive albumin in the urine. Hot baths were administered daily for one week, with the gradual disappearance of the anasarca and albuminuria. Of course other measures were used to combat the condition; regular doses of digitalis, mild salines, and attention to the diet. But the course of the disease seemed determined largely by the baths.

One of the conditions in which hot baths are particularly valuable is in premenstrual affections: amenorrhea, malaise, backache, or any of the distressing symptoms due to disturbed circulation at this period. Half an hour in the tub with the water at a temperature of 108° F. will afford great relief. In hemorrhagic conditions, however, the hot bath is contraindicated. In uterine and ovarian affections the beneficial action of heat is well recognized, and equally so, I think, the unsatisfactory results of ordinary douching, when a little spray of water is for a moment thrown against the mouth or neck

The following is a letter from S. Kitasato of Tokio in which he tells exactly how the Japanese take their hot baths:

"Dear Doctor

"You speak about the Japanese hot baths. The average temperature is from 108° F. to 115° F. The private bath-tub is made of wood, having the dimension of 3 by 4 by 4 feet. They first submerge their bodies as long as they wish (usually for a few minutes), and then get out of it and wash their bodies thoroughly until they wish again to enter the hot water. Thus they get into the bathtub three or four times before they finish their baths. The total length of time for each bath varies with the individual, but average Japanese men take one-half to one hour, while women will take sometimes two hours. They take these baths every day, of course, without exception. The value of such baths for the maintenance of health and cleanliness is great.

Very sincerely,

S. KITASATO"

of the uterus. The ovaries get no benefit at all, and almost all the good that results is the washing out of the secretions. I have devised a tubular vaginal douche made of aluminum, six inches long, two inches in diameter, perforated along the body, and open at the distal end, for vaginal insertion while the patient is in the tub. This tube distends the walls of the vagina and allows the hot water to remain in the canal as long as needed, until all the vaginal tissues feel the effects of the high temperature. In adhesions, endometritis, vaginitis, neuromata, and hyperesthesia I know of nothing so efficacious. The endometritis is relieved by continued treatment, the vaginitis responds readily, reflex neuroses are helped probably through vasomotor action, and hyperesthesia disappears. I have also a rectal tube for similar treatment of the rectum in inflammatory conditions, proctitis, fissure, and particularly the tenesmus of dysentery where the action of the heat is certain.

Professor Berne has recommended hot baths in whooping-cough. He calls a bath hot at 90° F. "It induces sleep, soothes the nervous system, and diminishes the paroxysms. The skin of children with whooping cough is usually pale and cool, indicating a contraction of the vessels of the skin, and the hot bath counteracts this, relieves the internal organs, and promotes the elimination of toxins." With a knowledge of the action of the hot bath upon normal as well as pathological tissues, we can understand how valuable it must be in diseases due to severe infections, with local inflammatory foci, rise of temperature, nervous disturbances, and subsequent toxic complications. In pneumonia we have an involvement of the lungs; in pleurisy, of the pleura; in diphtheria, of the throat, nose, etc.; in typhoid fever, of the intestinal mucosa; in nephritis, of the kidney, and so on. Treating these diseases according to our knowledge of their pathology, with vigilance and the proper use of the right therapeutic measures, we may well rely on the use of the hot bath as a valuable adjuvant, for the careful administration of these thermic immersions will give all the good effects of cold baths, without any of the disadvantages and dangers of the latter. In typhoid fever the temperature is reduced, nervous symptoms, such as insomnia, restlessness, and delirium, are relieved, and the patient *feels* better not only while in the bath but afterwards. The only contraindication is actual hemorrhage. Strange to say, intestinal disturbances, bourborygmis, and meteorism are relieved by the bath, and the liability to complications is reduced. In uremia, suppression of urine, and other toxic symptoms, the hot bath is particularly indicated, and its action upon the nervous centers is well recognized in the convulsions of children due to whatever exciting cause.

Later it is my intention to report a series of cases of typhoid fever in which hot baths were used not only by myself, but by a large number of physicians in this country, Mexico, Japan, and Canada.

Virulence and Toxicity of the Cholera Vibrio from Various Sources.—Ravenna after testing the virulence of the cholera vibrio taken from convalescents, from patients severely sick, and from carriers, has concluded that the source from which the vibrios come does not influence the grade of their virulence. But as to the grade of toxic action of the endotoxins or nucleoproteids, there is a very different action of the cholera vibrios according as they come from sick persons, convalescents, or carriers.—*Pathologica.*

THE SIGNIFICANCE OF THE RATIO OF FREE HYDROCHLORIC ACID TO THE TOTAL ACIDITY IN DETERMINING IMPAIRED MOTILITY OF THE STOMACH.

By A. E. AUSTIN, M.D.,

BOSTON, MASS.

PHYSICIAN TO MOUNT SINAI HOSPITAL AND BERKELEY INFIRMARY.

When to an inquiring, prospective passenger a train is reported late, it has little value for him unless he knows how late the train may be; so when we say that the motility of a stomach is delayed, this statement has but little value for the physician unless he can learn to what exent this retardation may exist. The patient will tell you that he can "taste" certain pungent articles of food like onions or Roquefort cheese for hours after they are eaten, a proof that fragments of them still remain in the stomach, yet a thorough washing of the fasting stomach fails to bring to light any food residue. To the presence of food residue in the stomach twelve hours after the evening meal we attribute the most importance since it is almost diagnostic of a narrowed pylorus, but the absence of food does not by any means exclude the possibility of impaired motility of a minor degree. What means are we to employ then to reach some accuracy as to the detection and measurement of the lesser stages of this condition? First, we have the Riegel meal to be removed seven hours after it is eaten, or rather the meager remains of it by lavage, for the normal stomach ought to be empty; if it is, the process is one easily carried out. But if the departure of the food from the stomach is delayed, the fragments of undigested meat plug the eyes of the stomach tube and often only by its removal can the obstruction be removed. This act is often interpreted by the patient as a failure in skill on the part of the physician and an effort to again insert the tube is met by a stubborn refusal on the part of the patient.

Then we have the relation of the solid to the liquid portion of the removed gastric contents after the test breakfast, a method on which Strauss laid great stress, believing it to be as simple as the reading of a thermometer. If the contents are allowed to remain in a measuring cylinder two hours and, if the solid portion is more than one-half of the total, there is impaired motility; if it is less than one-half of the total hypersecretion is present. Zweig modified this method by the use of the centrifuge. One-fifth to one-third solid contents indicates a hypersecretion while over one-half solid contents indicates impaired motility. Elsner washes out the stomach, allows the washings to stand twenty-four hours, and takes into account only the total solid contents without reference to the ratio of solid to fluid contents. The fallacy in all these processes is that one never knows with the tube alone whether he has all of the solid portion of the test meal in the stomach or not, since this fraction flows out with much more difficulty than the liquid. An excellent illustration of this can be seen in the mistaken idea, long prevalent, that in achylia gastrica because the tube could evacuate only a few cubic centimeters, a hastened motility existed; the fact is that if the achylic stomach is washed out, the usual amount of solid material will be found; in other words, there is a suppression or diminution of the gastric juice as a whole and not only the acid and ferments. Again the mastication of the food

makes a great difference in the volume of the solid residue of the removed gastric contents. Insufficiently masticated food always increases the non-liquid portion. If, as Cabot says, many a toothless individual is possessed of an excellent digestion it must be due to some dispensation of Providence, for the fragments in the removed meal compare with the ordinary finely triturated residue of a well masticated meal as paving stones do to raisin seeds. Again, it is often noticed that gastric contents, containing much mucus, settle with great difficulty even with the centrifuge and must have a significant part in rendering the solid portion much larger than it would otherwise be.

Now comes the third method which has been rejected by the builders but may still have some of the qualities of a corner stone. Riegel first called attention to the wide variation in the values of the free hydrochloric acid and the total acidity of the gastric contents when the second factor was increased and deduced this principle; when the hydrochloric factor is very small in proportion to the total acidity, it is evidence that there exists an impairment of the motility of the stomach since the longer the food remains in contact with the gastric juice the more of the acid will be bound by the protein and the less will appear free; as a corollary to this rule, however, there must be little or no organic acids. This does not necessarily mean that there is a narrowing of the pylorus, for many stomachs may possess motor insufficiency due to atony without showing residue in the morning washing. Lefmann agrees with this statement only to the extent that an increased total acidity often but not always means an impaired motility, yet the same author in the interpretations of the examinations of his published cases lays great stress on this relation.

In order to utilize this ratio what must we exclude? First the so-called hyperchlorhydria, for, if the stomach can secrete a gastric juice whose acid content may vary from day to day, we have absolutely nothing on which to base our inferences. But Bickel says that the gastric juice always contains the same percentage of hydrochloric acid and that the variations which we find chemically are dependent largely on the total amount of juice secreted and the rapidity with which the digested food leaves the stomach; in other words, that we may have an increase, a diminution, or an absence of gastric juice, but never a variation in its composition. This view, too, seems to be borne out by Lefmann's work in which six examinations of the gastric contents of a sufferer from gastric atony extending over a period of ten months showed a free hydrochloric acid varying from 40 to a deficit of 40, yet the total acidity never varied 5 points. It will be easily recognized how difficult it is to establish a ratio between a factor which is fixed, like the protein of the test breakfast able to neutralize a definite amount of acid, and a varying factor such as the amount of gastric juice secreted. But, if we consider in all cases of increased secretion that the impaired motility is primary (which is probably nearer the truth since practically all observers are agreed that both conditions generally exist together) we shall be able to say with truth that a conjoined free and total high acidity mean impaired motility. If hypersecretion may exist alone as a purely nervous affection, then all conclusions which are based on its relation to motility are false and Mayo may well refer to it as "Laughing Water." I am fully convinced, nevertheless, that the condition is due not to the greater excitation of the gastric glands by the food, but to the more prolonged excitation, just as the hand may be passed over a hot stove without harm but its delay there will cause a burn. This does not exclude the nervous element, for we all know that the minor degrees of impairment of gastric motility are often wholly of nervous origin. The other horn of the dilemma in which with increased total acidity we have diminished free hydrochloric acid can be attributed only to a predominance of the impaired motor factor and a lessened secretory function, while the main factor in both is the increased acidity. Without prejudgment with reference to the value of inferences drawn from this relation of free to total acidity, I have endeavored to satisfy myself as to its efficacy by the following simple course of investigation on patients at both the clinics in which I am interested as well as on private patients. At night a meal of meat, bread, and potato was taken together with a rice pudding containing raisins. Nothing else was taken before bedtime, and the next morning at nine o'clock and sometimes a trifle later the stomach was washed out thoroughly and there was given the usual test breakfast which was allowed to remain one hour. Then the free acid was determined both by Congo papers and Gunzburg's reagent and the total acidity by phenolphthalein. In the fasting stomach the first washing (a half-liter) was kept apart from the subsequent washings and was usually found to contain the major part of the residue, if any was present, and by its small volume greatly facilitated the subsequent sedimentation and centrifugation for microscopic examination when by gross appearances the nature of the residue could not be determined at a glance, as of course was not true of the raisin seeds. In this way there were studied 15 cases, of which I wish to consider two more at length than the others because both came to operation.

Case I.—B. M. was a married woman, 34 years of age, whose father had had "stomach trouble" all his life and at 60 years had died in an acute attack of the same difficulty. She was rather sickly until she was 12 years old, and was in a fair state of health until she was 18 years old, when she had a sharp attack of pain in the pit of her stomach and vomited blood freely. The attack was called ulcer of the stomach and the patient remained in bed three months on an appropriate diet. Since then she has been nervous but in very good health until four months ago, when she had an acute attack of pain in the stomach just under the breast bone accompanied by vomiting; the pain extended through to the back and was relieved by vomiting. Since then the attacks have come every week, sometimes accompanied by vomiting and sometimes not. The attacks of pain have been less severe than the first, come on within half an hour after the food is taken and sometimes she has to leave the table before the meal is ended and relieve the pain by vomiting. She had had no children. Physical examination showed that the woman was well nourished with a tendency to obesity, and there was no evidence that she had suffered any in nutrition from the vomiting, if it were as frequent as she stated. Her color was excellent and showed no evidence of anemia. A tender spot was found in the epigastrium just below the ensiform cartilage and a little to the right of the median line. A tender spot was also found in the back to the left of the spinous process of the twelfth dorsal vertebra. This latter point was not so well defined as the point in front, for some tenderness

could be elicited above this point in the same general line, that is along the left border of the spinal column.

The lower border of the stomach was well above the navel and there was no enlargement to the right of the median line. The feces showed no blood pigment on a meat-free diet, and the stasis test 14 hours after the meal showed a few rice grains and meat fibers; the first washing gave a marked reaction for hydrochloric acid. The urine contained a trace of albumin but no casts. After the test breakfast there were withdrawn 150 cubic centimeters of contents well digested with 20 per cent. residue whose hydrochloric acid figure was 70 and total acidity 90. No blood was found. Based on the history and the symptoms the probabilities that an old ulcer existed though no enlargement of the stomach was found were so strong that the patient was operated upon by Drs. Ehrenfried and Boothby, who found some thickening at the pylorus but no evidence of scar tissue anywhere, and in all other respects the organs normal.

The preceding is an instance of the combination of hypersecretion and pyloric spasm with undoubted impaired motility in which those who follow the Rochester teaching too closely will have an opportunity to be disabused of their opinion that this condition always is based upon organic disease of the stomach in distinction to functional.

Case II.—M. M., female, single, cook, 35 years of age, has had "stomach trouble" for seven years. As a child and in early youth was a sufferer from bone tuberculosis and spent many months in bed and on frames to stay the ravages of the disease, which ceased 15 years ago. She has had a burning sensation in the stomach which sometimes rises in her throat with eructations of extremely acid tasting fluid. This may increase until she has an intense pain extending to her shoulder blades. It often reaches an acme when she begins to vomit and may vomit everything for three to five days. These attacks come with considerable regularity in the fall and spring, and are relieved by food or alkalies, but even if food is taken the attacks usually recur in twenty minutes. Rarely they occur at night accompanied by the sensation of intense hunger (*Heisshunger*).

There has never been any headache with the attacks nor blood in the vomitus. Physical examination showed an anemic looking individual whose hemoglobin was 90 per cent. (Tallquist). The gums were colorless but there was no sign of jaundice or cachexia other than the pallor. The lower border of the stomach when inflated with carbon dioxide was two fingers above the navel and extended well to the right of the median line. The kyphosis was so marked, however, that the position of all the organs was distorted, the lower liver dullness being found two fingers' breadth above the costal border in the right mammary line. There was a localized area of tenderness in the epigastrium but none in the back. Halfway between the navel and the xyphoid and to the right of the median line there were some small disseminated masses the size of a pea which were either in or just below the abdominal wall. The fasting stomach contained 30 c.c. of bile-stained contents with a strong HCl reaction but no food fragments either macroscopic or microscopic could be washed out. Nor was any blood (guaiac) found in this or the stool on a meat-free diet. After the test breakfast, free HCl, 46; total acidity 70. A reaction for blood was given by this contents but not more than is often produced by the introduction of the tube. The patient was operated upon by Drs. Tenney and A. J. Hamilton who found the scar of an old saddle ulcer which did not involve the pylorus and performed a posterior gastrojejunostomy with complete relief.

From the consideration of these two cases we will see that the first with microscopic residue and probable gastric insufficiency which was due to myasthenia since no pyloric obstruction was found at operation, had an HCl content which was 79 per cent. of the total acidity and that the second which showed no retention though an old ulcer existed had HCl which was only 65 per cent. of its total acid. Another feature of the chronic gastric ulcer was the persistent presence of bile both in the gastric juice withdrawn from the fasting stomach and in the washings of the same though the washing was repeated several times. Until the operation my interpretation was that the ulcer scar involved the pylorus by which complete closure of the orifice was impossible. This allowed the duodenal contents to freely enter the stomach though there was an absence of stasis. For the other cases an artificial division has been chosen which, perhaps, could not be verified if a larger number had been included. These are cases in which macroscopic or microscopic residue is found in the washings of the fasting stomach twelve hours after the evening meal. This individual has been regarded as the victim of delayed motility or insufficiency of the stomach without necessarily a narrowing of the pylorus which produces a residue under the same conditions much more extensive in amount. I am assured that we shall be led into error as I have been, if we regard every microscopic residue of food at even this length of time after a meal as meaning gastric stasis and this word is used possibly without justification as synonymous with pyloric narrowing. The cases with the results of this test are as follows:

Case III.—C. B. No residue in fasting stomach; gastric contents, 120 c.c., 20 per cent. solid, HCl, 45, and total acidity, 60.

Case IV.—Succussion at navel, extends to right of median line; residue in fasting contents (starch grains), marked HCl reaction in wash water. G. C., at 45 minutes, 120 c.c., 25 per cent. solid; HCl, 68; T. A., 148.

Case V.—M. L. No food fragments, marked HCl reaction of wash water; HCl, 51; T. A. 70.

Case VI.—C. D. No residue and no HCl reaction of wash water; G. C.: 240 c.c. 50 per cent. solid (gravity); HCl, 34; T. A., 71.

Case VII.—A. H. Lower border of stomach 2½ centimeters below the navel at which there is succussion. No food residue but marked HCl reaction of washings; HCl, 40, T. A., 69.

Case VIII.—F. V. Residue both macroscopic and microscopic; marked HCl reaction of wash water; lower border of stomach at navel with succussion at the same point; HCl, 45, and T. A., 68.

Case IX.—E. W. No residue, but marked HCl reaction of wash water. HCl 19, T. A., 55, after test breakfast.

Case X.—R. K. No succussion and no enlargement of the stomach by percussion; microscopic residue. G. C.: 20 per cent. solid, HCl, 56, and T. A., 77. No lactic acid.

Case XI.—Succussion extends to navel. No macroscopic or microscopic food remnants. HCl, 40; T. A., 70.

Case XII.—D. L. Prolapsed stomach, no residue. G. C.: HCl, 20, and T. A., 58.

Case XIII.—J. F. Succussion at navel. Fasting, 240 c.c. withdrawn containing numerous food fragments. G. C.: HCl, 40 and T. A., 81. This case was on the border line and it has not yet been determined whether it is a marked insufficiency or a true stasis due to pyloric narrowing.

Case XIV. B. R. No food fragments, wash water freely bile stained. G. C.: HCl, 18, and T. A., 58.

Case XV.—H. B. No food fragments and the skiagraph showed a very small (puerile) stomach. G. C.: HCl, 51; T. A., 81.

Now we find upon looking over these results that wherever macroscopic or microscopic food residue has been found in the fasting stomach, the total acidity after the test breakfast has been over 60, the usual upper limit for a normal digestion. Hence, if we reject all those without food residue whose total acidity is below 60, we have a basis of comparison for the remaining cases. While increased acidity of gastric contents, due to hydrochloric acid, does not invariably accompany impaired motility of the stomach, yet Schütz and also Lefmann regard the delay of food in the stomach as responsible for the excitation of a much larger flow of gastric juice than otherwise occurs in a normal digestion. Furthermore regarding 60 per cent. as a dividing line between the residue containing and the non-residue containing stomachs, we find that, of the five former, four have more than that amount of free acid as compared with the total acidity, while of the seven latter, three have more than 60 per cent. and four less. Of course I appreciate that many of those not showing even microscopic residue at twelve hours may have done so at eight or ten hours when the normal stomach should be empty but in an out-patient clinic, it is very difficult to control patients with accuracy enough to decide the condition at these varied periods after the test meal (meat and potato). It can be plainly seen that there is not distinction enough in these differences from which to deduce any conclusions; perhaps a larger amount of material might afford more definite conclusions. Let us now consider Schütz's rule which is that normally there are twenty points between the free hydrochloric acid and the total acidity after a test breakfast. If there is hypersecretion, the difference may be less, since in this case a large amount of hydrochloric acid is secreted without an opportunity for an intimate mingling of the albumin and the acid, while in impaired motility the difference is greater than twenty because the long delay of the food in the stomach causes a more complete binding of the acid by the food. It seems to me that there is an error here and the statements should be reversed, but I have written them as he gave them. Curiously enough the difference is almost exactly twenty in three instances in which residue was found, while only one of the non-residue containing class has anything approaching this difference, so that such a principle must have a great number of exceptions; of the other two cases in the former class the difference is much greater than twenty, which ought to put them in the hypersecretion group though residue is present; it is probable that the two groups are so closely associated that it will be difficult to separate them and we can only hope to determine which is primary—the lack of motility or the hypersecretion. Cohnheim and Dryfus have very ingeniously decided this matter experimentally by introducing a rubber ball through a fistula into the duodenum of a dog and by inflation producing a closure of the canal and preventing the discharge of digested food from the stomach; it was found that by thus delaying the emptying of the stomach the acidities rose much beyond what they otherwise had been normally.

How much the results of these experiments can be applied to human beings and whether a lack of propulsive force on the part of the stomach would produce the same effect as the partial closure of the pylorus still remains to be investigated.

Kreidl and Mueller have attempted to settle this question by the removal of the muscles of the stomach in dogs and have found in fact that there was a large increase in the acidity of the gastric contents: while Cohnheim states that in most respects the laws governing digestion in dogs are very similar to those in human beings so that while there may be no value in the ratio of free acid to total acidity in determining either pyloric narrowing or gastric insufficiency there may be significance in the increased acidity. In my own cases, comparing the average of the acidities in the residue-containing stomachs with the five non-residue containing ones which have the highest acidities, we find ninety-four in the former group and seventy-four in the latter, though there are exceptions in both classes in either direction. Lefmann has studied this question by lessening the motility of the stomach by an injection of morphine and has found that after such a procedure the total acidity was invariably higher, so that he draws the conclusion that in almost every case a high acidity may be clinically interpreted as indicating a lessened motility without a necessary obstruction at the pylorus. The free acid, however, varies very greatly and even when the acidity is high, we may have an absence of free acid but a high combined hydrochloric acid as determined by estimation of the deficit.

The practical inference from these facts is that alkalies and belladonna only relieve the symptoms in these high acidities and that we must direct our attention to the underlying cause, impaired motility, and employ the limited means in our power to hasten the emptying of the stomach. Small frequent meals, hydrotherapeutic measures, nux vomica, massage and possibly faradization, and postural treatment (lying on right side after meals), though I am inclined to think the latter two act more by suggestion, have aided me more in the treatment of gastric hyperacidity, not fermentative, than alkalies and agencies limiting secretion. As fats are known to delay the emptying of the stomach, oil should never be employed except in cases in which examination has shown a pyloric narrowing.

110 Marlborough Street.

Foreign Body Retained in the Nose for Fourteen Years: a Grain of Germinating Indian Corn.—H. J. Davis reports the case of a girl, aged 19, who had been attending hospitals on and off for rhinorrhea ever since she was aged 5. Originally she was taken to the casualty department, as "she had pushed a piece of maize up her nose instead of giving it to the canary, as she had been told to." Attempts had been made to extract the foreign body without avail. Rhinorrhea and purulent discharge followed, and the nasal bridge sank in, almost occluding the left nostril. The exhibitor saw her a few months ago and mistook the case for a sinusitis. Shadows were equal, etc. After using drops of H_2O_2 she had violent sneezing, and in blowing her nose the foreign body exhibited was expelled. It was flattened from side to side and germinating. The girl was now quite well and had ceased to attend the hospital.—*Proceedings of the Royal Society of Medicine.*

THE INFLUENCE OF SODIUM CHLORIDE UPON THE HYDROCHLORIC ACID OF THE GASTRIC JUICE.

BY SAMUEL FLOERSHEIM, M.D.

NEW YORK.

(FORMERLY GASTROENTEROLOGIST, GERMAN POLY-CLINIC)

STATEMENTS are current that sodium chloride instilled into the human economy acts as a factor in increasing the production of hydrochloric acid in the stomach. Abstinence from salt would therefore be followed by a material diminution of the hydrochloric acid in the gastric juice while imbibition of it would be followed by increased acidity. It is a generally accepted fact that the hydrochloric acid is derived from the chlorides in the blood circulating in the stomach mucosa. It need not necessarily be the sodium salt that is required, but it is the most serviceable, readily attainable, and easily transformed. If this assumption is correct we should have a method of treatment for increased or decreased HCl acidity of the gastric fluid which would commend itself for its simplicity, its adaptibility, and its cheapness.

Again, in excessive HCl acid, with or without excess of fluid secretion, the most potent, universal, cheap, and efficient remedy, sodium bicarbonate, is an excellent temporary measure. In a number of cases (without carefully searching for the etiology) a cure is effected. In administering the bicarbonate of soda as an antidote we, at the time time, according to the above statement, place within the affected area the exciting cause that is believed to bring on this very condition which we are attempting to cure or relieve.

For the past few months experiments have been undertaken to determine the influence upon the HCl of sodium chloride when taken in the stomach by mouth; in the rectum, by proctoclysis. From a number of patients, eight were taken for experimental purposes, four in whom the free HCl of the gastric contents registered persistently above 80 and four in whom the free HCl was observed to be constantly below 15°. In the hyperacid cases salt was omitted from the diet while in the hypoacids it was allowed to be taken by mouth and a number of times by proctoclysis. No other form of treatment was instituted and the usual mode of living was advised.

In the beginning of the experiments each patient was properly prepared for the ordeal. The usual Ewald test meal was given and routinely examined every fourth day. Five tests were made in each subject. It was constantly noted that in the excess HCl secretion there was no appreciable diminution of the acid content in the aggregate (variations with each test meal were observed); likewise in the low free acid cases there was no conclusive or sharp increase of free HCl secretion.

The reverse experiments were then undertaken, *i.e.* salt and salines in the cases of excess, and practical exclusion of them in the subacid cases. Again it was noted that the results obtained did not warrant the assertion that salt per os or saline proctoclysis was followed by increased acid secretion in the gastric juice.

In three of the hyperacids bicarbonate of sodium was administered for experimental purposes. In two of the cases the HCl became at each examination materially decreased, while in the other case there was no specific change noted. General states, neurasthenia, diabetes, lithemia, and other metabolic, arterial, or nerve conditions were neither considered nor treated.

It would seem, therefore, that the introduction of sodium chloride into the system has no special influence upon the production of hydrochloric acid by the stomach.

It may justly be argued that the number of cases taken is small, yet it should be considered that the experiments were made upon subjects taken at random from quite a number without being specifically selected which would otherwise probably give the unusual occurrence. My belief has always been that which has been brought out by these experiments, and in the treatment of deficiencies or excesses of HCl I do not advise a change from the usual in the salt element.

808 LEXINGTON AVENUE.

Congenital Rickets.—R. Labbé considers that there can be no doubt that children are born with evidences at birth of a rachitic process exactly similar to those seen in older children. The process has gone on in the uterus before birth, and malformations have resulted. It is very difficult to assign to this disease strict limits; there are other conditions that are difficult to differentiate; such are achondroplasia, periosteal diplasia, etc., which may be distinct diseases or simply types of the same disease. Mixed cases in which several of these conditions are combined are not rare. The etiology is still confused; the causes invoked are multiple; they are toxi-infections, heredosyphilis, and predispositions. Distinctions between rickets, achondroplasia, and periosteal diplasia are founded on pathological anatomy alone; the lesions are brought about by the same cause acting with greater or less virulence, intensity, and duration, and the effect depends on the resistance of the organism; they thus may produce very different lesions. New studies of uterine conditions and those begun at birth are needed in this line. —*Revue Mensuelle de Gynécologie, d'Obstetrique et de Pédiatrie.*

Treatment of Uterine Fibromata by Radium.—H. Cheron states that radium is of great value in the treatment of small pelviabdominal fibromata, especially when so deep seated that they cannot be reached by the *x*-rays. The first effect of the application is the arrest of hemorrhages and the moderation of the menstrual period. It also lessens pressure and pain by the decongestion that is produced in the uterus and in the tumor. A definite menopause will be established if the application be persisted in. At the same time the ovaries will not be caused to atrophy, and pregnancy will occur in cases in which the menopause is not produced. Contraindications are malignant degeneration of the tumor, severe hemorrhage with marked anemia which will require a rapid effect, and cases with dangerous compression or symptoms or torsion of the ureters. The application is made by placing the tube in the cervix reaching up to the isthmus, and using one which gives out the ultrapenetrating rays. It should be kept in place eight hours, and the application repeated every three or four days for twelve sittings, if it is desired to establish the menopause.—*Journal de Médecine de Paris.*

Conservative Treatment of Aneurysms and Hematomata.—C. Monod and J. Vanverts state that the surgical treatment of aneurysm includes extirpation, incision, or obliteration of the sac. For aneurysms of the neck and limbs the proportion of cures is 74 per cent. for ligature, 80 per cent. for incision, 90 per cent. for obliteration, and 89 per cent. for aneurysmorraphy. After careful consideration of the different methods of operation and their results the authors give the following conclusions: conservative operations are characterized by a considerable number of successes and an almost complete absence of gangrene; but recurrences and postoperative hemorrhages are somewhat frequent, due to insufficiently solid union of the vessel walls. The artery generally remains permeable immediately after the operation. After some days this permeability seems to disappear in a considerable number of cases; but this secondary thrombosis has few inconveniences, since the collateral circulation has been established before arterial obstruction became complete. Arterial lesions of traumatic origin are easier to treat than others because of the less friable condition of the arterial walls.—*Revue de Chirurgie.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery

New York, June 8, 1912.

THE PRESIDENT OF THE AMERICAN MEDICAL ASSOCIATION.

Of all the honors that have come to Abraham Jacobi none has been greater than that which signalizes his inauguration as President of the American Medical Association. A little over one year ago the MEDICAL RECORD proposed for this high office the name of one "who has ever by his teaching and his conspicuous example reflected credit upon the profession of medicine," and it now extends to Dr. Jacobi its best wishes for a successful administration.

The portrait of Jacobi, which appears as a supplement in this issue of the MEDICAL RECORD, will be prized by all who perceive in the life of the "grand old man" of the profession the ideal of the modern citizen and physician. Few men have ever enjoyed Jacobi's rare privilege of maintaining for fully two generations a position of leadership in public and scientific activities. Few men have ever been able to so thoroughly weld the culture of the Old World with the freedom of the New, or have so sturdily carried the torch of truth into the busy marts and assemblies of men. It is quite fitting that he who raised pediatrics to the dignity of a specialty in this country should in his presidential address plead for the conservation of infant life. An unceasing devotion to his chosen specialty has not deterred Jacobi from proclaiming the headship of the general practitioner whose interests, whose sympathies, and whose usefulness are not limited by the narrow boundaries of any specialty, and who, in spite of a busy career, must ever be ready to lend a hand in shaping the destinies of the state.

THE PRINCIPLES OF MEDICAL ETHICS.

THERE is a full report, on page 1112 of this issue, of the Principles of Medical Ethics as adopted last Tuesday by the House of Delegates on the recommendation of the Judicial Council of the American Medical Association. In comparing the revised principles with those adopted nine years ago at the New Orleans meeting, one notes in the former a vast improvement over the latter, chiefly in the elimination of unnecessary verbiage and obsolete inhibitions, and in the more definite statement of the fundamental principles of ethical professional conduct. Of particular interest is the fact that while fee-splitting is still regarded as an evil to be deplored, nevertheless the physician is permitted to give or receive a commission or divide a fee for medical advice or surgical treatment, provided "the patient or his next friend is fully informed as to the terms of the transaction." In other words, it is only secret fee-splitting that is condemned. Moreover, "the patient should be made to realize that a proper fee should be paid the family physician for the service he renders in determining the surgical or medical treatment suited to the condition, and in advising concerning those best qualified to render any special service that may be required by the patient." It would appear from this unequivocal statement that an honorable division of fees is not only condoned, but is even encouraged. Evidently a new element, that of medical economics, has been introduced into the Principles of Medical Ethics.

PHYSIOLOGICAL CYCLOTHYMIA

IN no department of practical medicine have there been so many and such radical changes in recent years as in psychiatry. The entire domain of this subject, in fact, has been almost revolutionized. In order to account for the well known periodicity of psychoses and psychoneuroses a fundamental substratum termed cyclothymia was first evolved, which counted as a form of psychopathy upon which a number of actual diseases are developed. Further study, however, tended to show that cyclothymia is in its essence perfectly physiological and only when transcending a certain limit does it imply actual psychic inferiority. In its physiological expression, we would expect to see a period of superior mental efficiency succeeded by one of diminished efficiency without much change in the emotional sphere. Many engaged in creative work would simply abandon their efforts until the creative impulses returned. Others would become depressed and worried at the apparent failure of their powers and a rest would be thrust upon them by their counsellors. Several other types of behavior readily suggest themselves. It by no means follows that this condition cannot be minimized. If a man while in his best working period does not apply himself too severely, and does take an occasional week end to himself, or vary his daily work with physical exercise or mental distractions of any kind, it often happens that the inefficient phase of the cycle seems to remain in abeyance. Under such circumstances the more or less prolonged summer vacation replaces the minus phase of the cycle.

A. Zweig in a digest of the progress of psychiatry in 1911 (*Berliner klinische Wochenschrift*, April 29) lays stress on the physiological nature of simple cyclothymia. The plus phase actually represents an excess of psychic health, and the reactionary phase must necessarily represent a deficit. He sees a sort of parallel between this condition and the rut of animals. Even anomalies of character and personality he would not regard as abnormal. In the plus phase these anomalies would be as marked as in the minus phase and each would be characteristic. In the former we should see the so-called eccentricities of genius, self-sufficiency, optimism, recklessness, and in the latter the opposite qualities.

TREATMENT OF THE TYPHOID CARRIER.

Despite all the claims that have been made in reference to the successful sterilization of typhoid germ carriers, there is good reason for the belief that many individuals supposed to be sterile remain a menace not only to others but to themselves as well. This persistence bears a definite relationship to the survival of living organisms in the gall-bladder; for the assertion that these may also persist in the spleen, lymph nodes, and bone marrow appears to be made chiefly on theoretical grounds.

To remove the intact gall-bladder of a carrier with the intention of doing away with the focus of disease is hardly a justifiable routine procedure, but every surgeon who operates on this viscus owes it to science to test the bile very carefully for Eberth's bacillus; and if the latter is present the subsequent treatment must be conducted with the accessory idea of so sterilizing the bile passages that the bile and feces may no longer harbor the organism.

Dehler, who has made a special study of the carrier problem (*Münchener medizinische Wochenschrift*, April 16), says he would not hesitate to extirpate the gall-bladder in the case of an employee who has charge of the food supplies of a large number of people, of a woman with a large family in which one or more deaths from typhoid had already occurred, and under other similar conditions. The operation should be followed by persistent hepatic duct drainage. The author by no means asserts that he would thus interfere until ordinary serotherapeutic resources had been thoroughly tested, but he is satisfied that such sterilization is not to be depended on. Nor would he interfere if repeated examinations of blood and urine had shown by delicate tests that bacilli were present in locations other than the bile and intestines.

A STANDARD OF FEEBLE-MINDEDNESS.

While the terms idiocy, imbecility, and feeble-mindedness have a fairly definite signification, there is no hard and fast dividing line between them. Still less is a sharply drawn distinction possible between the lower grades of normal mentality, and the lesser degrees of feeble-mindedness. This difficulty is keenly appreciated in the public schools where it becomes necessary to separate backward children from those who are normally bright. What is a fair measure of normal mentality, and how shall we determine practically just which ones are normal, and just what degree of mental development is present in the backward ones? Feeble-mindedness is a relative term, and is interpreted differently by different observers. Who are the feeble-minded, and how are they to be recognized?

W. C. Sullivan (*Lancet*, March 23, 1912) maintains with good reason, that the method of Binet and Simon comes nearest of any method so far suggested, to offering a solution of these questions. He quotes the report of the Royal Commission on the care and control of the feeble-minded, which defined feeble-mindedness as the mental state of "persons who may be capable of earning a living under favorable circumstances, but are incapable from mental defect existing from birth or from an early age (*a*) of competing on equal terms with their normal fellows, or (*b*) of managing themselves or their affairs with ordinary prudence." While this definition does not furnish any criterion of judgment, it has the merit of being founded on strictly empirical data. Sullivan concludes that the empirical test of the Commission must be developed more fully and precisely, so as to define feeble-mindedness by reference to an accepted standard of intelligence. Many besides Sullivan have come to this same conclusion, which is logical and sound, but not all have had the insight and skill in elaborating a standard of intelligence, which has attended the work of Binet and Simon.

The principle of this method is very simple. By extensive observations on French school children, the authors arranged a large number of mental tests in a series of groups, graduated according to their increasing difficulty so that each group corresponds to what the average child of a given age can do. For the most part, the tests are of such a nature as to make negligible the personal equation of the examiner. Thus each group of tests furnishes an index of the mental status of the normal child of a corresponding age. For several years, according to Sullivan, this method has been employed in certain primary schools of Paris, as a means for the detection and classification of mental deficiencies. Binet states that a mental development corresponding to twelve years is sufficient for the ordinary needs of an adult under present industrial conditions. Consequently a mental development of twelve years is the minimum normal for an adult. Below two years Binet places the idiots; between two and seven, the imbeciles, and between seven and twelve, the feeble-minded. We have thus an empirical method for recognizing feeble-mindedness and a standard of normal intelligence based on the average mentality of a certain age.

A special report to the New York Society for Prevention of Cruelty to Children, dated February 13, 1912, states that there are in the New York City schools about 10,000 feeble-minded children, and that nearly a third of these are the offspring of the immigrants who have come in the last ten years. Recent census statistics show that 30 per cent. of the feeble-minded children in the general population of the United States are the progeny of aliens or naturalized citizens. The last annual report (for the fiscal year 1911) of the Commissioner of Immigration for the Port of New York, emphasizes the fact that present facilities for inspection are entirely inadequate for the detection of feeble-mindedness in immigrants. Thus it is evident that immigration constitutes probably the largest single factor in the increase of feeble-mindedness in this country. To establish a practical and efficient inspection for this condition among immigrants would be to cut off a large source of the increase of mentally retarded individuals. Realizing the condition as it exists, and its vital relation to the general welfare, the medical officers at Ellis Island have instituted an effort to determine a standard of normal intelligence for the various races which send immigrants to the United States, somewhat after the fashion of the Binet-Simon system. As is necessary and desirable, this

effort is under the direction of men who have had special training and experience in the diagnosis of mental disorders. The Binet method is not applicable under the changed conditions and with the types which prevail among immigrants. But the same general principle is being followed. The investigation is being conducted only on illiterates, those who have attended school being rejected. The purpose in this is to determine the intellectual status of the average illiterate of each race, and to establish this as the minimum standard of normal mindedness. Obviously those who have attended school will rank well above this standard, but if the person being examined has mentality of the average illiterate of his own race, he should not be considered feeble-minded, for the purposes of alien admission.

This method provides a more or less arbitrary division between normal and retarded mental development. But if a satisfactory standard of illiterate normal mindedness can be determined, and suitable tests provided for each race, it will afford a just, quick, and fairly accurate means of detecting feeble-minded adults. To apply the method to children, a long and patient series of examinations will be necessary for the purpose of establishing a standard for different ages. Probably three groups below the age of fifteen will be sufficient, and this age can be taken as the adult minimum standard, although these figures may require modification to suit different races. The need and necessity for a means of detecting feeble-mindedness in immigrants is generally conceded. Every effort should be made to facilitate the development of some such procedure. This method promises to meet the need, and is to be commended.

The Midwife.

Somewhat out of the usual order of presidential orations is the earnest and eloquent plea for the babies made by Dr. Jacobi at the meeting of the American Medical Association this week. In this address, published together with a report of the proceedings of a great part of the session in this issue of the Medical Record, the speaker boldly combats what was until quite recently the prevailing opinion in the medical profession. It has been long and practically universally held that midwives are ignorant and dirty old women who should absolutely be forbidden to follow their dangerous calling, but Dr. Jacobi pertinently asks what the poor would do without them. With all the present overcrowding in the ranks of the profession there are not physicians enough in any of our large cities to attend to all the child-bearing women in the homes of the poor. If all women could be brought for delivery to lying-in hospitals the matter would be simple enough, and everything would speed along as easily and as pleasantly as at a husking-bee. But all women cannot or will not be confined in an institution; they must have some assistance, they cannot pay for the attendance of a trained physician, so to the midwife is their only recourse. The duty of the medical profession, as the orator makes clear, is not to suppress the midwife but to educate her. This is done in other countries to the manifest benefit of the nation, for many lives not only of productive women but of future citizens—maybe a Kent or a Helmholtz or a Jacobi—are thereby saved. Many other counsels for the reduction of infant mortality are to be found in this notable oration, but the one which we have picked out for comment is especially worthy of attention on the part of medical men and legislators in this land.

Salvarsan Therapy of Scarlatina.

To exhibit a drug like salvarsan by the intravenous route in scarlatina of ordinary severity would seem at first sight in every way unwarrantable save perhaps in an occasional fulminating case. The severer manifestations of this affection are commonly believed to be due to the ordinary streptococcus, a germ which has shown no tendency to yield to salvarsan, but a considerable disposition to yield to prophylactic vaccination. On the other hand the actual cause of the disease, which is often assumed to be a protozoan, is doubtless responsible for the occasional severity of the affection in particular years and localities, and evidently is able to show great fluctuations in virulency which can hardly be explained by the behavior of the streptococcus. In certain epidemics the mortality of the disease under the best symptomatic treatment may be very heavy, and we do not yet know whether antistreptococcus vaccinotherapy can affect the mortality favorably in such severe epidemics—which are fortunately by no means of common occurrence. It is rational therefore to have something of possible efficacy in reserve in such cases. At the recent meeting of the German Congress for Internal Medicine (*Deutsche medizinische Wochenschrift*, May 9) Klemperer reported on the intravenous use of salvarsan in an epidemic of scarlatina of such severity as to cause, despite the most approved management, a mortality of nearly 25 per cent. The mortality in the salvarsan series was about 8 per cent. In every case treated the injection was followed at once by a fall of temperature, a phenomenon never seen in any of the forms of sepsis, rheumatism, or tuberculosis. Hence there is a specific quality of drug action hereby suggested.

Organic Disease of the Eye from Solar Light.

It has been reported on numerous occasions that solar rays are able under certain conditions to cause partial blindness which may or may not be permanent. This has been noted especially as a result of watching solar eclipses with the naked eye. The common use of smoked glass in this connection is therefore much more than a mere matter of comfort. The damage appears to be effected when the disk of the sun first appears from behind the shadow. A central scotoma is the result and this may be merely transitory or permanent. At a recent meeting of the Berlin Medical Society (*Berliner klinische Wochenschrift*, May 6) Seeligsohn mentioned the cases of several persons who were more or less blinded in the recent solar eclipse which was visible in Berlin. In all but one of these the fundus was normal, so that the central scotoma had only a functional basis. In three subjects the acuteness of vision was considerably depressed. In all probability these patients will recover completely within a few weeks. It is very different with the solitary case mentioned in which the fundus showed structural alteration. The image of the emerging disk of the sun upon a retina already exposed for an hour, with no protection, had evidently left an

indelible impression in the middle of the foveal centrals where a small round yellow spot was visible, surrounded by an intensely hyperemic zone. Many individuals have so damaged their sight by this imprudence as to be unable to earn their living.

News of the Week.

Health of the Canal Zone.—The report of the Department of Sanitation for the month of March, 1912, places the total number of deaths from all causes among the employees of the Canal Commission at 30, of which 28 were due to disease and 8 to violence, making the annual average death rate for the month only 8.45, the lowest so far recorded for March. Among the white employees the rate was 2.75 and among the colored 7.90. The deaths from the principal diseases were as follows: Chronic nephritis, 3; dysentery, 2; lobar pneumonia, 3; measles, 2; tuberculosis, 0; typhoid fever, 1. One case of yellow fever from Guayaquil was taken from the steamship Chile at the Culebra Island quarantine station on March 2, and the patient died on March 4. With this exception no cases of yellow fever, smallpox or plague originated on or were brought to the Isthmus during the month.

Crocker Cancer Fund.—The final step in the organization of the Crocker Cancer Fund of Columbia University was taken by the trustees of the university on June 3 in the appointment of Prof. Francis Carter Wood to the position of director. Until arrangements are completed for the permanent housing of the working staff of the fund research will be continued as heretofore in the various laboratories of the College of Physicians and Surgeons.

Vital Statistics in France.—During 1911 there were in France 770,933 deaths and only 742,144 births, a preponderance of deaths over births of 34,869. Although the birth rate is said to be diminishing throughout Europe, the total number of births still exceeds the number of deaths in all countries except France.

Philadelphia Polyclinic.—Dr. Ralph Butler has been elected professor of diseases of the nose and throat in succession to Dr. Joseph S. Gibb, resigned.

Medical Society Enjoined.—Dr. Robert Kunitzer, visiting physician to Sydenham Hospital, New York, obtained a temporary injunction in the Supreme Court on May 27 restraining the New York County Medical Society from taking further action under a resolution of December 27, 1910, recommending that Dr. Kunitzer be expelled from membership. The society had planned to take action that evening, but was of course unable to do so under the injunction. The charges against Dr. Kunitzer are in connection with those against Dr. L. A. Ewald. In his petition Dr. Kunitzer stated that he was charged with complicity in altering records of Sydenham Hospital in regard to operations performed by Dr. Ewald, and asserted that he had never had a fair trial, that the society had refused to hear his witnesses, and that at the time of the falsification of the records he was in Switzerland. A motion to make the injunction permanent was argued before Justice Gerard in the Supreme Court on May 29, counsel for Dr. Kunitzer declaring that at the time when the report of the committee appointed to investigate the charges was received by the society six hundred members of the society were present, although the vote polled was 302 against Dr. Kunitzer and 32 for him, and that therefore the three quarters vote of members present necessary for expulsion was not cast. A permanent injunction would prevent any further action being taken on the report of this committee and would necessitate an entirely new trial.

Advance in Aviation.—The second international congress for the purpose of framing aviation laws which met recently in Paris adopted the following resolution: "In the event of a birth or a death occurring on an aircraft, the pilot must enter the event in a logbook and notify the authorities at the first place where he descends."

City Death Rate.—For the week ending May 23, the death rate in New York City was 14.83, a slight increase over the same week last year, when the rate was 14.75. For the previous fifteen consecutive weeks the 1912 rate had been lower than that for 1911, and the average for the entire twenty-one weeks is still considerably less, being 15.05 for 1912 and 16.93 for 1911. During the week there were 108 deaths from violence, 134 from pneumonia, 243 from pulmonary tuberculosis, 183 from heart disease, and 29 from diphtheria. There were 279 deaths under one year of age, 459 under five years of age, and 266 over sixty-five years. Deaths in institutions numbered 530 and in tenements 614.

Will Marry Healthy Only.—Two hundred clergymen in Chicago have approved of the suggestion of Dean Summers that a health certificate as well as a marriage license be demanded from those desiring to marry, and have passed a resolution urging pastors throughout the country to direct their energies toward influencing public opinion to endorse the plan.

Diplomas for Nurses.—At the commencement exercises of the Training School of the Jewish Hospital, Philadelphia, on May 30, diplomas were awarded to fourteen young women graduates.

Flower Hospital to Move.—At the annual commencement exercises of the New York Homeopathic Medical College and Flower Hospital, held on May 29, plans for the removal of the entire plant to a new site were discussed. In its fifty-two years of existence the hospital has outgrown its quarters on the Eastern Boulevard and it is hoped that money for a new structure on a site not far removed from the old one may soon be available. At the exercises twenty-five graduates received the degree of M.D., and on the previous evening nine young women received diplomas at the tenth annual commencement of the Flower Hospital School for Nurses. The annual banquet of the alumni of the medical college was held at the Hotel Astor on May 30.

Lightning Strikes Hospital.—During a severe storm in New York on May 30 the cornice on the roof of the Rockefeller Institute Hospital was struck by lightning. A section of the granite cornice was dislodged and a shower of bricks fell, but no other damage was done.

To Help Peru.—In answer to a request from the Peruvian Government, Dr. George Converse has been assigned by the Public Health and Marine-Hospital Service to take charge of the sanitary improvement work at Iquitoes, for which one million dollars has been appropriated. Dr. Converse has been given a two years leave of absence, and will shortly leave for South America.

New Cattle Serum.—Professor Wilhelm Grugel of the University of Rostock, Germany, has announced that he has discovered the bacillus causing foot and mouth disease in cattle, and has also been

able to prepare a serum immunizing cattle against the disease. The serum is preventive, not curative, and in a large number of experiments has proved very successful. Further investigation will determine the necessary strength of the serum and the length of time for which the immunity remains effective. It is said that the serum can be produced so cheaply as to make the cost of immunization only about seventy-five cents per animal treated.

Hospital Doctors Sued.—A resident of Patchogue, Long Island, has brought suit in Kings County, New York, against six physicians of St. Peter's Hospital, Brooklyn, for alleged malpractice, and demands $30,000 damages. The plaintiff claims that after being injured by a fall in November, 1910, he was taken to the hospital, where he was improperly treated and neglected. The defendants, who unite in denying the charges and in praying for an early trial, are Drs. Charles B. Gildersleeve, John D. Rushmore, Thomas Brennan, Francis H. Bermingham, William G. Siegel, and William J. Donahue.

Street Accidents.—Fifty-two persons were killed and 176 were seriously injured by vehicles in New York City during the past month. Of these automobiles killed 15 and injured 112, and trolley cars killed 10 and injured 30. On the highways of the State outside of New York City, 19 persons were killed and 178 injured during the same time.

New Course in Medicine.—The University of Kansas at Lawrence, Kan., is making plans for a post-graduate course in hygiene and preventive medicine to be given during the summer of 1913 and thereafter, to be open to physicians and seniors in the medical school, and to lead to the degree of Doctor of Public Health. During the present summer the course for health officers which was given last year will be repeated, beginning on June 10 and lasting one week.

Jailed for Selling Bad Meat.—Two butchers in Philadelphia were on May 28 sentenced to serve thirty days each in the county prison for selling tuberculous beef and were also fined $100 each and costs. Five other butchers in court on the same charge changed their pleas to guilty and were fined $500 each.

Would Oust Four Physicians.—The Medical Society of the County of New York has applied to the State Board of Medical Examiners for a revocation of the licenses of four physicians of New York City, on the ground that they have been convicted of crime in connection with their medical practice. Three of them are now serving sentences in the Federal prison at Atlanta, Georgia. They are Samuel E. Hyndham and Ferdinand Hartman, convicted on using the mails to defraud; John E. W. Thompson, sentenced to serve four years for depositing non-mailable matter in the mails for delivery; and Simeon B. Minden, who was convicted of violation of the trademark laws and pleaded guilty to receiving and selling cocaine which had been smuggled into the United States.

Gifts to Charities.—By the will of the late Joseph Hirsch of New York, the following institutions receive bequests of $500 each: Mt. Sinai Hospital, Montefiore Home, Hospital for Deformities and Joint Diseases, Beth Israel Hospital, German Hospital, and Sydenham Hospital. The National Jewish Hospital for Consumptives at Denver receives a bequest of $250.

The German Hospital and Dispensary of New York also receives the entire estate of the late George Piff, valued at about $10,500.

The Montefiore Home receives $1,000 and Mt. Sinai Hospital $2,500 by the will of the late Irving Bamberger.

Mt. Sinai Hospital also receives a bequest of $2,500 under the will of the late Mrs. Bella B. Heiden of New York.

National Association for the Study and Prevention of Tuberculosis.—At the session of this association held in Washington during the last week in May the following officers were elected: President, Mr. Homer Folks, New York; vice-presidents, Dr. Robert H. Babcock, Chicago, and Dr. Edward R. Baldwin, Saranac Lake, New York; secretary, Dr. Henry B. Jacobs, Baltimore; executive committee, Dr. William H. Baldwin, Washington; Dr. Charles H. Hatfield, Philadelphia; Dr. Frederick L. Hoffman, Newark; Dr. George M. Kober, Washington; Dr. S. A. Knopf, New York; Dr. W. R. Steiner, Hartford; and Dr. W. C. White, Pittsburg. Mr. Folks is the secretary of the New York Charities Aid Association and is the first layman to be chosen to head the national society.

Connecticut Homeopathic Medical Society.—The following officers were elected at the sixty-second annual meeting in Hartford on May 21: *President*, Dr. Henry M. Pollock, Norwich; *vice-president*, Dr. Royal E. S. Hayes, Waterbury; *treasurer*, Dr. Henry P. Sage, New Haven; *secretary*, Dr. Samuel Worcester, South Norwalk.

The Long Island College Hospital Alumni held their annual dinner at the Union League Club, Brooklyn, when Dr. Joseph J. O'Connell, the newly appointed health officer of the Port of New York and an alumnus of the college, told of the precautions being taken at Quarantine to prevent the admission of cholera

State Charities Aid Association.—In celebrating the fortieth anniversary of its existence, the association has issued a leaflet listing its accomplishments, either singly or in conjunction with other agencies. Among the more important of the seventy odd items enumerated are the following: First training school for nurses established at Bellevue Hospital; tenement house reform initiated; law enacted providing State care for all the insane; Craig colony for epileptics established; campaign for the prevention of tuberculosis begun, and enactment of laws defining the powers and duties of health officers and authorizing the establishment of general hospitals by cities, towns, and villages. It is hard to believe that these have all been accomplished within the last forty years.

Canadian Medical Association.—The forty-fifth annual meeting of this society will be held at Edmonton, Alberta, on August 10 to 14. The first day, Saturday, will be devoted to business, and the following Monday, Tuesday, and Wednesday to the scientific program. The railroads offer an excursion rate of one way fare plus twenty-five cents, and additional attractive excursions are being arranged.

New Medical Law.—The law passed recently by the Virginia State Legislature requires that within one year from its passage all licensed practitioners of medicine in the State shall reregister in the office of the county clerk. Circulars of information and copies of the law giving full particulars will be sent upon request to Dr. R. S. Martin, Secretary of the State Examining Board, Stuart, Va.

Connecticut State Medical Society.—At the one hundred and twentieth annual meeting, held re-

cently in New Haven, the following officers were elected: *President*, Dr. Edward T. Bradstreet, Meriden; *Vice-Presidents*, Dr. Frederick Gilnack, Rockville, and Dr. Alvin E. Barber; *Secretary*, Dr. Wilder Tileston, New Haven. It was voted to hold the semi-annual meeting in October at Willimantic and the next annual meeting at Hartford.

Texas State Association of County Secretaries.—The following officers were elected at a recent meeting: *President*, Dr. L. Thomas Dorbandt, San Antonio; *Vice-Presidents*, Dr. J. C. Calhoun, Henrietta, and Dr. R. H. Cochran, Coleman; *Secretary-Treasurer*, Dr. J. E. Robinson, Coleman.

Franklin District (Massachusetts) Medical Society.—At the annual meeting on May 14 the officers elected were: *President*, Dr. C. F. Canedy, Greenfield; *Vice-President*, Dr. J. E. Urquhart, Ashfield; *Secretary-Treasurer*, Dr. W. H. Clark, Greenfield.

Iowa State Society of Medical Women.—The fifteenth annual meeting was held in Burlington on May 6 and 7, the following officers being elected: *President*, Dr. Georgia Stewart, Des Moines; *Vice-Presidents*, Dr. Florence Sherbon, Colfax, and Dr. Julia Donohue, Burlington; *Secretary*, Dr. Clara Whitmore, Cedar Rapids; *Treasurer*, Dr. Grace Yerger, Waterloo.

Obituary Notes.—Dr. Samuel Johnson of Asbury Park, N. J., a graduate of the College of Physicians and Surgeons, New York, in 1867, died at his home on May 24, aged 66 years.

Dr. Joseph Dwyer of Passaic, N. J., a graduate of the College of Physicians and Surgeons, New York, in 1900, died in the Passaic General Hospital on May 28.

Dr. Howard Parker of Edgar, Ill., a graduate of the Kentucky School of Medicine, Louisville, in 1897, and a member of the Illinois State and Edgar County Medical Societies, died as the result of an accident on May 22, aged 38 years.

Dr. H. M. Sherman of Peoria, Ill., a graduate of the American Medical College of St. Louis in 1878, died at the Proctor Hospital, Peoria, of Bright's disease, on May 16.

Dr. James A. Mannon of Sherrard, Ill., a graduate of the University of Illinois, College of Medicine in 1894, died suddenly in Excelsior Springs, Mo., on May 12, aged 57 years.

Dr. Joshua Worley of Belle Plaine, Ia., a graduate of the Starling Medical College, Columbus, Ohio, in 1861, a member of the Iowa State and Benton County Medical Societies, and formerly president of the Belle Plaine School Board, died at his home on May 16, aged 78 years.

Dr. John Nicoll of Elizabeth, N. J., a graduate of the Yale University medical department in 1854, died at his home on May 22, aged 81 years.

Dr. James T. Burdick of Brooklyn, N. Y., a graduate of the Worcester, Mass., Medical College in 1853, and a veteran of the Civil War, having served as surgeon in the 147th New York Volunteers, died at his home on May 19, aged 80 years.

Dr. Frederick E. Rabe of New York, a graduate of the New York Homeopathic Medical College and Hospital in 1883, and a member of the New York Academy of Pathological Science, died at his home on May 21, aged 58 years.

Dr. Abraham Finegold of St. Mark's Hospital, New York, a graduate of the University and Bellevue Hospital Medical College in 1911, died on May 19 after a short illness of meningitis, aged 21 years.

Correspondence.

Our London Letter.

(From Our Regular Correspondent.)

TROPICAL DISEASES BUREAU—SANATORIUM PROVISION—CHILD STUDY CONFERENCE—INSURANCE PLEDGE—SCHOOL DIET—INCURABLES—OBITUARY.

London, May 17, 1912.

The Sleeping Sickness Bureau, which has done such excellent service, will be known from July 1 as the "Tropical Diseases Bureau." That is the official announcement of the Colonial Office at the head of a lengthy statement of the origin and work of the organization, which is to be expanded to an extent corresponding with its new title. You will remember that the bureau originated in the international conference in London on sleeping sickness (1907-8). When that failed to establish an international bureau to contend with the disease Lord Eligin, our Colonial Minister, set up one for Britain, the good work of which is known throughout the medical world. Its bulletin has seconded every research on trypanosome diseases, collected a library relating to them, and distributed information to inquirers. It has also initiated the despatch of several expeditions to Africa to investigate sleeping sickness. It has for some time been evident to the medical men engaged or interested in these expeditions that they are equally adapted and qualified for the study of all tropical diseases, and the Colonial Office deserves credit for the support it has hitherto given and to this decided advance. The new tropical bureau will deal with all exotic diseases prevalent in the tropics and subtropics, and will issue a Bulletin expanded with the extended work; an enlarged journal, in fact, carrying on the record of the progress of tropical medicine. The tropical diseases of animals are to be dealt with in a distinct publication, and that this department will be officially conducted we may judge from the fact that Sir J. Macfadyean and Mr. S. Stockman have joined the committee to represent veterinary science. The treasury has agreed to increase its contribution to the funds and the other governments will doubtless raise their subscriptions, so that the Tropical Diseases Bureau has a good prospect.

The Local Government Board has sent a circular to the authorities concerned with the sanatorium provision of the Insurance Act. They remark that in many areas there are some beds available in smallpox or other hospitals which might be utilized, and in most places some existing accommodation that could be adapted for a dispensary. As a first step in formulating any scheme it is suggested that the medical officer of health should be asked to submit a report on the means of treating tuberculosis in the district. When complete schemes will involve delay, interim schemes should be submitted and the outlines of a complete organization indicated.

The National Sanatorium Association has simultaneously held its annual meeting and the chairman was very optimistic because they had seen the Government adopting their views. They had been at work a very short time, but he considered they had made history and changed the face of the anti-consumption crusades. It would be found, too, that treatment by scientific methods was going to yield financial profit to the insurance scheme. The beds available at their Beninden Sanatorium had been increased to 105, they were always fully occupied,

and for their few private beds there were applicants to fill them for years to come. Of 280 patients in 1911 no fewer than 91 left with the disease arrested, and 137 much improved. Of those received in the first stages 93 per cent. had the disease arrested. He anticipated better results still if the dispensary system, which was progressing, should send them a larger proportion of patients at early stages.

We have had a three days' conference, held at the London University and organized by the Child Study Society. Naturally the ladies took their share in the discussion and some of them offered very severe criticisms on the education and management of children by parents and teachers. There were also papers on the medical aspects of the study. Dr. Kerr Love had a paper on the "Influence of Defects of Hearing," in which he argued that the acquisition of speech made this sense of the first educational importance. Absence or defect of hearing arrested mental progress so far that a deaf child of seven had a brain less than normal. Thought processes were, therefore, slower in the deaf. But where only the hand and eye, muscle and bone, and tendon and nerve were chiefly or entirely concerned the deaf were equal to those who heard. He concluded that young deaf children should begin language training at three; that the semi-deaf should attend special schools, from which the totally deaf should be excluded. Mr. Yearsley maintained that there was no connection between deafness and mental defect. He agreed, as did several subsequent speakers, that special provision was needed for the education of the deaf.

The sense of sight was the subject of another discussion started in a paper by Mr. Bishop Harman, who spoke of the difficulty of stimulating the other sense faculties of blind children. As regards myopia, he said the London County Council found it desirable to segregate shortsighted scholars, teaching by the blackboard necessary script and other things by oral instruction, bearing in mind that the eye of the child was immature and must not be strained. Dr. Edridge-Green wanted the society to study the ages at which each color sensation was developed.

The "Tuberculous Child" was the subject of a paper by Dr. Jane Walker, who regarded dispensaries and sanatoria as our first line of defence. The latter could provide education as well as treatment. Miss Broadbent and Dr. Hayes advocated open air teaching and gave information as to schools established for this, as well as for some in which house and garden classes were both established, a plan advised for normal children as well as for the tuberculous.

Dr. T. B. Hyslop read a paper on "Mental Hygiene in Relation to the Development of the Child." He would rejoice if children under six were excluded from school. It was not so much to knowledge as to habits that attention should be paid in the early years. Cleanliness, temperance in eating and drinking, everything comprised in hygiene should be taught. The common system forced the brain too much, and to tax the nation's brain to excess would lead to its decadence, of which he saw signs already. Sir Crichton Browne remarked that it was possible to dictate too much to teachers. Scientific tyranny would be resented as much as priestcraft. The doctors would give teachers better material to work upon whenever they could insist on better conditions in the earliest childhood. Dr. Mumford found want of sleep more often the cause of breakdown than pressure in school work. Miss Bathhurst, ex-inspector for the Education Board, would prohibit the three R's until after six years. A visitor from Massachusetts, Dr. Kirkpatrick, said to make a child learn certain things in a particular way, above all, to pass an examination in them, was bound to injure its mental health. He was supported by other speakers, but some said a child might be better in school than running about the streets. Dr. Alice Corthorn, while criticising mothers in some respects, declared that after all they were the greatest experts, and should be helped rather than hindered in their work, for no one else could do it as well.

The first meeting of the Advisory Committee to the National Health Insurance Joint Committee was addressed by the Chancellor of the Exchequer, who told them whatever their opinions the act was now the law of the land and everyone's duty to obey it. He admitted that it might have defects, and if such should be discovered they could be remedied. Whatever else might be altered he was sure two things would not, (a) compulsory contributions by employers and employed, with State subsidy; (b) general character of the benefits. He boasted that 13,000 officials of friendly societies had attended the gratuitous lectures he had organized to explain the complexities of his act. At his suggestion the committee divided into two sections, one dealing with contributions and accounts, which retired to another room, the other remaining with him to consider questions relating to medical aid. The Advisory Committee consists of 159 members, of whom 33 are medical men, while 67 represent the friendly societies and trade unions, 25 employers' associations, and the others local authorities, insurance commissioners, and insured persons. The medical men are thus outvoted by the interested parties, and the neutrals cannot hold the balance.

The new pledge proposed by the British Medical Association has been made prematurely public by the newspapers and is exciting various comments. Some cordially commend the determination shown to resist the attempt to extend contract practice on pauperizing terms; others declare that the adoption of something like a strike is unworthy of the profession. The collection of pledges still goes on and it is hoped the committee will be able on June 30 to give six months' notice, to expire on the date when the medical work under the Insurance Act is to begin. It is reported that the sum expended by the association on the campaign against the Insurance Act to the end of last year reached above £8,000 and much more must have been added this year.

The Lord Mayor, Sir T. B. Crosby, M.D., opened on Monday a conference at the Guildhall on diet in schools. Speaking, he said as a medical man, the food should be ample, simple, well cooked, and varied. Also the time for taking meals should be ample and the hours fixed and regular. These points were enforced by subsequent speakers, who added a few others equally obvious, and related their experiences. Dr. Dukes reprobated the monotony too common; Dr. R. Hutchinson the tuckshop and sweets with meals. Dr. Shelley said children should be taught mastication, which was better than the tooth brush. One head master said hygiene had been taught at his school over twenty years. Another objected to coddling boys as to food. In his school days the present diet would have been regarded as unheard-of luxury, but his fellows were fairly healthy.

The British Home and Hospital for Incurables had a cheerful report to submit to the annual meeting. More money had been received than in any previous year and a hope was held out of laying the foundation stone of the new wing during the summer. The pensioners on the books numbered 375. The home had been full throughout the year. Towards the £30,000 needed for the new wing and increasing the pension fund, £17,250 had been promised, including a gift of £2,000 from the president (Lord Strathcona) and £5,000 from Mr. Mullins for five beds in the new wing.

Surgeon-Major Frank Powell, M.B., an Indian Mutiny veteran in the Bengal Medical Service, died on May 9 at Redhill, aged 82.

Major T. E. Stuart, who died on the 28th ult. at the age of 48, had served as a civil surgeon in the South African War and received the medal with four clasps. He afterward settled at Leamington.

OUR BERLIN LETTER.

(From Our Regular Correspondent.)

THE WOMAN'S CONGRESS — LARYNGOSCOPY — MESOTHORIUM AND ITS THERAPEUTIC USES.

BERLIN, April 15, 1912.

THE Congress of Women attracted considerable attention during its recent meeting in this city, and the exposition of the work accomplished by women in the home and in the industrial world was visited by a large crowd. Of special interest was the section which dealt with the activities of women as nurses. Sisterhoods of the Catholic and Evangelical sects furnish a large proportion of the hospital nurses in Germany, the former providing 50,000 nurses in 1,100 hospitals, and the latter providing 21,000 nurses. Both organizations display a most rigid discipline, and the sisters who have once adopted the nurses' calling never forsake it. Unlike the deaconesses the Catholic sisters work for no pay. In addition there are 5,000 nurses belonging to the Red Cross, and these are so well organized and so well provided with the necessary military equipment, that at least half of them are ready for the field on the tenth day of the mobilization of the army for war. In time of peace they are always prepared for service. Besides the members of these organizations there are a large number of nurses in private practice, but the absence of uniformity in their work renders the compilation of statistics regarding them impossible.

Schwebe's method of laryngoscopy representing a substantial advance in the operative technique on the larynx and bronchial tubes, was the subject of a discourse before the Berlin Medical Society, March 13, by Killian, the successor of Fränkel in the chair of laryngoscopy. The first attempt to see the larynx directly was made by Kirstein. Since his tubular speculum limited the freedom of mobility of the instrument, a speculum having the form of a spatula has been contrivel. The first experiments were made on the cadaver. Then the experiments were tried on individuals anesthetized with chloroform. Later scopolanim-morphine was tried, and it was finally discovered that local anesthesia by means of cocaine was sufficient for the purposes of the examination. The instrument consists of a spatula with V-shaped edges, and of a suspension apparatus for the spatula. This apparatus is a sort of gallows fastened at the head of the operating table, upon which the patient is placed, with his head supported by an assistant. The spatula, fastened to the gallows, is then introduced into the patient's mouth and the head is gradually released so that it is suspended from the gallows. In order that the spatula may not slide out there is attached to it a lever which grasps the chin between the rami of the mandible. The weight of the head suffices to push upward the root of the tongue so that a splendid approach to the larynx is provided. The method has not been devised for diagnostic purposes or for minor procedures about the larynx. It has been devised rather for operative purposes. With the aid of this contrivance it is possible at one sitting to perform most elaborate operations, in cases in which hitherto a number of sittings have been necessary. The following conditions have already been noted with the aid of this method: Lupus, foreign bodies, pachydermia, tuberculosis, and papilloma. Particularly in children is the removal of a papilloma rendered a simple operation.

Mesothorium was the subject of an address by Bickel at the same meeting. Regarding the thorium emanations there are four preparations representing different stages in the evolution of this substance, namely, mesothorium 1, mesothorium 2, radiothorium, and thorium X. The most available for the thorium emanations is the last preparation for this maintains its activity for five days while the other preparations maintain theirs in part for a much shorter time. These preparations have the following properties: Mesothorium has rays with an intensive action upon the skin and eyes; radiothorium causes inflammatory lesions in the skin, and also stimulates markedly the autolytic ferments. Thorium X is the best for internal administration, for out of it the emanation is developed within the body. In patients to whom this preparation has been administered, the thorium X as well as the emanation can be detected in the urine and in the expired air. Bickel has administered three times daily after meals a dose of 1,000 to 8,000 Mach units. The remedy was employed in a number of cases of chronic rheumatism of moderate severity, with results that were identical with those obtained from the use of radium. Some of the cases were not benefited, but in a larger number the pains and swellings in the joints were diminished. In some of the cases, irrespective of the dose of thorium, there was an aggravation of the symptoms.

In the discussion considerable interest was aroused by the remarks made by Plesch, who in this work started out with the idea that the radioactive substances must not only be permitted to act for a longer time, but should also be used in larger doses. He found that thorium had certain advantages over radium. The radium emanation is a gas which is effective only as long as it is inspired in a closed space. The thorium emanation is decomposed during the period taken by the blood in accomplishing one circulation, and the decomposition products remain in the blood. It is possible to inject large quantities of thorium. Its cost is considerably less than that of radium. It may be injected intravenously without ill effects. When used subcutaneously it causes abscess formation. It is excreted chiefly by the intestine and in the urine. Intravenous injections of large doses had the following effects. Immediate relief was obtained in cases of severe cardiac dyspnea, as well as of pneumonia. It caused a reduction of blood pressure to 100 mm. of mercury, and maintained it at this point for several weeks. Cases of angina pectoris were benefited. Diuresis resulting from vasodilatation fol-

lowed each injection. A favorable action was observed in gout as well as in rheumatism and in leucemia there was a marked reduction in the number of leucocytes.

OUR VIENNA LETTER.

(From Our Regular Correspondent.)

BRONCHIAL ASTHMA—RATIONALE OF THE THERAPEUTICS OF ADRENALIN IN ASTHMA—THE PARASECRETION OF THE STOMACH—CONGENITAL MYXEDEMA.

VIENNA, April 1, 1912.

The pathology and therapeutics of bronchial asthma have been made the subjects of study by Leo Pollak and Hans Januschke, who sought particularly to find an experimental basis for the favorable effects of injections of adrenalin in bronchial asthma. The statement made by Brodie and Dixon that large intravenous doses of suprarenal extract have a weak bronchoconstricting action has been at variance with the clinical findings. If a dog or cat that has not been experimented upon before is injected with adrenalin there results a slight increase in the respiratory movements as determined by the plethysmograph. If by means of a preliminary injection of muscarine a spasm of the bronchial tubes has been evoked, then this spasm is quickly overcome by the adrenalin. A bronchial spasm produced by peptone is also neutralized by adrenalin, but not that produced by imidazolylethylamine. The question arises: How may one explain the antagonism between muscarine and adrenalin? The respiratory inhibition produced by muscarine and provisionally attributed to bronchoconstriction has been conceived by various authors, chiefly by Grossmann, as an expression of pulmonary rigor resulting from stasis in the pulmonary circulation. Upon the basis of this explanation the activity of adrenalin would be understood, since this drug would overcome the stasis in the pulmonary vessels. Measurements of the blood pressure in the left auricle following the administration of adrenalin and muscarine, respectively, show that the former produces a stasis in the pulmonary circulation as great as, if not greater, than that produced by the latter. Since, furthermore, the experiments performed with the aid of ergotoxin have refuted the conception that adrenalin relieves respiratory embarrassment by removing the swelling of the bronchial mucosa, the conclusion seems justified that muscarine evokes bronchoconstriction, while adrenalin evokes bronchodilatation. This relaxing effect of adrenalin with respect to the tone of the bronchial musculature can be utilized clinically in counteracting the bronchoconstrictor components of various forms of dyspnea.

The parasecretion of the stomach, as revealed by the *x*-rays, was the subject of a report made before the Imperial Association of Physicians by K. Fujinamo and Docent Holzknecht. By parasecretion is meant the secretion of gastric juice that occurs at a time when the stomach contains no food. To detect this secretion there are employed two capsules, one filled with bismuth and the other only partly filled with bismuth. These capsules are swallowed by the patient, and if the stomach contains any fluid the filled capsule sinks and the one partly filled floats on the surface of the fluid. In the normal empty stomach the swallowed capsules lie next to each other. In a stomach containing parasecretion the vertical distance between the capsules represents the height of the fluid. The normal empty stomach contains no parasecretion. In pathological conditions there may be detected free hydrochloric acid and parasecretion, with or without evidence of stagnation of the stomach contents. In stenosing carcinoma of the stomach there coexist stagnation of food and parasecretion, but there is no free hydrochloric acid. By means of a phantom meal, that is the chewing of foods without swallowing them, there may be evoked in the person experimented upon a flow of parasecretion, which begins within ten to twenty minutes after the food is taken into the mouth.

Myxedema in the newborn was observed in a case reported recently by H. Abels. A few hours after birth the infant presented the following picture: a bluish-red, cool skin without any apparent cyanosis of the mucous membranes; a wide open mouth with protruding tongue; thick lips; almost constant wrinkling of the fleshy forehead; baglike protrusion of the upper lids; broad and somewhat hanging cheeks; abundant, long, and soft hair growing down over the forehead and cheeks; a strikingly short neck with a slight arching of the supraclavicular region; a normally sized fontanelle with hard borders; a flat bridge of the nose, and marked bowing of the tibiæ. Within the next few days the diagnosis of congenital myxedema was confirmed by the continuous pronounced hypothermia of 34.5° to 35° C., with an initial birth weight of 3090 grams; protracted bradycardia of about 104, the bulging of the abdomen, and the existence of moderate constipation and general sluggishness. The infant died at the age of five weeks from bronchopneumonia. Autopsy revealed complete absence of the thyroid, small cysts in the upper pair of the parathyroid bodies, a characteristic tumor at the root of the tongue, and an abnormally small thymus. The mother of the infant and her sisters, as well as the infant's father, showed evidence of goiter.

7. The Prevention of Occupational Diseases. H. Linenthal.

2. **The Eradication of Typhoid Fever.**—A. J. McLaughlin states that for this purpose the campaign of education should be systematically planned and should press into service every available agency. The public press, the clergymen, the settlement workers, and the school teachers should take a prominent part in disseminating the necessary information. The gospel preached by these lay workers should be simple and need not involve more than two primary facts: (1) Contamination of food or drink by careless fingers may be equivalent to homicide. (2) Such dire results can be avoided by careful cleansing of hands and finger nails after using the toilet and before handling food and drink. This simple instruction should be general. More intensive and complicated instruction should be given only by professional nurses and physicians where actual cases of illness exist in the proper care and disinfection of human excreta. Such a campaign of education would not only reduce the typhoid fever prevalence, but would be followed by a decrease in bacillary dysentery and in the group of entities commonly classified as diarrhea and "enteritis of children."

5. **Hypodermic Injections of Iron and Arsenic in Secondary Anemia.**—J. H. Musser, Jr., concludes that the intramuscular injection of an organic compound of iron and arsenic is entirely practical in office and dispensary work. It is a valuable adjunct to the treatment of anemia secondary to some relatively mild condition. It affords a method of giving the drugs in which the exact amount administered is accurately known. It obviates the annoying complications frequently resulting from the administration of the drugs by mouth.

7. **Prevention of Occupational Diseases.**—H. Timon thal states that for the prevention of industrial diseases the following measures should be adopted: The collection of complete and accurate data regarding industrial processes, the conditions under which the various industries are carried on, and the effect of occupation on morbidity and mortality records. The instruction of the medical student in this important field of preventive medicine. The placing of the specific industrial diseases on the list of diseases notifiable to the central health authority. The periodical examination of all workers in certain industries, these industries to be named by the central health authority. The exclusion of minors and women from certain industries which are designated by the central health authority as injurious to health. The enactment of adequate laws regulating sanitary conditions and protective devices in industrial establishments. The issuance by the central health authority of regulations for certain dangerous trades with instructions to employers and employees as to how they may guard themselves against the ill effects of their work, and the posting of these instructions in the workrooms.

1. **Hysterical Dreamy States.**—By A. A. Brill. (See MEDICAL RECORD, May 11, 1912, page 918.)

3. **Research in Psychiatry.**—B. Holmes states that research in psychiatry ought to be undertaken according to the clinical method of Sydenham and the laboratory method of Metchnikoff, and every State should expend for research not less than 10 per cent. of the appropriations which are so liberally made for custody and confinement. When the State has devoted a tithe of the energy now expended in custody and confinement upon research and cure, when all natural, rational avenues for disease have been followed out, and no physical basis of such long lasting conditions as dementia precox have been discovered, then it seems to the author that every good citizen, every rational physician, every sociologist and humanitarian would unite in such an effort as will make it possible to obtain for these afflicted ones the remedy of euthanasia. By the law of equity which provides a remedy or attempts to provide a remedy for all legal torts, according to the author, it ought to be possible for the friends of the committed insane to appear in court and secure an order which would command the sheriff or his deputy to execute the hopelessly insane and remove them from the consuming custody of the State and from their own hopeless calamity.

4. **Application of Psychoanalysis to Insanity.**—By C. M. Campbell. (See MEDICAL RECORD, May 11, 1912, page 919.)

7. **Old Age in Its Medicolegal Aspects.**—I. L. Nascher states that ignorance of the physical changes of old age is responsible for errors as to the character, extent, and permanence of injuries, their secondary effects, and the effects of shock. Ignorance of the senile mentality, especially during the senile climacteric, is the cause of errors relating to the responsibility of the aged individual, the extent of his judgment and reason, his conception of his acts, his lucid intervals, and the rationality of acts performed during these intervals. In old age there is a greater liability to fracture of the bones. The immediate and remote results of shock are far more serious than at maturity. The sight and hearing are generally impaired, and there is weakened mentality. The stiffening of joints and waste of muscles increase the liability to accidents. The senile climacteric is the critical point of the period of decline and occurs about the middle of the eighth decade of life. From the beginning of the period of decline to the climacteric the mental changes are not very marked. The memory is weakened, the brain works more slowly and becomes fatigued sooner than in maturity. Prominent traits of the aging mind are self-interest, egotism, and suspiciousness. The postclimacteric period is marked by senile dementia. Reason and judgment are clouded and the impairment is progressive until complete dementia is reached. In old age the moral sense is frequently blunted and the lessened control over the emotions and conduct may give rise to acts of impropriety and immorality. During the senile climacteric, or the transition period between old age and senility, every possible manifestation of insanity may occur. As to the testamentary capacity of aged individuals, a recent decision says that "to avoid an instrument on the ground of the alleged mental incapacity of the person who executed the same, such person must be so deprived of his mental faculties as to be wholly unable to understand or comprehend the nature of the transaction."

8. **Addition of Lactalbumin to Modified Cow's Milk.**—E. M. Sill concludes from his experience that the addition of powdered lactalbumin to modified cow's milk has a great field of usefulness, especially for those infants that are ill nourished or under weight for their age, and that do not seem to be making satisfactory gains. This soluble albumin seems to supply that ingredient which is not present in the diluted cow's milk in sufficient quantities to produce a healthy and rapid growth.

11. A Rare Case of Lymphatic Leucemia. C. E. Holzer.

1. **Operative Treatment of Fractures.**—W. O'N. Sherman concludes that fractures of long bones should be treated by the open method and the bones plated, if it is found that reasonably accurate approximation cannot be secured by splints, extension, and other mechanical appliances. There is no evidence to justify the assertion that the presence of a foreign body is the exciting cause of rarefying osteitis. There would be fewer cases of nonunion if the faulty approximation were early recognized and corrected. It is necessary to have the proper operating equipment and to exercise a most rigid technique. The

periosteum should be preserved and the tissues handled with delicacy. The operation should be done quickly; thoroughness, however, should not be sacrificed for speed. The uncertainty of continuous approximation during convalescence, caused by restlessness, delirious patients, or accidents, is obviated by the use of plates. It will be found necessary to remove the plates and screws in the majority of the compound cases, the plate causing sufficient irritation to allow of the persistence of a small sinus.

2. **Myasthenia Gravis.**—V. McL. Hamilton reports a case of the asthenobulbospinal type of this disease occurring in a girl who was first seen at the age of fourteen, when the disease had existed for two years. There was a general weakness shown in the performance of every voluntary act, mostly on the right side; the tongue was involved and the speech was ataxic and clumsy. Thyroid extract was first given with poor results, and then, following the views of Mandelbaum and Celler as to the thymic origin of the disease, the patient was given 5 grams of thymus extract thrice daily, with apparent immediate improvement, which has continued until the present time, eleven years afterward. The author is aware of no other case that has survived as long as the one he reports.

3. **Eructations of Gas from the Stomach.**—T. W. Grayson states that a slight eructation of air after meals is perfectly normal. True fermentation may be present in stasis, but this is comparatively rare. It is the unusual accumulation instead of the excessive production of gas in the stomach which gives rise to the annoying symptom commonly called "gas on the stomach." When this condition annoys a patient he is usually nervous and has too much acid in the gastric contents. One should then give him alkalies, a proper diet, and general treatment. Disease of neighboring organs may cause a feeling of fulness wrongly interpreted as "gas on the stomach."

4. **Gonorrhea in Girls.**—L. Morrow and O. Bridgman recommend the following treatment: (1) For cases in which the speculum can be used, semi-weekly treatments, once with 25 per cent. silver nitrate to the cervix and 10 per cent. to the vagina followed by an application of petrolatum, and once by a 25 per cent. paste of iodoform in glycerin have given the best results. This treatment is not improved by the use of gonococcus vaccine. (2) For little girls and in virgins with an innocent infection, local cleanliness and the use of gonococcus vaccine give the best results. Because of the tendency to recurrence of the infection, however, this is not entirely satisfactory. (3) Vaccine is of the greatest use in cases with joint complications. Here it is almost invaluable.

5. **Abdominal Pain as an Initial Symptom in Typhoid Fever.**—H. S. Carter notes that in a total of 1,815 cases of typhoid occurring between 1897 and 1911 in the Presbyterian Hospital, New York, there were twenty-four cases of acute complicating cholecystitis, and of these four cases were the only ones in which pain was an initial symptom. Adding two cases seen in consultation makes twenty-six in all, and these are analyzed as follows: Eleven were males and thirteen females. Their ages ranged from eleven to sixty-two years. None gave a definite history of previous trouble. Less than a third were severe. In the other twenty-two cases the pain with evidence of gall-bladder involvement appeared from the seventh to the sixty-fifth day of the typhoid fever and, in the average on the nineteenth day, lasting in most cases only a few days. In all, the pain was referred to the region of the gall-bladder and local tenderness existed in practically all. In eleven cases the gall-bladder could be definitely palpated and in all but two of these there was a large and palpable liver. There was jaundice in four cases. Except in some of the severe cases there was little increase of fever and in the majority there was no change in the leucocytosis. In the whole series there were three cases of complicating acute appendicitis, in one of which the abdominal pain from this cause was the initial symptom. In the 1,815 cases of typhoid fever there were twenty-six complicated by intestinal perforation, but in no one of these was the perforation the initial symptom. It is occasionally stated in text-books that such perforation may be the first recognized symptom of typhoid fever. This the author considers true, but of rare occurrence.

8. **Atrophy of Bone and Muscle Resulting from Joint Disease.**—R. W. Lovett reports five cases of bone and muscle atrophy associated with disease or injury of joints. He calls attention to certain points not very often alluded to in the literature. The muscular element in joint injuries has received too scant attention. In some cases of injury to large joints complete recovery does not occur as usual in a few weeks. The joint becomes irritable and painful on use, its circulation is impaired and the tone of the muscles about it is reduced. The bone also may be involved in cases of long duration and the *x*-ray shadow in the spongy portion is not so distinct and may be almost lacking. Very few cases are reported, and the importance of this factor in joint injuries is not sufficiently appreciated. With every sign of synovitis or arthritis there is muscular atrophy, some of which persists in acute cases and continues as a complicating factor in chronic cases. It is one thing to treat synovitis in college athletes and another to treat it in men and women with poor muscles or in middle life. The author would not abandon fixation in acute cases, but wishes to call attention to the inevitable muscular atrophy in any event and its increase through prolonged fixation. He insists on the importance of attention being paid to the after-treatment. In regard to bone atrophy, either alone or complicating other conditions, one should bear it in mind as a competent cause of pain, swelling, stiffness and disability when the *x*-ray shows marked loss of spongy tissue and clear white lines defining the cortex. As to the therapeutics of both conditions, the author states that rough or excessive massage invariably aggravates symptoms and overuse causes symptoms so severe that one is tempted to abandon the treatment. Massage, heat, passive congestion and active exercises in the smallest possible doses, followed by active progressive use of the joint, are the measures most likely to be of use.

2. **Myeloid Leucemia.**—P. N. Panton and H. L. Tidy state that the average duration of this disease in its chronic form is only fifteen months from the time of coming under observation in the fatal cases. In a small percentage of cases the immediate cause of death may be an intercurrent affection. Death may occur by failure of the erythroblastic function of the marrow, and the presence of severe anemia with large numbers of nucleated red cells in the blood is of grave prognosis. The more usual mode of death would seem to be by exhaustion of the leucoblastic tissues, as evidenced by the decreased production of leucocytes and the immaturity of the type produced. Treatment by arsenic and *x*-rays produces no alteration in the condition, or brings about a remarkable though temporary improvement, or in some cases appears to precipi-

tate the fatal issue. The most interesting blood change observed in the author's cases was the replacement of the typical granular cells by non-granular myeloblasts shortly before death. The myeloblasts are present in the stage of compensation, but in small numbers; they may come to outnumber all the other varieties of cells. The large type of myeloblast can be differentiated by Leishman's stain from other non-granular cells. The highest percentage of this type recorded in the author's series was thirty. In another case the percentage was 05, but a proportion of these cells were either intermediate in size or of the small type. The appearance of myeloblasts in large numbers is of importance, not only because of the grave prognosis associated with their increase, but also from the point of view of the relationship between the two leucemias. The fact that a typical myeoblast can be differentiated from a typical lymphocyte does not negative the view that one cell is derived from the other. The numerous intermediate cells which are found connecting the myeloblast with the polynuclear neutrophile suggest that the latter is derived from the former. The cases described by the authors as acute might have been acute only in their termination. They could obtain no evidence, however, of any prior chronic condition in any of the cases, and their clinical condition was scarcely suggestive of chronic myelemia even in its terminal stages. The absence of marked splenic enlargement in the acute cases suggests a failure of any protective action of the spleen. The leucopenia present in one case, in spite of the overproduction of red marrow, is difficult to account for, and in two cases the type of leucocyte present was remarkable. The condition of "hyalemia" present in two cases almost exhausts the possibilities of leucocytic blood changes, and has an important bearing upon the knowledge of the source and mode of production of this cell.

4. **Neuralgic Pain in the Arms after Childbirth.**—J. C. Geddes reports a case of this condition in a patient aged thirty years. The pain was most intense over the lower part of the deltoid and middle third of the biceps, and was aggravated by standing or by attempting to lift a weight. The diagnosis was that the pain was due to pressure of the fifth cervical nerves against the transverse processes of the fifth cervical vertebra; that this was the result of a descent of the shoulder girdle consequent upon the descent of the ribs; that the ribs descended because they lost the support of the diaphragm which followed the viscera down when they gravitated toward the pelvis after childbirth; and that the viscera descended further than is usual because of the atrophy which was superadded to the inevitable relaxation of the abdominal muscles. The immediate treatment suggested was to force up the diaphragm by allowing the weight of the abdominal viscera to come against it when the head and shoulders were depressed and the pelvis elevated, and then to apply some abdominal support (a folded towel placed inside the ordinary corset was used) before assuming the erect attitude. The ultimate treatmeat was to redevelop the abdominal muscles.

5. **Cystitis and Urinary Antiseptics.**—C. Williams concludes from his investigations on the administration of hexamethylenetetramine that there was no decomposition in either neutral urine or urine acidified with acid sodium phosphate in 10 minutes, but in 20 hours there was evidence of slight formaldehyde formation in urine so acidified. This would indicate that to obtain formaldehyde liberation from hexamethylenetetramine the simultaneous administration of an acid rendering substance is necessary, and *per contra* the compound should not be given with drugs in sufficient quantity to produce an alkaline urine.

6. **Treatment of Cancer with Selenium.**—C. E. Walker records the results of his experiments with selenium at the Glasgow Cancer Hospital laboratory. The first preparation tried was colloidal selenium and eosin, which apparently form a colloidal complex. These experiments are of particular interest in view of the claims now made for colloidal selenium. It has been suggested that chemically prepared colloidal selenium is not in sufficiently finely divided particles, and that resort has been had to the electric arc, as is the case in the preparation of the colloidal forms of the metals. The author notes that it is difficult to see how this has been possible as selenium is a very effective non-conductor. Its conductivity is increased, or rather its non-conductivity is decreased, by a very strong light, but the production of an electric arc in distilled water between points of selenium would appear to be so difficult as to be almost impracticable. The satisfactory preparation of selenium for therapeutical purposes in the colloidal form by chemical methods is sufficiently difficult. It is easy enough to arrive at the colloidal condition, but the difficulty is to obtain a permanent preparation. The colloidal selenium tends, upon the slightest provocation, to precipitate in the red amorphous form or to turn into the dioxide (SeO_2). With experiments extending over two months sufficient facts were added to those already available to obtain a permanent preparation. The statement that the particles are not sufficiently small except when the electrical method is resorted to, if any electrical method has been discovered, does not apply to the preparations made in the author's laboratory, and the colloid is just as active at the end of six weeks as on the day it was made, and is not precipitating. Eosin is supposed to be an electrolyte to colloidal selenium. Practically the eosin used by the author has not so acted. Mice and rats with grafted malignant growths of various sizes have been absolutely unaffected by intravenous injections of this preparation except that they have turned pink within 30 seconds or a minute of the injection, and their excreta have been pink for two or three days. Wassermann's preparation was highly toxic. The colloidal selenium, with or without eosin, is non-toxic. The author has injected 0.25 c.c. into mice and 1 c.c. into rats without any ill effects. It is pointed out in this connection that 0.25 c.c. in a mouse corresponds roughly to 700 c.c. in a man. No effect whatever was produced upon the tumors in either mice or rats. The author has found that colloidal selenium is not toxic to monkeys, and the French reports state that it is not toxic to man.

7. **Sterile Abscesses Following Use of Tuberculin.**—D. Forbes and C. Banks analyze a series of 13 cases in which cold abscesses developed after the use of large doses of tuberculin. Twelve of the patients had received from 1/20 to 1/5 of a milligram of tuberculin at the abscess site. The thirteenth patient had received only 1/50 and 1/40 of a milligram. The abscess developed from two to three weeks after the injection, and seemed in no way to affect the general health. The contents of the abscess showed no other organism than the tubercle bacillus. The cause by the abscess formation was not the presence of living tubercle bacilli, but the irritation due to the presence of dead tubercle bacilli.

2. **Pyelonephritis of Pregnancy.**—H. R. Andrews states that the symptoms of this condition usually begin during the second half of pregnancy, and vary greatly in severity. In some cases there is only aching in the lumbar

regions with no constitutional disturbance. Cases in which there are no acute symptoms are comparatively common. If they are unrecognized, and therefore untreated, the patient undergoes a considerable amount of pain and discomfort, which might be relieved fairly easily. The symptoms in more severe cases are pain in the loins and lower abdomen, sometimes very severe, with acute exacerbations, suggesting renal colic, and accompanied by vomiting. The pain may be so severe that the patient's sleep is interfered with to a serious extent. It may be impossible to say whether the affected kidney is enlarged or not, the presence of the pregnant uterus rendering palpation of the kidney regions difficult, but tenderness of one or both kidneys and tenderness along the course of the ureters is found on pressure. In some cases there is little impairment of general health and nutrition; in others the patient is obviously very ill. The temperature is usually raised, and there may be a high degree of pyrexia, usually with oscillations, and rigors may occur. The pulse rate is, of course, rapid when there is much pyrexia. On vaginal examination the intrapelvic portion of the ureter may be found to be tender, and if there is cystitis the base of the bladder is tender to the touch. Micturition may be frequent and painful. The urine is usually acid, and on superficial examination, even when severe symptoms are present, it may show little that is abnormal. After it has been allowed to stand for some time, however, or after centrifugalization, a deposit of pus is found. Sometimes there is a very large amount of pus, but pus may be almost or entirely absent on a single examination. It is possible that the occasional absence of pus may be accounted for by temporary blocking of the ureter on the affected side. Bacteriological examination reveals the presence of microorganisms, most commonly the *Bacillus coli communis* or a "coliform" bacillus. Recurrence in subsequent pregnancies is common.

3. **Etiology of Excessive Vomiting of Pregnancy.**—J. H. Martin states that the various explanations of the causes of excessive vomiting during pregnancy may be classified under three main groups: (1) toxemic, (2) reflex, and (3) neurotic. The theory of the toxemic origin of the hyperemesis is the most rational one. Dirmoser believes that the excessive vomiting is a reflex irritation of the central nervous system, commencing in the internal sexual organs, and through the secretory and motor nerves of the sympathetic, leading to biochemical changes in the digestive tract with the increased production and absorption of toxins. Cazeaux lays stress on the severe constipation associated with excessive vomiting. Williams emphasizes the importance of the high ammonia coefficient of the urine. Behm refers the autointoxication to syncytiolysin. Freund believes the source of the toxins is in the periphery of the ovum or corpus luteum or placenta. As regards the reflex causes it is stated that many observers have noted that displacement of the uterus is a frequent cause of hematemesis gravidarum. Other causes are hydramnios and twins; rigidity, deep tears, and erosions of the cervix; and enlargement and congestion of the inferior turbinate bones. The neurotic cause of the excessive vomiting is frequently hysteria.

4. **Fever in the Newborn.**—E. Cautley states that roughly speaking sepsis is the cause of quite 50 per cent. of the cases of fever in the newborn. About 25 per cent. can be ascribed to gastroenteric infection, but it is probable that many of these are really septic in origin and the alimentary affection is purely symptomatic. Various causes account for the remaining cases. One may leave out of consideration the occurrence of fever transmitted by the mother while suffering from some specific fever, malaria, or variety of sepsis. The malarial parasite may be present in the blood at birth, yet not cause fever until some days or weeks have elapsed. The sources of septic infection are numerous. It may be antenatal, maternal, or congenital; natal, due to infected liquor amnii or vaginal secretions; or postnatal, due to dirty hands, scissors, ligatures, powders, dressings, bath water, sponges, flannels, etc. Often it is impossible to ascertain the portal or source of infection. Sepsis may occur, although apparently the strictest precautions have been taken throughout. Occasionally the evidence of infection by the mouth is fairly conclusive. Clinically there are various types of septic infection. There may be no symptoms except sudden collapse, rapid fall of temperature, and death—a type most common in premature infants. Often it simulates acute gastroenteritis, with vomiting, diarrhea, and high fever. In other cases, cerebral and meningeal symptoms or pneumonic conditions predominate. Or there is severe toxemia, with fever, grayish pallor, and hemorrhages. Hemorrhage after the second day of life is almost always septic. Many cases of hematemesis, melena, and adrenal apoplexy are of this type. Tetanus, hemorrhagic disease, and the affections named after Winckel and Buhl are also septic in origin. The chief affections of the navel giving rise to fever are omphalitis; gangrenous lymphangitis, probably a variety of erysipelas; umbilical ulcer, subnavel abscess, and gangrene; and erysipelas, usually localized at first and insidious in onset, but generally fatal. In these affections the fever begins at the end of the first or beginning of the second week of life, sometimes later.

Berliner klinische Wochenschrift

May 20, 1912.

Can the Blood Stream Be Reversed?—Rothmann sums up the conclusions to date from the experimental work in this field: When the veins are well provided with valves this reversal is impossible, for the resistance is too great to be overcome. In localities where the veins are valveless, and where one vein alone drains the area it is possible to reverse the circulation. The injection fluid, however, only partly escapes by the arteries, the balance appearing in the tissues as edema. If the veins of the locality are without valves, and several veins drain the area, the blood stream can in part be reversed if the fluid is thrown into the single veins. Some of the fluid finds its way out by the arteries but most of it escapes into the other veins by the anastomoses. The authors made several sets of experiments in which arteries and veins were united by anastomoses or cannulas. The mechanical conditions alone were tested, the animals having been bled and artificial fluids infused into the veins. The crucial part of the experiment was the study of the capillary circulation under the microscope.

Errors in Diagnosis of Malignancy.—Fabian relates three cases styled by him "interesting." The first patient, a man aged 44, presented the picture of cancer of the hepatic flexure of the colon. Laparotomy revealed a mass of adherent intestines in which the kidney appeared to be engaged. The liver was studded with metastatic nodules. The case was pronounced inoperable and the wound was closed. The patient even improved at first, but within a month the symptoms reappeared. Patient was lost to view, but five years later reappeared as a dispensary patient. The mass was still present in the right hypochondrium. It was now evident that the lesion had either been syphilitic or tuberculous. Positive Wassermann. Patient made a marvelous recovery on KI. The second case was diagnosticated cancer of the gall-bladder, pronounced inoperable after trial laparotomy. About six years later the patient again appeared without sign of tumor. What she had actually suffered from it was impossible to tell. Syphilis could be excluded, and as the patient when last seen was perfectly well, other destructive processes could also be left out of account. The third case was one of simulation of malignancy by tertiary syphilis.

Ovarian Grafting at the Artificial Climacteric.—En-

gel refers to the conflicting character of some of the clinical results. The difficulty of determining whether ten days or follicular tissue has really healed in must first be overcome before we can pronounce on the therapeutic efficacy of the procedure. A young woman who had been castrated for local causes developed within two months the picture of acute ovarian insufficiency. Ordinary treatment having proved unsatisfactory laparotomy was performed for the purpose of remedying any imperfections resulting from the operation. Scars were excised, adhesions resected, and the uterus freed from a ventrofixation. No benefit resulted. The patient's psyche now began to show improvement. The healthy ovary from a myoma castration was then transplanted into the patient's vagina. It was first fixed to the cervix and then buried beneath the vaginal mucosa. During the next few months the patient steadily improved up to complete recovery. Although the ovary was purposely grafted in a locality where it could readily be studied the author neglects to mention its state at the completion of the cure.

May 14, 1912.

Artificial Impregnation.—Doderlein writes in part as a commentary on Rohleder's recently published monograph on this subject. The percentage of sterile women appears to range from 8 to something over 20, according to the material studied. In recent years our knowledge of the causes of sterility has increased notably. In a large proportion of cases the causes can be determined and perhaps corrected, but there is a residue in which no cause is to be found in either husband or wife. It is this so-called essential or functional sterility in which artificial impregnation appears to be indicated. We know that after years of sterile wedlock these women may suddenly conceive and this appears to justify anticipating this possible climax, especially as animal experiment gives positive results which are suggestive for human work. The author, like Rohleder, has one personal case to his credit. His patient, aged 24, had been sterile six years and had undergone the usual treatment of the cervix. The husband's spermatozoa were normally active. Some of the latter were injected into the uterus just before menstruation. The next period was normal, but after that the menses ceased. There had been no coitus meanwhile. The woman is now four months pregnant. This is the sixth attempt of the author in this field. The technique is simple. With everything in readiness coitus is performed with a condom, the semen transferred to a sterile dish and a little of it at once thrown into the uterus with a Braun's syringe. In theory great care should be employed throughout to secure asepsis, for a case is on record in which as a probable result of gonorrheal spermatocystitis the wife was infected through the intrauterine exposure. As a matter of fact, however, accidents of this sort must be extremely infrequent and too much asepsis would be felt by the spermatozoa, for example should the syringe be first boiled in caustic soda. Care must be taken not to inject too much semen lest it make its way from the uterus to the tubes and peritoneal cavity, there perhaps to set up ectopic pregnancy.

Annular Scotoma from Sun Blindness.—Jess writes of the peculiar forms of sun blindness so called due to watching solar eclipses. The actual lesion of the macula is well known, as it appears under the ophthalmoscope as a reddish-yellow spot with a red areola. This lesion is virtually a burn, caused doubtless by the action of the lens in focusing the solar light upon the retina. Subjectively a central scotoma is caused, which varies greatly with the individual. There are associated with it as a rule more or less clouded vision and diminished acuteness. At the recent eclipse visible in Germany over 100 cases of sun blindness are known to have occurred in Dresden. Careful testing shows that the scotoma is really annular. It is evident that if these retinal burns are sufficiently shallow complete restitution occurs.

May 16, 1912.

Lesions of the Eye from Watching a Solar Eclipse.—Feilchenfeld states that the eclipse of April 17 was viewed in Berlin through a perfectly cloudless sky and at a very convenient period of the day. These two factors conspired to make the event a source of some danger to the beholders' eyes. These eclipses occur so rarely that one generation does not profit by the experience of its predecessors. The last event of the sort took place in 1887, and as the day was cloudy and the eclipse occurred soon after sunrise on a long summer day not many people saw it, and but few cases of ocular trauma are known to have occurred. On the present occasion the public was warned as usual by the daily press to protect the eyes. It was advised that the eclipse be viewed through a minute opening in a piece of cardboard. This counsel is evidently very unwise, for although much light is shut out by following it, the macula is exposed especially to a sharp pencil of rays which pass through the paper. Immediately after the event colored vision was common, with scotomata and unpleasant subjective sensations. But in the majority of cases all such symptoms vanished in a few hours. In a large number of cases the effects persisted and professional advice was sought. All the local eye specialists are believed to have seen many cases. The author reports a number of illustrative cases. Patient No. 1 watched the eclipse with the naked eye and had a scotoma of the right eye for two days, but rapidly recovered. A second patient also watched the eclipse with naked eyes and was bothered for a time by dark specks before the eyes and blurring of vision. After the symptoms had become aggravated for a day he began to improve. The third patient watched the eclipse for twenty minutes with smoked blue glasses. She saw red spots and had cloudy vision. Her symptoms became worse day by day and the ophthalmoscope showed on the fifth day lesions in both maculæ. These slowly resolved, the vision becoming normal. A fourth patient saw the eclipse with naked eyes. By the sixth day she had a left central scotoma of 5 mm. diameter on the perimeter, due entirely to a lesion which could be seen on the macula. This slowly underwent resolution. The author saw no cases of permanent injury resulting from exposure of the eyes to the intense light of the sun.

Appendicitis in a Case of Transposed Viscera.—Muhsam calls attention to the fact that on June 15, 1911, he reported a case of this association before the Hufeland Society of Berlin. That it escaped the attention of the profession appears from the fact that Hollenbach some time afterward reported a personal case with no allusion to the author's or indeed to any previous case. At least 200 cases of transposed viscera are upon record, but up to a few years ago but one case of associated appendicitis was mentioned in standard authors. But since two cases have now been reported in neighboring localities and at nearly the same period it is possible that the condition is by no means as rare as has been believed. The author operated on a young man for acute appendicitis, the diagnosis of inverted viscera having previously been made. In Hollenbach's case on the contrary the condition in the female patient had not been surmised by several abdominal surgeons who had done in succession an operation for a left floating kidney, a ventrofixation, and a right-sided ovariotomy. After appendicitis had developed an *x*-ray readily revealed the transposition.

Insurance Medicine.

The Acceptability of Applicants with a History of Operations.—Flesch says that at one time the history of an operation served as sufficient cause for declining an applicant. This was because at that time operations were performed only as procedures of last resort, when the patient had been between life and death for many days, and his recovery meant good fortune more than the result of operation. It could therefore be concluded that the patient remained very weakened by the preceding illness. Things have changed nowadays, yet a history of an operation must be carefully considered if given by an applicant.

Such postoperative cases may be considered under several headings. First are applicants who must be declined however successful was the operation. These are the applicants with malignant disease, who have recently been operated upon, whether the neoplasm was a cancer of the breast, of the uterus, or of the intestines. Persons in whom one kidney has been removed for tuberculosis must be classified with those suffering from malignant disease.

The second group includes persons operated upon for affections that frequently are only a part of a general predisposition or "morbid diathesis." Here belong caries of bones, syphilitic joint diseases, local extrapulmonary tuberculosis, extirpation of lymphnodes, cholecystotomy and cystectomy, bladder and kidney stones, gastroenterostomy for gastric ulcer, gastric dilatation, etc. Caries of bone and lymphnode tuberculosis are usually diseases of childhood and youth, and applicants with operative history for these affections are acceptable if some ten years have gone by without new foci of disease and without signs of general organic weakness. Tuberculosis of the testicles should be especially carefully dealt with. Mere cholecystotomy with drainage for gallstones does not insure against recurrence of stones. Cholecystectomy should, of courses, be judged more favorably. If stones have been removed from the genitourinary system, careful examination of the urine should precede insurance: excess in uric acid or in phosphates should disqualify the applicant. After gastroenterostomy with a favorable result, marked by cessation of symptoms of gastric ulcer, gain in weight, etc., an applicant could be recommended for insurance if three years have elapsed. If dilatation with marked motor insufficiency existed the application should be denied, as "restitutio ad integrum" may be considered impossible in such cases, however good may have been the functional result. Patients who have been operated upon for abdominal symptoms, nothing more than adhesions having been found, should be handled with suspicion, for the true cause of the symptoms may turn up later and prove much more serious.

Appendectomy resulting in a good scar without tenderness in the appendix region should result in acceptance of the applicant. If little change has been found in an appendix where several abdominal symptoms existed, a postponement is advisable; it may be that another cause for the symptoms has been overlooked. Mastoid operations should not stand in the way of insuring an applicant. Radical operations for hernia should be judged similarly. Removal of benign thyroid tumors should be judged leniently; patients operated upon for exophthalmic goiter, on the other hand, should usually be refused.

Operations in the female genital sphere, as a rule, form no obstacle to insurance; indeed, hysterectomy or double oophorectomy, will save the dangers accompanying possible pregnancy in a female applicant. Operations for empyemata of the sinuses about the nose and face should not be counted against an applicant. In general it must be said that division of applicants into the three groups mentioned above is advantageous, yet each applicant must likewise be individually judged.—*Zeitschrift für Versicherungs Medizin*, March, 1912.

Loss of One Eye in Reference to Insurance.—Hilbert concludes that persons who have lost one eye through disease or accident, in whom the stump of the eye has been satisfactorily removed, and whose employment does not contain any conditions dangerous to the other eye, may be insured just as healthy persons and at the same rates. If the stump has not been removed insurance should be declined until this has been done. If the occupation is a hazardous one for the remaining eye, a special clause limiting liability in case of loss of that eye should be included. Applicants who have lost one eye because of a non-malignant growth should likewise be insured at the ordinary rates; on the other hand, if giving a history of melanosarcoma, glioma, or simple sarcoma of the eye or neighboring structures, they should be declined or insured for a short term only.—*Wochenschrift für Therapie und Hygiene des Auges*, XV, 18.

Responsibility in Industrial Accidents.—L. Berard states that accidents resulting from labor of various kinds may be caused through the fault of the employer or of the workman; by accidental circumstances; by catastrophe, such as lightning and earthquakes; and by an unknown factor. It is calculated that one-fourth of all accidents are referable to the employer, another fourth to the laborer himself, and the other half to the three remaining causes. An accident is defined as something that occurs suddenly and unexpectedly. Thus industrial poisoning does not come under the head of accident, since it occurs slowly and gradually. Another important question is, what part the previous health and diseases of the individual take in the liability for damages. This is a most important question and one that is not easy to decide, but it should be studied by physicians in order that they may properly assist the courts in determining the responsibility for accidents and the amount of damage to be paid for injury. About 25 per cent. of all laborers have hereditary or acquired syphilis; the victims of alcoholism are many, and tuberculosis is another important factor in accidental injury. The author classifies accidents in relation to disease as follows: First, accidents determined by a previous condition of disease, but resulting directly from circumstances of labor, as when an epileptic falls and is injured; second, accidents aggravated by a previous disease, such as a fracture in a tuberculous subject; third, accidents which aggravate a preexisting disease, such as epithelioma infected through an accident; fourth, the results of an accident aggravated by a previous diathesis, as gangrene from injury in a diabetic subject; fifth, accidents aggravated by a previous accident resulting in some disability, as when a new cicatrix is opened afresh after injury. In all of these cases the employer should be considered entirely responsible, since the accident was the cause of the development of the disease which previously existed.—*Le Bulletin Médical*, February 7, 1912.

Book Reviews.

GESAMMELTE WERKE VON ROBERT KOCH. Unter Mitwirkung von Prof. Dr. G. GAFFKY, Geh. Ober-Med.-Rat in Berlin, und PROF. DR. F. PEUCH, General-Ober-Arzt a. D. in Berlin. Herausgegeben von Prof. Dr. J. SCHWALBE, Geh. San.-Rat in Berlin. Drei Bände mit 104 Textabbildungen, 43 Tafeln, dem Protrat Robert Kochs und der Abbildung seiner Grabstätte im Institut für Infektionskrankheiten zu Berlin. Price, 80 marks, bound, 88 marks. Leipzig: Verlag von Georg Thieme, 1912.

IN these days of rapid advances in medicine it is not every man's works, however valuable they may have been when published, that are worth preserving or rather republishing in permanent form. Many of them may be of interest in an historical sense and may serve as valuable documents for the student of medical history, but the busy practitioner could ill afford the time for rereading them, since their teaching, modified or simplified as the case may be, is embodied in the current literature. But the case is different with the outgivings of a genius; the creations of his brain are imperishable; a seer, far in advance of his time, his outgivings are ever of contemporaneous interest as well as historically valuable. It is therefore gladly that we welcome this publication of the celebrated works of Robert Koch and we can but be grateful to the editors of these three ponderous volumes for their piety in collecting from all sources, often rescuing from the obscurity of comparatively unknown publications and disinterring from volumes of society transactions, all the products of this master's ready pen. Many of these articles—addresses, brief essays, and discussions of various subjects, preserved only in manuscript or privately printed reports—are here published for the first time in a collected edition.

The writings of Robert Koch represent practically the history of modern bacteriology, so closely has the name of this indefatigable worker been identified with the progress of this science from its very beginnings—from the investigation of the etiology of anthrax to that of the origin of sleeping sickness. His fame, however, would have been no less than it is if his achievements had ceased with the discovery of the tubercle bacillus. In collecting in one edition the numerous and varied writings of Robert Koch the editors have acquitted a task of no small magnitude, and have rendered an immeasurable service to all students of modern bacteriology and hygiene. Unlike many medical writings, the works of Robert Koch will ever remain a source of inspiration and profit to all students of disease, whether in its individual aspects or in its larger rôle as a national or international scourge. It is pointed out by Schwalbe in the preface to this edition that Koch's writings were comparatively few, reaching barely one hundred. He wrote with few exceptions only when he had something new to convey. He wrote few monographs and never published a textbook. His epoch-making investigations on tuberculin were responsible for only six articles on the various phases of this subject.

The first volume contains the series of brilliant articles that represent the work of the pioneer in modern bacteriology: the investigations on the etiology of anthrax; the methods of studying bacteria; the relation of bacteria to infectious diseases; the rôle of bacteria in wound infections; recurrent fever and the spirochetes; anthrax vaccination; methods of studying bacteria in the soil, air, and water; disinfection; and the series of articles on tuberculosis and the tubercle bacillus. These latter include the following: The etiology of tuberculosis; the campaign against tuberculosis; the transmissibility of bovine tuberculosis to man; the immunization of cattle against tuberculosis; the Nobel lecture on the modern status of the antituberculosis movement; preventive measures against tuberculosis; the relation between human and bovine tuberculosis; the epidemiology of tuberculosis; bacteriological research; remedies for tuberculosis; the newer tuberculin preparations; the treatment of pulmonary tuberculosis with tuberculin; and the agglutination of the tubercle bacilli and its practical value.

The first part of the second volume contains the important articles on cholera and its epidemiology and diagnosis. These articles include the reports on the expedition sent in 1883 to study cholera in Egypt and India; the Berlin conference on cholera; the cholera organisms; modern cholera diagnosis; water filtration and cholera; cholera in Germany during 1902 and 1903; and the means of combating cholera. There are also the valuable articles on the following subjects: The prevention of infectious diseases, particularly in armies; the campaign against typhus; malaria in East Africa and blackwater fever; medical observations in the tropics; the results of the expeditions to Italy for the study of malaria, the development of the material parasite; and the fight against malaria. Then follow the more recent studies on sleeping sickness as follows: The trypanosome diseases, the results of the German expedition to East Africa in the study of sleeping sickness, anthropological studies undertaken during the expedition to Victoria-Nyanza; the bubonic plague in India and Africa; and the spread of bubonic plague. The second part of the second volume contains the following articles: Frambesia tropica and tinea imbricata; travel reports on rinderpest, tropical malaria, etc.; the immunization of cattle to surra; Rhodesian redwater fever or African coast fever; and vaccination against horsesickness. In addition to these there are a large number of miscellaneous articles, addresses, and unpublished reports and discourses before various assemblies. These latter are too numerous to enumerate in detail. An excellent portrait of Koch forms the frontispiece of the first volume, while that of the second volume shows Koch's epitaph in the Koch-Mausoleum of the Institute for Infectious Diseases in Berlin. The illustrations and colored plates accompanying the text are in keeping with the monumental character of this work, which in every respect represents the best of the publisher's art.

DIE ZUCKERKRANKHEIT: IHRE URSACHEN, WESEN, UND BEKÄMPFUNG. Gemeinverständlich dargestellt von Dr. med. A. SÖPP. Price, marks 1.50. Würzburg: Curt Kabitzsch, 1912.

DIABETES is so essentially a disease that requires skilled medical supervision for its proper management that the wisdom of placing in the patient's hands a popular treatise that is likely to lead to efforts at self-treatment is more than questionable. Aside from its object, however, of instructing the laity there is little to criticise about the present pamphlet of seventy pages. It is clearly written, in easily understandable language, and gives useful warnings in regard to the so-called carbohydrate-free diabetic foods and the various nostrums advertised as remedies. Serviceable diet lists and tables of food values are included.

DUODENAL ULCER. By B. G. A. MOYNIHAN, M.S. (Lond.), F.R.C.S. (Leeds). Second Edition, Enlarged. Illustrated. Price $5.00. Philadelphia and London: W. B. Saunders Company, 1912.

DR. MOYNIHAN'S epoch-making book on duodenal ulcer now appears in an enlarged edition less than two years after its first appearance. Its contents have become part and parcel of advanced medical and surgical knowledge of to-day, and the second edition, therefore, requires but brief notice. It contains, among new matter, extended discussion of the differential diagnosis of duodenal ulcer and the result of *x*-ray examinations of the stomach after the administration of bismuth.

Moynihan's work consists of two parts, the first of eleven chapters giving the etiology, symptomatology, and treatment of duodenal ulcer; the second contains two appendices giving a detailed statement of 305 cases of duodenal ulcer observed and operated upon by the author since 1900. This wealth of material shows that no surgeon or internist who claims to be progressive can afford to be without this monograph on the subject.

TEXTBOOK OF OPHTHALMOLOGY IN THE FORM OF CLINICAL LECTURES. By Dr. PAUL ROEMER, Professor of Ophthalmology at Greifswald. Translated by Dr. MATTHIAS LANCKTON FOSTER, Member of the American Ophthalmological Society; Member of the American Academy of Ophthalmology and Oto-Laryngology. With 180 illustrations in the text and 13 colored plates. Volume I. Price $2.50. New York: Rebman Company, 1912.

THE translation of Roemer's textbook has been very well done by Dr. Foster. The author endeavors to cover the subject of clinical ophthalmology by a series of lectures didactic and clinical in nature. The text, written in the style of a monologue, is informal and pleasing, and the meaning that it is intended to convey is easily grasped. The arrangement is systematic; the illustrations well chosen and sufficient in number. The colored plates are excellent. Refraction and conditions of the ocular muscles are not considered. There is no bibliography. In the presentation the author displays a profound, up-to-date knowledge of the subject. There is much of the personality of the writer in evidence. However, this does not detract from the work. The volume, which is one of 275 pages, is heartily recommended for perusal and study by all who are practising ophthalmology.

THE TREATMENT OF SHORT SIGHT. By Dr. J. HIRSCHBERG, Geh. Med. Rat in Berlin. Translated by G. LINDSAY JOHNSON, M.D., F.R.C.S. With twelve illustrations. Price $1.25. New York: Rebman Company, 1912.

PROFESSOR HIRSCHBERG'S Essay on Short Sight forms a small volume of 123 pages. It is a rather comprehensive statement of his views on the subject founded on "an uninterrupted ophthalmic practice extending over several decades." Professor Hirschberg's well-known exceptional powers of observation and his erudition entitle his writings to careful consideration. In the monograph the history of myopia is given; then follows a description of the various forms of myopia; its correction by the use of glasses; the anatomical conditions met with; the operative and non-operative treatment, including removal of the crystalline lens in high degrees, and of that frequent complication, namely, detachment of the retina. The essay merits careful perusal by all who are interested in the subject.

DIAGNOSE UND THERAPIE DER MAGEN- UND DARMKRANKHEITEN. Anhang: Die chemische und mikroskopische Untersuchung des Mageninhaltes und der Fæces. Von PRIV.-DOZ. DR. WALTER ZWEIG, Abteilungsvorstand am Kaiser-Franz-Josef-Ambulatorium in Wien. Zweite, vermehrte Auflage. Mit 35 textabbildungen und 1 farbigen tafel. New York: Rebman Company; Berlin: Urban & Schwarzenberg, 1912.

ZWEIG has furnished us with a new book on the diagnosis and therapy of diseases of the stomach and the intestines. Respecting the treatment of hyperacidity he says that Rosenheim and Ehrmann introduced a soluble aluminum silicate called neutralon. Its effect develops through the gradual splitting up of aluminum silicate by the muriatic acid secreted into silicic acid and aluminum chloride, which is astringent and disinfectant. The amount of HCl neutralized by neutralon in the course of a few hours can be considerable, as a teaspoonful of the powder is able to neutralize 400 c.c. of a 0.2 per cent. HCl solution during the course of a few hours at body temperature. The author has used neutralon in many hundreds of cases and has been very well satisfied with its effect. It is best to give a teaspoonful t.i.d. in a wineglassful of water ½ hour before meals. In severe cases 0.02 g. ext. belladonna may be added. Referring to the point of tenderness in ulcer Zweig maintains that we must consider whether this pain is caused by gastric ulcer, gallstones, or gastroptosis. In favor of ulcer: Pain after taking of food, more intense after solid than liquid substances, stronger in the upright than recumbent position, pain lasting for weeks, improvement after milk diet, occult hemorrhages. In favor of cholelithiasis: Occurrence of pain in attacks with intervals free from pain; pain radiating to right, liver large, sometimes jaundice, pain independent of quality of food, pain not influenced by lying down. In favor of gastroptosis: Not dependent on quality of food, cessation of pain on lying down and active support of abdomen, pulsation of aorta, other signs of intestinal neurosis, lack of occult hemorrhages.

When may we consider an ulcer to have been healed? This question we can only rarely answer with certainty. We have no single symptom which will indicate to us unfailingly whether the ulcer has healed, and we are never able to judge of the firmness of the scar tissue. We have only two criteria in reference to the healing of the ulcer. The one is complete cessation of pain and the other, examination for occult blood in the stool with meat-free diet, as recommended by Boas. As long as there are pains after meals and as long as blood can be demonstrated in the stool we cannot consider the ulcer healed. The finding of occult blood is in these cases more important than the pain. The ulcer may be entirely healed and yet a certain tenderness persist which can be referred to adhesions or hyperacidity. Blood in the stool, however, proves that the ulcer is not yet entirely healed. In such a case another period of exclusive milk diet must be inaugurated and the patient kept under observation until repeated stool examinations have proved that there is no longer any occult blood. Frequently several ulcer cures will be necessary.

Zweig's book may be recommended to physicians interested in gastroenterology.

DIE CHRONISCHE ENTZÜNDUNG DES BLINDDARMANHANGES (Epityphlitis Chronica). (Chronic Inflammations of the Appendix.) By Dr. FRITZ COLLEY. Price, 6 marks. Berlin: August Hirschwald, 1912.

IT is the writer's aim to present in this manual a résumé of the numerous studies on the subject of chronic appendicitis, in which he discusses principally the pathology, symptomology, and diagnosis, not giving more than a cursory attention to the operative technique, as he considers that this varies to such an extent with the individual surgeon that a general account must be unsatisfactory. In this book of over 200 pages the text is made up largely of didactic discussions, from which it would appear that the contentions between the internists and the surgeons in this field have not been adjusted. Colley, in fact, makes it appear as if the views of these two classes of observers were further apart at the present time than ever before and that the surgeons seem to have developed the subject to the exclusion of its treatment by the medical men. Colley believes that the future will demonstrate that the pathogenesis of so-called chronic appendicitis has resolved itself into a problem dependent on obstipation and that to the appendix has been falsely attributed the reason for this condition. In view of the existing uncertainty regarding the precise pathology of the acute as well as chronic varieties of appendicitis, the author considers it dangerous to depend on a spontaneous cure of the same and regards surgical interference as invariably indicated. The book may be regarded as a valuable contribution to the literature on this important subject.

FOOD FOR THE INVALID AND THE CONVALESCENT. By WINIFRED STUART GIBBS, Dietitian for the New York Association for Improving the Condition of the Poor; Teacher of Economic Cookery, Teachers' College, Columbia University; Author of "Lessons in the Proper Feeding of the Family." Price, 75 cents net. New York: The Macmillan Company, 1912.

SO capricious is the appetite of many invalids that a fresh viewpoint on diet for invalids and convalescents is always welcome. The present little volume contains many helpful hints. How to Buy, How to Eat, and How to Cook are among the problems considered. The preparation of the various classes of foods next claims the reader's attention while Part II is devoted to special menus and diets. Unfortunately, there is no index—a defect even in the smallest volume of reference.

DIE ZUCKERKRANKHEIT UND IHRE BEHANDLUNG. Von Professor Dr. CARL VON NOORDEN. Vorstand der I medizinischen Universitätsklinik in Wien. Sechste vermehrte und veränderte Auflage. Price 10 marks. Berlin: August Hirschwald, 1912.

THE sixth edition of von Noorden's classical work on diabetes contains about twenty pages more than its predecessor, and comparison of the two volumes shows that the revision has been thorough in nearly all sections of the book. The most important additions, perhaps, relate to the subject of the oatmeal cure—the *modus operandi* of which the author admits is still something of a mystery. Three possibilities suggest themselves: the oatmeal may contain substances that modify in some specific way carbohydrate metabolism in the liver, or the carbohydrate of oatmeal behaves differently in the course of its breaking up in the body from starch of other origin, or the oatmeal has the effect of causing greater efficiency of the renal filter. None of these theories, however, suffices to explain the clinically well demonstrated fact of the utility of the oatmeal cure, which in many instances is extremely great. The very valuable bibliography has been brought up to date, and the index has been considerably changed, though as the latter alteration consists in reducing its size to about one-half it can hardly be considered an improvement.

PHARMACEUTICAL BACTERIOLOGY. WITH SPECIAL REFERENCE TO DISINFECTION AND STERILIZATION. By ALBERT SCHNEIDER, M.D., Ph.D., Professor of Pharmacognosy, Histology and Bacteriology, California College of Pharmacy; Pharmacognosist, U. S. Department of Agriculture. Price $2.00 net. Philadelphia: P. Blakiston's Son & Co., 1912.

AS bacteriology develops and becomes broader in its practical applications, the need arises for special text-books designed for the use of a single profession. This is the first work to appear devoted entirely to pharmaceutical bacteriology. Its aim is to give the pharmacist a fair knowledge of microorganisms in general and sufficient familiarity with bacteriological technique to enable him, first to prepare and keep sterile medicaments and second to assist the physician and sanitarian when necessary in bacteriological investigation. The book is sufficiently complete for its purpose. The directions are clear, though in places perhaps somewhat lacking in detail, and the text contains much of value. The volume may be recommended.

Society Reports.

AMERICAN MEDICAL ASSOCIATION

Sixty-third Annual Meeting, Held at Atlantic City, N. J., June 3, 4, 5, 6, and 7, 1912

(Special Report to the Medical Record)

HOUSE OF DELEGATES.

Monday, June 3, First Day.

THE PRESIDENT, DR. JOHN B. MURPHY, OF CHICAGO, IN THE CHAIR.

President's Address.—Dr. John B. Murphy, after expressing his appreciation of the honor conferred upon him in electing him to preside over the most representative body of medical men in the world, said that it was customary on this occasion for the president to express his estimate of the work done during the year and to give his opinion as to the activities which were desirable in the future. While the work accomplished was not all that they desired it was the best that was possible.

Medical interest in public welfare had been characteristic of the profession through the centuries and had become axiomatic. During the year there had been an organized attack against this work for the public welfare. False statements had been so persistently reiterated that many right minded people had come to believe them true. Its most conspicuous efforts had been directed against the movement for the establishment of a National Health Bureau. As was well known those most active in this movement were the food adulterators and patent medicine men, Christian Scientists, osteopathists, eclectics, etc. It was time to put before the public the real position of the profession. Every time one of their speakers appeared before the public, the medical profession should have one of its members on the ground, on the same platform if possible, in order to refute false statements and to place the matter before the people in its true light. In their work toward securing a National Health Department two points were important, first, that of public education, and second, that of securing men familiar with legislative procedures who would push the work for them. This work should be transferred from the Council of Public Health to the Council on Legislation. The secretary of the association should be secretary of this council. Activity on the work of organization had about reached a standstill. Several thousand members had resigned and they should find out why the association was losing prestige. There were 102,000 medical men in the United States and only 34,000 in the association; in some states as many as 66 per cent of the profession were affiliated with the organization while in others as few as 22 per cent. belonged to the association. They must find out why this was so and do what they could to retain the interest and support of the rank and file of the medical profession. Dr. Murphy, therefore, recommended that a Council on Organization be appointed to consist of five members. The work of such a council could only be advanced by direct contact with the members of the profession in their home localities. After speaking of the creditable work of the Journal Dr. Murphy spoke of the surplus funds which had been accumulated and the necessity of expending them for the benefit of the profession. It seemed advisable that the amount of reading matter in the Journal should be increased as there were many excellent papers for which they now had no space. He thought that an addition of 50 to 100 per cent. to the present amount of reading matter could be made with advantage. They should give more attention to matters concerning state and county societies and should have a bureau of inqury and information. Whether the additional matter should be added to the Journal in its present form or issued as a supplement was a question for the editors to decide, but the House of Delegates should insist that something in this direction be done. The last century had been a century of reading and the present century was one of observation, and inspection; it seemed advisable, therefore, that they should have three clinical days in connection with these meetings, Monday, Friday, and Saturday. The committee appointed last year to consider this matter should be made a permanent one. In closing Dr. Murphy suggested that in the selection of officers and the appointment of committees the House of Delegates should endeavor to avoid any tendency to plutocracy or autocracy.

Report of the Secretary.—Dr. Alexander R. Craig said that there had been added 3,474 names to the membership roll, of which 2,353 were transferred from the subscription list. The membership of the association on May 1, 1912, was 34,283, a net increase for the year of 323. A committee to represent the American Medical Association at the Third National Conservation Congress was constituted and the following were appointed: Chairman, William A. Evans of Chicago; Abraham Jacobi of New York; Norman Bridge of Los Angeles, Cal.; Hubert Work of Pueblo, Col.; Oscar Dowling of Shreveport, La., the Very Reverend Andrew J. Morrissey of South Bend, Ind. In order that all the activities of the association might be coordinated it was advisable that the House of Delegates extend the courtesies of the floor to the members of the various Councils and especially that it request the secretaries of these Councils to attend the sessions of the House, according them the privilege of the floor, in order that the House might be constantly in position to obtain information concerning work that was being done by these Councils that this body might direct these activities. In order that this end might be attained, it was advisable that the reference committee should meet at places and times which should be publicly announced in order that not only members of the House but that the members of the association might appear before these reference committees. The House should know when a reference committee reported that it had carefully considered the subject and that an opportunity to be heard had been granted all members of the reference committees as well as members of the association; the importance of the work demanded the service of the delegates. It was advisable that the House of Delegates should define what was understood by the term "invited guest." The ruling in the past had been that as associate membership in the association was limited to those who were not eligible to regular membership, so it was evidently intended that "invited guests" should be limited to those who were not eligible to membership in the organization. Reading the section of the by-laws with reference to invited guests, it would be noted that this was not definitely stated since the term Scientists could be held to include certain men who could become members in their local societies. If the House concurred in the precedents that had been established, section 9, chapter 1 of the by-laws should be amended to read as follows: "Sec. 9—Invited Guests.—Scientists, who are not eligible to membership in the component society of the locality in which they reside, may be invited by the general officers or by the officers of a Section to attend any annual session and to take part in the scientific work. They shall be designated as invited guests and be entitled to participate in the scientific and social functions." One of the most important reports submitted this year to the House of Delegates was that of the Judicial Council, embodying as it did a revision of the Principles of Medical Ethics, so framed that it could be regarded as a code of laws governing the membership of this Association. This report should have the serious consideration of the House. The Council had gone over the revision proposed at both meetings which that body held and a number of the preliminary proofs of the revision were submitted to the past officers of the Association and a considerable number of the House of Delegates for their criticism. The entire subject was presented to the House of Delegates for its consideration, but it should be remembered that unless some action was taken at this session, the Judicial Council would have no laws under which cases might be brought to its attention until the Association did frame some legal code.

Report of the Board of Trustees.—Dr. W. W. Grant, Chairman, congratulated the House on the continued prosperity of the Association, on the splendid work it was doing through its publications and its councils for the improvement of medical education, and for the enlightenment of the public regarding health matters and public sanitation in its broadest conceptions. It was a pleasure to state that Library Hall, in the new building, had been dedicated to the memory of Dr. N. S. Davis, and a bronze statue of the distinguished founder of the Association would be placed therein. The button, the emblem of the Association, was something more than the button; it was, in a sense, their trademark. It was used as such, at least, on their books, pamphlets, etc. Not only this, but as a button on the lapel of the coats of their members—over 20,000 had been distributed—it had become well known and was generally recognized as the emblem of the organized medical profession. Therefore, it should not be given up for the new one which had been suggested which was not distinctive and they urged the House of Delegates to consider this matter more carefully. As regards membership in the Association, they regretted not being able to make a satisfactory and final report. The question had been referred to the State societies for action and report to the Board. Most of them evidently did not understand it and did not take specific action. They felt compelled to refer the whole matter back to the House

of Delegates for more elaborate inquiry and fuller investigation. As regarded the matter of organization, they felt that this should be transferred from the Council on Health and Public Instruction to the Judicial Council. It was believed that to the Judicial Council would be gradually transferred all matters affecting the internal relations of the profession, and to the Council on Health and Public Instruction all matters affecting external matters of the organization, that was, its relation to the public and to nonmedical organizations. The Board therefore recommended changes in the by-laws which would effect this transfer. In regard to the *Archives*, now in its fifth year, and the *Journal of Children's Diseases*, both had fulfilled all expectations, and they now had in hand a petition of about 100 of the most distinguished surgeons of the country urging the publication of a surgical journal by the Association along the lines of the *Journal de Chirurgie*. In regard to the report of the Council of Pharmacy and Chemistry, it appeared that there was an agreement among a few firms in this country to ignore the Council, while practically all of the reliable foreign firms were finding it of decided advantage to have their products passed on by the Council. Of course, it rested with the profession whether this opposition by some firms should continue. A most important work had developed in connection with the work of the Council on Pharmacy and Chemistry. This was the work that was enlightening the public in regard to the frauds connected with patent medicines and quackery in general. A large amount of this matter had been gathered into book form and published under the title "Nostrums and Quackery." In speaking of the third edition of the American Medical Directory they called attention to the fact that the present book contained 180 pages more than the preceding one and, above all, that the information it contained was based on official information and was thoroughly dependable. This report also contained a detailed report of the finances of the Association which showed the total assets of the Association to be $511,750, and that the net income for the present year was $53,815.

Report of the Judicial Council.—Dr. ALEXANDER LAMBERT of New York presented this report. As there were no methods of procedure and no laws to govern the personal conduct of a member in his relation with other members this Council offered a set of rules for its government and a method of procedure for conducting cases which might be brought before the Council. The Judicial Council approved the method of procedure for transferring membership from one component society to another, including the "member's transfer card," as outlined by the Committee on Uniform Regulation of Membership. The Judicial Council specially recommended to the House of Delegates that laws be enacted by the Association condemning the secret division of fees and the giving of commissions; also, laws for the proper control of contract practice, and further, that the House of Delegates request that similar laws be enacted by the several state associations.

Report of Council on Medical Education.—Dr. ARTHUR DEAN BEVAN presented this report. He stated that ten years ago when the Council began its work there were 160 medical colleges in the United States, today there were only 118. Since the Council's first classification was made, in 1907, 53 medical colleges had been closed by merger or otherwise. That further persistent work was necessary was evidenced by the fact that at least 45 medical colleges were still adhering to less than a four-year high school education, many were still conducted for profit, at least 50 carried on no research work, and while this country had 118, or about 10 per cent. of the world's supply of medical colleges, only about 30 per cent. of those in this country could compare at all favorably with the medical schools of the leading nations abroad. There were still several states where non-graduates are admitted to take the examinations of the state licensing boards. Dr. Bevan requested the delegates from those states to use every effort to wipe off this blot. The smaller irregular schools of medicine were fast disappearing; this was true of both eclectic and homeopathic schools. There were a few good homeopathic schools left and they were attempting to teach modern scientific medicine. At the recent conference on Medical Education of the American Medical Association they had come to the general agreement as to what was necessary to give the student in order to make him a safe practitioner of medicine. They had found that the necessity for an arts or science degree as a requisite for entrance to a medical school demanded so much time, that the average age of those who followed this plan was between twenty-eight and twenty nine years when they began the practice of medicine. This was too late. In England the average age of the graduate in medicine was between twenty-five and twenty-six years. It was now thought that the minimum requirement should be only one year in the study of physics, chemistry, and biology, in addition to the high school course. The highest extreme at present should not be more than two years of university science. The interne year in a hospital should be made a requirement throughout the country by state medical licensing boards within the next two or three years. There were now in this country at least 2,500 hospitals, having 25 or more beds each, and having a total of at least 200,000 beds. There was no doubt but that interneship could be provided in the better portion of these hospitals for every one of the 4,000 senior medical students now enrolled in the medical schools of this country. The House of Delegates should instruct the Council on Medical Education to make a preliminary investigation of the hospitals of the country similar to that made of the medical schools; they should be graded in the same way that the medical schools now were. Such a work would not only lead to providing interneships for students, but would result in elevating the standards of hospitals. The report then referred to the great assistance rendered by Mr. Frederick G. Hallett, secretary of the Examining Board in England, at the recent conference of the Council, and believed that it would have splendid results in this country. Mr. Hallett's visit had been so satisfactory that they would recommend a similar measure for the coming conference where the problem would probably be to ascertain the best scheme of reorganizing the clinical years of the medical course, and at the same time developing the best clinical teachers. Hence, they would like to have the authority to invite one of Germany's great clinicians, such as Professor Frederick von Muller. The report then considered the methods of grading the colleges and said that in the third inspection of the medical colleges of the country they had adopted the plan of having an A minus class comprising those colleges which were fairly well equipped but still lacked something. Tabulated lists of the colleges in the various classes were presented and statistics showing the number of students taking examinations for licenses, the number from each college that passed, and the number who failed. This, while not an entirely reliable index of the condition of the medical colleges, was of some decided value. As to future work the report stated that there were three great tasks to be performed: (1) The State licensing board must require that amount of medical training which was necessary before the medical student could safely begin medical practice; this requirement should be put into effect in the next few years. (2) Sufficient funds should be secured to reorganize the medical departments of the general lines of the German universities. (3) Proper affiliation should be secured between our great charity hospitals and their medical schools. Forty-seven colleges are now requiring the one year additional preparation in physics, chemistry, and biology. If their plans could be carried out they hoped within the next few years to reduce the number of medical schools to 70 or 80.

Afternoon Session.

Report of Committee on National Health Legislation.—Dr. JOHN B. MURPHY of Chicago made this report, which stated that the committee had considered Senate Bill No. 1, some suggestions made were incorporated into the bill, and it was reported into the United States Senate with a favorable recommendation from the Committee on Health. They had done all they could to forward the interests of this bill.

Report of Committee on Memorial to Medical Officers Who Lost Their Lives in the Civil War.—Dr. WILLIAM C. GORGAS of Panama made this report. He reported progress and stated that through the courtesy of the Surgeons General of the Army and Navy a list of the surgeons who lost their lives in the Civil War was being compiled. It had been ascertained thus far that 51 surgeons were killed, 83 seriously wounded, and that 283 died from wounds or disease contracted in the Civil War. The committee recommended that it be continued with the same instructions and appropriation authorized by the House of Delegates in 1909.

Report of Committee to Advise with the Red Cross.—Dr. A. T. MCCORMACK of Bowling Green, Ky., made this report. He said that in forming an organization which should cooperate with the Red Cross Society in times of great disaster it was difficult to find out how many men were available and how many were competent. They were convinced of the great advantages that would accrue to the public by an organized medical service which

would cooperate with the Red Cross Society and advised the appointment of a committee consisting of three members, one to be appointed by the Surgeon General of the Army, one by the Surgeon General of the Navy, and one by the President of the House of Delegates, who should further consider the matter of forming such an available body of men for times of disaster. Furthermore, if they were to be available in times of disaster they must be kept in training, and to this end they should have a central organization and should cooperate with all existing forces working for public health and the solution of sanitary problems, and they should not rest satisfied until they had small towns and rural districts as sanitary as Colonel Gorgas had made Panama.

Report of Committee to Consider the Mode of Commemorating the Completion of the Panama Canal.—Dr. A. L. Brittin of Athens, Ill., presented this report. The report stated that it was the opinion of the committee that a Congress on Tropical Medicine and Hygiene should be held just after the meeting of the American Medical Association in 1915. This congress should be held by preference in San Francisco and under the auspices of the American Medical Association and the authorities of the San Francisco Panama Exposition. Such a congress should receive the official commendation and support of the United States Government by congressional act. This would provide for the proper invitation of foreign delegates. The report then outlined a plan for such a congress and suggested that the American Medical Association should memorialize the congress with a view to a permanent monument in recognition of the great and glorious work of Americans in sanitary science and preventive medicine. Such a monument might take the form of a hospital for tropical diseases, to be located within the confines of the United States, or more properly in the Canal Zone itself, and the dedication of such a memorial could be contemplated among the plans for the celebration in 1915.

Home Offered for Physician's Widows and Orphans.—Dr. G. Lane Taneyhill of Baltimore spoke of the many sad and pitiful cases of the widows of physicians who were left destitute and who were debarred from other homes for the aged because of lack of funds. In Baltimore the physicians had a three story brick building free from encumbrance which they would like to deed to the Association if the Association would accept it and maintain it. In case they did not wish to do this he suggested that a gift toward the support of the home of $1,000 to $1,500 per year would be acceptable. This matter was referred to the Committee on the Establishment of a Physician's Sanatorium for consideration.

Report of Committee to Formulate Amendments to the Constitution and By-Laws to Extend Membership.—This committee reported that if any other plan than the one now in force was adopted it must be: first, to extend membership to all members of the constituent medical association so that every physician who became a member of his county and state organization should automatically become a member of the American Medical Association; second, to increase the dues collected by the county societies so as to include in addition to the county and state dues a sufficient sum of money to carry on the work of the American Medical Association. Investigation showed at once that the second plan was impracticable. The first plan was the only one considered. In accordance with this plan section 2 chapter 1 of the by-laws should be changed to read as follows: "The American Medical Association shall consist of the membership of its state and territorial associations and the Association shall be divided into two branches, (a) business branch, (b) scientific branch." To further the interest of the scientific branch it was recommended that upon making application on suitable blanks and paying the sum of $5.00 a member of the American Medical Association might become a fellow of the American Medical Association, which would carry with it the rights and privileges which were now accorded those at present known as members of the American Medical Association.

Report of Committees on Scientific Research.—Dr. Ludvig Hektoen made this report, in which he said that since the last meeting of the House of Delegates grants of money for purposes of scientific research had been made to Dr. R. M. Pearce of Philadelphia for an investigation entitled "Studies on Experimental Blood Infection," and for investigation by H. T. Karsner and J. B. Nutt, entitled "The Relation of Toxic Doses of Horse Serum to the Protective Dose of Atropin in Anaphylaxis"; to Dr. E. C. Rosenow of Chicago in support of his work on "Autolysis of Pneumococci"; to Dr. K. K. Kroessler of Chicago for work on "Antibodies in Scarlet Fever"; to Mary R. Lawson of Boston for work on "The Development of the Tertian Malarial Organism," and to Dr. G. B. Webb for further investigation on the "Production of Immunity by Inoculation with Living Bacteria."

Committee to Investigate the Advisability of Publishing a Small Medical Journal.—Dr. J. N. McCormack of Bowling Green, Kentucky, made this report. He stated that there were at present 278 medical journals published in this country and he questioned the advisability of publishing another. He suggested that the by-laws might be amended so that any medical editor who accepted advertisements of a fraudulent character should be debarred from membership in the American Medical Association. This would curtail the incomes of a number of journals and might force them to discontinue and the American Medical Association might assist other journals in securing honest advertisements and also in obtaining reading matter on subjects of interest to the general practitioner.

Presentation of Resolutions.—A resolution was presented stating that, *Whereas*, the present name of the Section on Obstetrics and Diseases of Women was ambiguous and obsolete, *Resolved*, That the name of the section be changed so as to read "The Section on Obstetrics, Gynecology, and Abdominal Surgery." Resolutions were also presented asking for the creation of a Section on Orthopedic Surgery and also one on Physical Therapeutics.

Report of the Committee on Anesthesia.—Dr. Yandell Henderson, chairman, said that the functions of the committee were to gather and analyze data regarding anesthetics, to initiate and stimulate investigation, and to make such recommendations to the House of Delegates and to the members of the American Medical Association generally as a careful consideration of the present status of anesthesia might suggest. Recent developments in this field afforded ground for the hope that they were today at the beginning of an epoch of progress in anesthesia unequalled since its original discovery and introduction. In the judgment of the committee the easiest and safest line of approach to many of the practical problems of anesthesia today lay in the recognition of anesthetists as specialists on a par in the importance and difficulty of their work with those of other branches. It should be recognized that the welfare of the patient demanded skill on the part of the anesthetist no less than on that of the surgeon. Anesthesia should cease to be regarded as merely an adjunct of surgery. Every hospital should have a regular member of its staff an attending anesthetist whose authority in his special department should be as complete as was that of the attending physician or surgeon in their fields. The following specific recommendations were offered:

(1) The use of chloroform as the anesthetic for major operations was no longer justifiable. Scientific investigation and clinical experience agreed in demonstrating that necrosis of the liver ("delayed chloroform poisoning") followed in a by no means inconsiderable percentage of cases. The mode of causation of this sequel was unknown. There were therefore no precautions that could be intelligently taken against it. Accordingly the surgeon whose patient died in this manner a day or two after operation must face the responsibility of having knowingly taken an unnecessary chance—and lost. They saw no reason to believe that in respect to toxicity there was more than a slight quantitative difference between chloroform alone and such chloroform mixtures as A. C. E., anesthol, etc.

(2) For minor operations also the use of chloroform should cease. In general it might advantageously be replaced by nitrous oxide or nitrous oxide-oxygen. It was a mistake to think that a fatality under anesthesia was necessarily due to an unusually large administration of the anesthetic. A previous condition of suffering or anxiety, or a prolongation of the stage of anesthetic excitement rendered a subject who would otherwise be able to resist a large dosage liable to collapse even under a small dosage. The practical importance of avoiding so far as possible all anxiety and pain had been demonstrated on the clinical side by Crile, and experimentally by Henderson. It was noteworthy that Levy (with Cushny) had recently demonstrated that in cats a sudden heart failure (fibrillation) was induced by a period of *light* chloroform anesthesia, while this form of death was not inducible by deep anesthesia. Risks of this sort were far greater with chloroform than with ether, and greater with ether than with nitrous oxide. As they could not be foreseen, they could not be avoided, except by replacing a dangerous anesthetic by a safe one.

(3) Chloroform was sometimes found convenient for initiating anesthesia in alcoholics or other difficult sub-

jects. As a means of avoiding the ill effects of a prolonged period of ether excitement the temporary employment of chloroform for this purpose was perhaps sometimes the lesser of the two evils. It was justifiable only when nitrous oxide was not available. If chloroform was to be used, it should be given as soon as it was evident that the patient would not go under ether readily. Unless the change to chloroform was made early it should not be made at all. They wished especially to emphasize the point that chloroform should never under any circumstances be administered after a prolonged period (10 or 15 minutes or more) of ether excitement. Even a small administration of chloroform was then peculiarly liable to induce respiratory or cardiac death. As soon as full anesthesia was attained ether should be substituted. (4) As regarded ether, the two points to be especially emphasized were that anesthesia should always be induced quickly, and that throughout its entire duration it should be as nearly uniform as possible. Physiology had demonstrated that the predominant stimulant maintaining respiration in a normal subject was the CO_2 in the blood. If for even a few minutes this gas was exhaled more rapidly than it was being produced, a compensatory period was liable to follow in which all spontaneous breathing ceased. This apnea vera tended to last until the body had reaccumulated its normal store of CO_2, and the respiratory center was thereby again stimulated to its normal activity. During the initial period of etherization, the so-called stage of excitement, the subject generally breathed excessively. The analyses of Henderson had shown that if this period was prolonged a condition of intense acapnia (deficiency of CO_2) resulted. When full anesthesia was thereafter attained the subject, although acapnic and prone to apnea, was still sufficiently stimulated by the influence of ether so that, in the majority of cases, an apparently natural or even excessive respiration was maintained. This condition might continue even up to the end of a long operation. At any time, however (and the tendency increased as time went on), the balance between the stimulant action of ether and the depressant influence of acapnia might become negative, and the subject might stop breathing. If the acapnia was sufficiently intense, this respiratory failure (apnea) might continue until death resulted from lack of oxygen. Fortunately lack of oxygen also exerted indirectly some stimulating influence upon respiration. Otherwise such fatalities would be much more frequent than they were. They were of the opinion that respiratory failure must be in certain cases the indirect result of an unskillful timidity which, by prolonging the stage of excitement, induced acapnia, rather than the direct result of over-boldness in the administration of ether at the moment of failure.

(5) It was a well demonstrated and important rule that a subject who had once been etherized or chloroformed could not be again anesthetized within a few hours without great risk. Essentially the same danger was involved in allowing the intensity of anesthesia to vary during an operation. It was not the anesthetist who at all times maintained uniformly deep anesthesia whose patient stopped breathing. This accident came particularly to those who administered it so irregularly that the patient at times came nearly out of anesthesia and again was plunged into profound narcosis. In the production of a fatality the intervals of incomplete anesthesia played a part as great as, or even greater than, the period of profound narcosis which immediately preceded the respiratory (or cardiac) failure. Anesthesia was good in proportion as it was uniform. (6) Offenses against this principle occurred most frequently in adenoid and tonsil operations. When the death of the patient (usually a child) resulted it was assigned either to "heart disease" or to an "unrecognized condition of status lymphaticus." It was probable that in most cases these deaths were merely the natural result of intermittent anesthesia and of the increased susceptibility induced by fear. Under the ordinary methods the anesthetist and the operator were alternately in control of the patient's nose and mouth. The method of intratracheal insufflation introduced by Meltzer and Auer appeared to be peculiarly well adapted to afford a safe anesthesia and at the same time to keep the field of operation clear, and the anesthetist out of the way. There was now a sufficient accumulation of clinical experience with this method to demonstrate its safety and convenience. They recommended that it be widely adopted. For operations upon the head and neck when it was advantageous to keep the anesthetist out of the surgeon's way, most of the advantages of intratracheal insufflation were afforded by intrapharyngeal insufflation with the simple apparatus (air blower, ether vaporizer, and catheter inserted through one nostril) devised by Thoms. Gwathmey had shown the marked advantage of warming ether vapor, even in the ordinary methods of administration. For any form of insufflation an arrangement for heating was essential. (7) Theory and practice alike demonstrated the propriety in the large majority of major operations of administering subcutaneously a liberal dose of morphine half an hour or more before initiating anesthesia. It obviated anxiety, diminished the intensity and duration of the stage of excitement and lessened pain after the anesthesia was terminated. These were all points of marked advantage in conserving vitality. Morphine was par excellence the prophylactic against shock. Against the use of morphine it had been argued that it depressed respiration and thus tended to delay the elimination of the anesthetic after the operation. This was true, and it was a point of importance. In the next section was set forth a method of overcoming this disadvantage.

(8) The committee suggested that in every operating room there be kept on hand and available for immediate use tanks of oxygen containing 8 or 10 per cent of CO_2. They had communicated with all of the principal companies manufacturing gases for clinical use, and they had been informed by them, not only that they could supply such a mixture, but that as soon as there was a considerable demand for it they would be able to do so at the same price as that charged for pure oxygen. It had been demonstrated that CO_2 (properly diluted) was by far the most efficient (because it was the natural) respiratory stimulant. The carbonated oxygen was conveniently administered by means of such a mask and bag as was ordinarily used for nitrous oxide. It should be administered at the first sign of respiratory or circulatory failure. By using it at the outset of anesthesia by any "closed" method a more rapid absorption of ether would be obtained, and a consequent shortening of the period of excitement. By administering it alone after the operation respiration was stimulated to a more rapid elimination of the anesthetic in even a deeply morphinized subject. It was thus easy to prevent the prolonged period of subnormal breathing with its cyanosis and ether retention which now frequently followed anesthesia. For the last mentioned purpose it would be equally effective and much cheaper to employ pure CO_2 (such as was used in the manufacture of carbonated table waters) diluted with 10 to 12 volumes of air. An apparatus for effecting this dilution was now being devised and tested by a member of this committee, and would probably be available for general use within a few months. (9) The most important event in the recent progress of practical anesthesia was the demonstration by Gatch of the beneficial effects of a certain amount of rebreathing in nitrous oxide-oxygen anesthesia. It afforded a clinical confirmation of the validity of the acapnia theory in relation to anesthetic fatalities. As the result of Gatch's work nitrous oxide-oxygen, re-enforced when necessary with a very small amount of ether, and administered by "rebreathing" methods, was being extensively adopted as the anesthesia of choice for major operations involving a considerable amount of shock, or upon already shocked subjects. A number of ingenious and convenient forms of apparatus for the administration of nitrous oxide had recently been devised and put upon the market. They had examined them, but feel that it was as yet too early to decide on their relative merits. In one respect all of those that they had seen were defective, namely, in the insufficient closeness of the mask upon the face. If the air in any quantity leaked into the mask and bag, the oxygen which it contained was quickly absorbed, and left the nitrogen. As air was 4 parts nitrogen to 1 of oxygen, the mixture of nitrous oxide and oxygen which the patient was breathing soon became so diluted with nitrogen that it neither prevented cyanosis nor maintained full anesthesia. Such troubles as occasionally arose with nitrous oxide anesthesia were principally due, in their opinion, to this dilution. To overcome this defect a mask which was at once light, easily adjusted, absolutely air tight on any face, quickly removable, and not requiring to be held by the hand of the anesthetist was the greatest need. They recommended that a prize of $200 be offered for the invention of a mask fulfilling these requirements—the award to be made by their successors on this committee. While nitrous oxide-oxygen appeared to afford the least deleterious of all forms of anesthesia, it was also unfortunately the most expensive. It was easily seen that the greater part of this cost was not for the nitrous oxide which was actually absorbed to induce anesthesia, nor for the oxygen which the patient consumed. The patient was constantly exhaling CO_2; and even when a considerable amount of rebreathing was practiced, the removal of this substance from the mask and bag involved the waste of 10 to 20 times as much oxygen, and 50 to 100 times as much nitrous oxide. It was the necessity of removing CO_2,

therefore which was the source of at least [illegible] of the cost of this form of anesthesia. As a [illegible] worth of sodium or potassium hydroxide will [illegible] all the CO_2 exhaled by the patient in many hours, and a member of this committee had undertaken the problem of devising a simple form of absorber. (10) Finally the committee recommended that the President of the Association in appointing their successors upon this committee make his selections not, as had been the custom in the past, wholly or almost wholly from the ranks of the surgeons, but rather from among those whose principal interest was in this field of work, and who during the past few years had themselves made contributions of value to the theory and practice of anesthesia.

Tuesday, June 4—Second Day

THE PRESIDENT, DR. ABRAHAM JACOBI, IN THE CHAIR.

Report of Committee to Investigate the Advisability of Publishing a Health Journal.—Dr. W. A. Evans, Chicago, Ill., made this report in which the committee expressed the opinion that the work along lines of hygiene and public health made such a journal desirable and recommended that the House report favorably on this subject.

Report of Council on Health and Public Instruction.—Dr. HENRY B. FAVILL presented this report. The report stated that the Council had been profoundly impressed with the interest evinced by the public in matters pertaining to health. It was their object to bring together the people and the profession, to restore confidence in the scientifically trained physician to-day that was formerly given to the family physician, and to unite the public and the medical profession in an intelligent and irresistible campaign for better health conditions. The following recommendations were made by the Council for guidance during the coming year: (1) That the Council declare that in its judgment its principal mission is the development of public confidence in the purposes and work of the American Medical Association and of the profession. (2) That in addition to its present work and committee and bureau activities already provided for, the Council concentrate its efforts during the coming year on the following: (a) Formulation and adoption of a platform setting forth the aims and purposes of the Association and the profession, and asking for the support and confidence of the public; (b) Continuation and extension of the Press Bureau; (c) Organization of a Speakers' Bureau; (d) Compilation of a handbook for speakers; (e) Organization and development of a Bureau of Literature. The Press Bureau was publishing a bulletin which was sent out every week to 4,900 publications which used the subject matter, sending it in turn to a circulation of 68,000 weekly. They had sent 2,500 copies of "Nostrums and Quackery" to various publications, many of which reviewed the book and commented favorably upon it. The attitude of the newspapers toward the work of the Press Bureau was most gratifying. Following the organization of the Press Bureau they had organized a Speakers' Bureau. The plan proposed was that appointment be made for public addresses for meetings held under the auspices of local medical societies in states adjoining that in which the speaker lived. A list of speakers was now available. The Speakers' Bureau had now been in operation four months and was still largely experimental. It was necessary to find out by actual experience how much demand existed for such meetings. It would be necessary in order to secure the interest and confidence of the public to approach them through the leaders in the profession; this would require a sacrifice on the part of some, but it would yield large returns in public support and confidence. After calling attention to the legislative work in the promotion of a bill for a National Health Department and to their work in the protection of medical research the report gave an account of their cooperation with the Electric Light Association in considering the question of the resuscitation from electric shock. The Council felt that it had reason to congratulate itself and the Association on the appointment of this committee which had established friendly relations with such bodies as the National Electric Light Association, the American Institute of Electric Engineers, the American Bar Association and the National Educational Association.

A second portion of this report consisted of the reports of the following subcommittees:

The Committee on the Prevention of Blindness reported during the past year propaganda on ophthalmia neonatorum had been so widespread that in almost every State there had been papers read before county and state medical societies, that the subject had been given wide publicity in the press, and that the last year had shown the practicability of the complete [illegible] earth infections of the eyes. A most unexpected [illegible] in the four years' study of the question in Massa[illegible] was that the doctors and not the midwives were [illegible] for blindness from ophthalmia neonatorum. It was not because the midwives had been careful but [illegible] they had figured in only a small proportion of the [illegible] recorded in the series investigated. This report further considered the subject of trachoma. This disease was assuming serious proportions in some localities among the Indians, especially in Oklahoma. It seemed imperative that measures should be taken by the Federal government to supplement the efforts of the few men who were now employed in fighting the disease in order that its extent might be determined and steps taken to prevent its further spread. The report then considered industrial accidents as one of the causes of preventable blindness, and blindness from wood alcohol.

The Committee on Visual Standards for Pilots reported that the standards adopted at the suggestion of this committee had created some dissatisfaction among the pilots and others affected by them, for a number who had been long in the service did not come up to the standard. Consequently the Department of Commerce and Labor was compelled to recede from its ruling of 1911, when all of the recommendations of this committee were adopted and, so far as the matter now stood, there was nothing to debar a marine officer from continuing his duties after he had once qualified at the original test, even if in after years his vision became seriously compromised.

The Report of the Committee on Uniform Regulation of Membership.—At the meeting of this committee in December, 1911, the following recommendations were adopted: (1) That the fiscal year of component and constituent societies should begin January 1 and end December 31, and that all annual reports from component county societies, including the names of officers, delegates and the roster of members for the ensuing year, together with the State per capita assessments, should be in the hands of the State secretary on January 1 of each year. (2) That it was advisable to devise and adopt uniform application blanks, receipt blanks, membership cards and transfer cards. (3) That all constituent state associations should hold charters from the American Medical Association. (4) That a uniform plan for the transfer of members from one component county society to another was necessary for the good of the organization. A second meeting was held in March, 1912, when the committee recommended that county societies be requested to hold their annual meetings in October, and that newly elected officers should assume office on January 1 following.

This committee further recommended that a meeting of the secretaries of constituent state societies be called in Chicago some time in the fall of 1912, and that this committee be instructed to present these recommendations to the State secretaries for their approval and adoption.

Invitation from the Australian Congress of Medicine.—Dr. A. W. BARRETT, of the Melbourne University, Australia, after having been introduced to the House of Delegates, said that he was on a tour of inspection of the medical colleges of this country and of Europe, and he had been instructed to extend an invitation to the American Medical Association to attend the next Australasian Congress which would hold its meeting in Auckland, New Zealand, in February, 1914.

The Report of Committee on Relief Fund and Physicians' Sanatorium.—Dr. EDWARD JACKSON of Denver, Col., reported that in view of the difficulties attending the raising and administration of such a fund it would be impracticable to do anything at present. They might possibly reach some compromise by accepting the offer of the Baltimore physicians of the building to be used as a home for physicians' widows and orphans.

Report of Committee to Arrange for Clinical Days.—This committee reported that after correspondence with the secretaries of the fourteen sections of the American Medical Association it had abandoned the idea of having the sections participate in the clinics and had arranged for a limited number of clinics which should not overlap. A supplementary program had been prepared by which clinics would be held in several of the Philadelphia and Baltimore hospitals on Friday of the week of meeting.

REPORTS OF REFERENCE COMMITTEES.

Report of Reference Committee on Amendments to the Constitution and By-Laws.—Dr. A. R. MCCORMACK of Bowling Green, Ky., reported for this committee. They approved the recommendation of the Secretary that "invited guests" of the Association be limited to those scientists who were not eligible for membership in the com-

ponent society in the locality in which they resided. The recommendation of the Secretary, in regard to extending the courtesy of the floor to members of the various councils, was approved and recommended for adoption. The rules and methods to govern the action of the Judicial Council were recommended for adoption, as also the Principles of Medical Ethics recommended by the Judicial Council. These measures and several others affecting membership and the transfer of membership were adopted by the House of Delegates.

The Principles of Medical Ethics.—As adopted by the House of Delegates these were as follows:

CHAPTER I.

DUTIES OF PHYSICIANS TO THEIR PATIENTS.

The Physician's Responsibility.

SECTION 1.—A profession has for its prime object the service it can render to humanity; reward or financial gain should be a subordinate consideration. The practice of medicine is a profession. In choosing this profession an individual assumes an obligation to conduct himself in accord with its ideals.

SECTION 2.—Patience and delicacy should characterize all the acts of a physician. The confidences concerning individual or domestic life entrusted by a patient to a physician, and the defects of disposition or flaws of character observed in patients during medical attendance should be held as a trust and should never be revealed except when imperatively required by the laws of the state. There are occasions, however, when a physician must determine whether or not his duty to society requires him to take definite action to protect a healthy individual from becoming infected, because the physician has knowledge, obtained through the confidences entrusted to him as a physician, of a communicable disease to which the healthy individual is about to be exposed. In such a case the physician should act as he would desire another to act toward one of his own family under like circumstances. Before he determines his course, the physician should know the civil law of his commonwealth concerning privileged communications.

SECTION 3.—A physician should give timely notice of dangerous manifestations of the disease to the friends of the patient. He should neither exaggerate nor minimize the gravity of the patient's condition. He should assure himself that the patient or his friends have such knowledge of the patient's condition as will serve the best interests of the patient and the family.

SECTION 4.—A physician is free to choose whom he will serve. He should, however, always respond to any request for his assistance in an emergency or whenever temperate public opinion expects the service. Once having undertaken a case, a physician should not abandon or neglect the patient because the disease is deemed incurable; nor should he withdraw from the case for any reason until a sufficient notice of a desire to be released has been given the patient or his friends to make it possible for them to secure another medical attendant.

CHAPTER II.

THE DUTIES OF PHYSICIANS TO EACH OTHER AND TO THE PROFESSION AT LARGE.

Article I.—Duties to the Profession.

SECTION 1.—The obligation assumed on entering the profession requires the physician to comport himself as a gentleman and demands that he use every honorable means to uphold the dignity and honor of his vocation, to exalt its standards and to extend its sphere of usefulness. A physician should not base his practice on an exclusive dogma or sectarian system, for "sects are implacable despots: to accept their thraldom is to take away all liberty from one's actions and thought" (Nicon, father of Galen).

SECTION 2.—In order that the dignity and honor of the medical profession may be upheld, its standards exalted, its sphere of usefulness extended, and the advancement of medical science promoted, a physician should associate himself with medical societies and contribute his time, energy and means in order that these societies may represent the ideals of the profession.

SECTION 3.—A physician should be "an upright man, instructed in the art of healing." Consequently he must keep himself pure in character and conform to a high standard of morals, and must be diligent and conscientious in his studies. "He should also be modest, sober, patient, prompt to do his whole duty without anxiety; pious without going so far as superstition, conducting himself with propriety in his profession and in all the actions of his life." (Hippocrates.)

SECTION 4.—Solicitation of patients by circulars or advertisements, or by personal communications or interviews, not warranted by personal relations, is unprofessional. It is equally unprofessional to procure patients by indirection through solicitors or agents of any kind, or by indirect advertisements, as by furnishing or inspiring newspaper or magazine comments concerning cases in which the physician has been or is concerned. All other like self-laudations defy the traditions and lower the tone of any profession and so are intolerable. The most worthy and effective advertisement possible, even for a young physician, and especially with his brother physicians, is the establishment of a well-merited reputation for professional ability and fidelity. This cannot be forced, but must be the outcome of character and conduct. The publication or circulation of ordinary simple business cards, being a matter of personal taste or local custom, and sometimes of convenience, is not *per se* improper. As implied, it is unprofessional to disregard local customs or offend recognized ideals in publishing or circulating such cards.

It is unprofessional to promise radical cures; to boast of cures and secret methods of treatment or remedies; to exhibit certificates of skill or success in the treatment of diseases; or to employ any methods to gain the attention of the public for the purpose of obtaining patients.

SECTION 5.—It is unprofessional to receive remuneration for patents for surgical instruments or medicines; to accept rebates on prescriptions or surgical appliances, or perquisites from attendants who aid in the care of patients.

SECTION 6.—It is unprofessional for a physician to assist unqualified persons to evade legal restrictions governing the practice of medicine; it is equally unethical to prescribe or dispense secret medicines or other secret remedial agents, or manufacture or promote their use in any way.

SECTION 7.—Physicians should expose without fear or favor, before the proper medical or legal tribunals, corrupt or dishonest conduct of members of the profession. Every physician should aid in safeguarding the profession against the admission to its ranks of those who are unfit or unqualified because deficient either in moral character or education.

Article II.—Professional Services of Physicians to Each Other.

SECTION 1.—Experience teaches that it is unwise for a physician to treat members of his own family or himself. Consequently, a physician should always cheerfully and gratuitously respond with his professional services to the call of any physician practicing in his vicinity, or of the immediate family dependents of physicians.

SECTION 2.—When a physician from a distance is called upon to advise another physician or one of his family dependents, and the physician to whom the service is rendered is in easy financial circumstances, a compensation that will at least meet the traveling expenses of the visiting physician should be proffered. When such a service requires an absence from the accustomed field of professional work of the visitor that might reasonably be expected to entail a pecuniary loss, such loss should, in part at least, be provided for in the compensation offered.

SECTION 3.—When a physician or a member of his dependent family is seriously ill, he or his family should select a physician from among his neighboring colleagues to take charge of the case. Other physicians may be associated in the care of the patient as consultants.

Article III.—Duties of Physicians in Consultations.

SECTION 1.—In serious illness, especially in doubtful or difficult conditions, the physician should request consultation.

SECTION 2.—In every consultation, the benefit to be derived by the patient is of first importance. All the physicians interested in the case should be frank and candid with the patient and his family. There never is occasion for insincerity, rivalry or envy and these should never be permitted between consultants.

SECTION 3.—It is the duty of a physician, particularly in the instance of a consultation, to be punctual in attendance. When, however, the consultant or the physician in charge is unavoidably delayed, the one who first arrives should wait for the other for a reasonable time, after which the consultation should be considered postponed. When the consultant has come from a distance, or when for any reason it will be difficult to meet the physician in charge at another time, or if the case is urgent, or if it be the desire of the patient, he may examine the patient and mail his written opinion, or see that it is delivered under seal, to the physician in charge. Under these conditions, the consultant's conduct must be especially tactful; he must remember that he is framing an opinion without the aid of the physician who has observed the course of the disease.

SECTION 4.—When a patient is sent to one specialist in the care of the condition from which he is thought to be suffering, and for any reason it is impracticable for the physician in charge of the case to accompany the patient, the physician in charge should send to the consultant by mail, or in the care of the patient under seal, a history of the case, together with the physician's opinion and an outline of the treatment, or so much of this as may possibly be of service to the consultant; and as soon as possible after the case has been seen and studied, the consultant should address the physician in charge and advise him of the results of the consultant's investigation of the case. Both these opinions are confidential and must be so regarded by the consultant and by the physician in charge.

SECTION 5.—After the physicians called in consultation have completed their investigations of the case they may meet by themselves to discuss conditions and determine the course to be followed in the treatment of the patient. No statement or discussion of the case should take place before the patient or friends, except in the presence of all the physicians attending, or by their common consent; and no opinions or prognostications should be delivered as a result of the deliberations of the consultants, which have not been concurred in by the consultants at their conference.

SECTION 6.—The physician in attendance is in charge of the case and is responsible for the treatment of the patient. Consequently, he may prescribe for the patient at any time and is privileged to vary the mode of treatment outlined and agreed on at a consultation whenever, in his opinion, such a change is warranted. However, at the next consultation, he should state his reasons for departing from the course decided on at the previous conference. When an emergency occurs during the absence of the attending physician, a consultant may provide for the emergency and the subsequent care of the patient until the arrival of the physician in charge, but should do no more than this without the consent of the physician in charge.

SECTION 7.—Should the attending physician and the consultant find it impossible to agree in their views of a case, another consultant should be called to the conference or the first consultant should withdraw. However, since the consultant was employed by the patient in order that his opinion might be obtained, he should be permitted to state the result of his study of the case to the patient, or his next friend, in the presence of the physician in charge.

SECTION 8.—When a physician has attended a case as a consultant, he should not become the attendant of the patient during that illness except with the consent of the physician who was in charge at the time of the consultation.

Article IV.—Duties of Physicians in Cases of Interference.

SECTION 1.—The physician, in his intercourse with a patient under the care of another physician, should observe the strictest caution and reserve; should give no disingenuous hints relative to the nature and treatment of the patient's disorder; nor should the course of conduct of the physician, directly or indirectly, tend to diminish the trust reposed in the attending physician.

SECTION 2.—A physician should avoid making social calls on those who are under the professional care of other physicians without the knowledge and consent of the attendant. Should such a friendly visit be made, there should be no inquiry relative to the nature of the disease or comment upon the treatment of the case, but the conversation should be on subjects other than the physical condition of the patient.

SECTION 3.—A physician should never take charge of or prescribe for a patient who is under the care of another physician, except in an emergency, until after the other physician has relinquished the case or has been properly dismissed.

SECTION 4.—When a physician does succeed another physician in the charge of a case, he should not make comments on or insinuations regarding the practice of the one who preceded him. Such comments or insinuations tend to lower the esteem of the patient for the medical profession and so react against the critic.

SECTION 5.—When a physician is called in an emergency and finds that he has been sent for because the family attendant is not at hand, or when a physician is asked to see another physician's patient because of an aggravation of the disease, he should provide only for the patient's immediate need and should withdraw from the case on the arrival of the family physician after he has reported the condition found and the treatment administered.

SECTION 6.—When several physicians have been summoned in a case of sudden illness or of accident, the first [illegible] arrive should be considered [illegible] in charge. However, as soon as the exigency [illegible] permit, or on the arrival of the acknowledged [illegible] attendant or physician the patient desires, [illegible] the first physician should withdraw in favor [illegible] attendant; should the patient or his family [illegible] one other than the physician known to be the [illegible] physician to be in charge of the case the patient should [illegible] the family physician of his desire. When, because of sudden illness or accident, a patient is taken to a hospital, the patient should be returned to the care of his known family physician as soon as the condition of the patient and the circumstances of the case warrant this transfer.

SECTION 7.—When a physician is requested by a colleague to care for a patient during his temporary absence, or when, because of an emergency, he is asked to see a patient of a colleague, the physician should treat the patient in the same manner and with the same delicacy as he would have one of his own patients cared for under similar circumstances. The patient should be returned to the care of the attending physician as soon as possible.

SECTION 8.—When a physician is called to the patient of another physician during the enforced absence of that physician, the patient should be relinquished on the return of the latter.

SECTION 9.—When a physician attends a woman in labor in the absence of another who has been engaged to attend, such physician should resign the patient to the one first engaged, upon his arrival; the physician is entitled to compensation for the professional services he may have rendered.

Article V.—Differences Between Physicians.

SECTION 1.—Whenever there arises between physicians a grave difference of opinion which cannot be promptly adjusted the dispute should be referred for arbitration to a committee of impartial physicians, preferably the Board of Censors of a component county society of the American Medical Association.

Article VI.—Compensation.

SECTION 1.—The poverty of a patient and the mutual professional obligation of physicians and certain public duties should command the gratuitous services of a physician, but institutions endowed by the public, or by the rich, or by societies, and organizations for mutual benefit, or for accident, sickness and life insurance, or for analogous purposes should be accorded no such privileges.

SECTION 2.—It is unprofessional for a physician to dispose of his services under conditions that make it impossible to render adequate service to his patient or which interfere with reasonable competition among the physicians of a community. To do this is detrimental to the public and to the individual physician, and lowers the dignity of the profession.

SECTION 4.—It is detrimental to the public good and degrading to the profession, and therefore unprofessional, to give or to receive a commission or to divide a fee for medical advice or surgical treatment, unless the patient or his next friend is fully informed as to the terms of the transaction. The patient should be made to realize that a proper fee should be paid the family physician for the service he renders in determining the surgical or medical treatment suited to the condition, and in advising concerning those best qualified to render any special service that may be required by the patient.

CHAPTER III

THE DUTIES OF THE PROFESSION TO THE PUBLIC.

SECTION 1.—Physicians, as good citizens and because their professional training specially qualifies them to render this service, should give advice concerning the public health of the community. They should bear their full part in enforcing its laws and sustaining the institutions that advance the interests of humanity. They should cooperate especially with the proper authorities in the administration of sanitary laws and regulations. They should be ready to counsel the public on subjects relating to sanitary police, public hygiene and legal medicine.

SECTION 2.—Physicians, especially those engaged in public health work, should enlighten the public regarding quarantine regulations; on the location, arrangement and dietaries of hospitals, asylums, schools, prisons and similar institutions; and concerning measures for the prevention of epidemic and contagious diseases. When an epidemic prevails a physician must continue his labors for the alleviation of suffering people, without regard to the risk to his own health or life or to financial return. At all times, it is the duty of the physician to notify the properly con-

stituted public health authorities of every case of communicable disease under his care, in accordance with the laws, rules and regulations of the health authorities of the locality in which the patient is.

SECTION 3.—Physicians should warn the public against the devices practiced and the false pretensions made by charlatans which may cause injury to health and loss of life.

SECTION 4.—By legitimate patronage, physicians should recognize and promote the profession of pharmacy; but any pharmacist, unless he be qualified as a physician, who assumes to prescribe for the sick, should be denied such countenance and support. Moreover, whenever a druggist or pharmacist dispenses deteriorated or adulterated drugs, or substitutes one remedy for another designated in a prescription, he thereby forfeits all claims to the favorable consideration of the public and physicians.

CONCLUSION.

While the foregoing statements express in a general way the duty of the physician to his patients, to other members of the profession and to the profession at large, as well as of the profession to the public, it is not to be supposed that they cover the whole field of medical ethics, or that the physician is not under many duties and obligations besides these herein set forth. In a word, it is incumbent on the physician that under all conditions his bearing toward patient, the public, and fellow practitioner should be characterized by a gentlemanly deportment and that he constantly should behave toward others as he desires them to deal with him. Finally, these principles are primarily for the good of the public, and their enforcement should be conducted in such a manner as shall deserve and receive the endorsement of the community.

Report of Reference Committee on Reports of Officers.—Dr. HUBERT WORTH of Pueblo, Col., reported for this committee. His report urged the House of Delegates to adopt the resolution requesting the Council on Education to provide some fitting way of commemorating the founding of the first medical school in this country by John Morgan of Philadelphia in 1765. They endorsed the resolution which proposed to make the clinical days a permanent feature of these meetings. They endorsed the resolution providing that the President and Secretary of the House of Delegates should become members *ex officio* of the Board of Trustees without voting power. These recommendations were adopted by the House.

GENERAL SESSIONS.

Tuesday, June 4—First Day.

THE PRESIDEN, DR. JOHN B. MURPHY OF CHICAGO, IN THE CHAIR.

Invocation.—The Reverend FRANCIS J. MCSHANE of Atlantic City made the invocation.

Addresses of Welcome.—MAYOR HARRY BACHARACH welcomed the Association on behalf of Atlantic City, and presented the keys of the city to the president of the Association.

DR. DANIEL A. STROCK, President of the New Jersey State Medical Society, made the address of welcome on behalf of the State of New Jersey, in which he took as his theme the work of the medical societies in that state. He spoke particularly of the pride they took on being one of the few states in which osteopathy was not recognized. In speaking of the disqualifying of lodge doctors from membership in their medical societies, he said he was not sure that this was the best way to deal with this problem. This problem was by no means satisfactorily solved. He also discussed the move to make every licensed practitioner eligible to the local societies. This would admit homeopathists.

GOVERNOR WOODROW WILSON made the address of welcome on behalf of the State of New Jersey. He said that the people who usually come to Atlantic City came as idlers, and he was glad to welcome those who came with a serious object in view. He recognized the medical profession not only as the guardian of the health of the community but of its morals as well. There was a sense in which the doctor represented the morality of the community. Knowledge was not vital and useful unless it went hand and hand with insight. It was regrettable that it had become necessary to specialize to such a high degree, as this had been responsible for the disappearance of the family physician. There had been one year in his life when for different members of his family it was necessary to call in thirteen different physicians; his father would only have had to call in one. He, himself, no doubt, had had better advice, at least he was still alive, but his father had had a faithful friend and a sympathetic confidant in his family physician. We of the present day had lost this comfort. If specialism had become a necessity the medical man should still endeavor to generalize so far as sympathy was concerned. He said that as the head of a university it had always been his object to make a boy just as unlike his father as possible; this was because by the time a man had a son old enough to go to college he had become narrowed by his special vocation and the boy should be given as broad a view as possible. The physician should never forget his general and geographical relation to mankind and should refresh his sympathies by reconnecting himself with the general life. Governor Wilson then proceeded to show that politics was much like surgery in that many things should be cut out of modern life, but no healthy tissue, and drew an analogy between political conditions and surgery, showing that both required diagnosis, dietary tonic, etc. There were even quacks in politics, and hence he was in a position to sympathize with the physician. He felt therefore that he, like the physician, was in a more difficult position than those wandering in broader society. The problems of life were all one, and by dividing life into sections one could not serve humanity with success. The whole problem was one of mutual comprehension, of effort to avoid separation of intelligences, to unite ourselves into one body moving toward a common end, and he challenged them to seek part in the accommodation of the various parts of life to one another.

Installation of the New President.—Dr. JOHN B. MURPHY of Chicago said it was a pleasure and an honor in retiring from office to have the opportunity to hand the honor to a man who stood for the highest ideals in medicine, who received the recognition of the entire world, to the Nestor of Medicine, a man who needed no introduction to the profession of medicine or to the people of the United States, Dr. Abraham Jacobi.

President's Address.—Dr. Abraham Jacobi delivered this address. (See page 1065.)

Introduction of Foreign Guests.—Dr. THOMAS W. HUNTINGTON, Chairman of the Section on Surgery, introduced Dr T. Rovsing of Copenhagen, Denmark, to the Association as the guest of the Section on Surgery.

SECTION ON PRACTICE OF MEDICINE.

Tuesday, June 4, 1912—First Day.

DR WILDER TILESTON OF NEW HAVEN, CONN., IN THE CHAIR.

Arteriosclerosis.—Dr. THOMAS D. COLEMAN of Augusta, Ga., read this paper. He said that for a profitable consideration of the subject certain fundamental facts of the physics of the circulation and the maintenance of cell life should be recalled. The proper nutrition of the different organs of the body was dependent not only on the functional activity of its own cells, but also on the vital activity of the cells making up the cardio-vascular mechanism. Not only must both cell elements remain structurally and functionally intact, but there should be a certain intravascular tension in the arteries, arterioles and capillaries. In the absence of tension he believed no physiologist held that tissue nutrition could be maintained. Why was sclerosis sometimes localized and sometimes general? As a working hypothesis it might be assumed (a) that there was a local defect, either congenital or acquired, in the organ or organs involved; or that (b) the specific toxin had a selective influence which acted upon the vasomotor or trophic centers, regulating the blood supply and nutrition of the part involved. Excessive muscular exercise, either general or local, might impair the integrity of the vascular mechanism; even in this it was likely that the toxins resulting from tissue destruction might be operative. It had been conclusively shown that local sclerosis, without marked sclerotic change in other parts, occurred in the vessels of the brain, and to this condition was due the reason why so many ruptures occurred in this portion of the arterio-capillary tree than elsewhere. The importance of this phase of the subject was apparent when one reviewed the number of sudden deaths, the frequent paralyses that made the further life of the sufferer a burden to themselves and the state, all the result of sclerosis not infrequently limited to the cerebral arteries. If the preapoplectic symptoms could be interpreted with any degree of accuracy, how many of these tragedies of existence might be averted? Dr Coleman had had the opportunity of being with a number of patients immediately before, during and after the rupture of cerebral vessels and beyond some increase in vascular tension and irritability of temper, or depression of spirits, there was nothing to give warning of the impending catastrophy. Sclerotic changes might occur in any portion of the arterial tree and athero-

matous patches were very frequent in the lar[illegible] after middle life, the coronary arteries being [illegible] subject to sclerotic degeneration. Coronary sclerosis had been frequently encountered. After middle life a certain degree of sclerosis was apt to be found in a [illegible] of persons. Though the expression was trite, nothing truer than the axiom, "a man is as old as his arteries." The life of an engine was dependent upon the metal [illegible] went into its construction and the care that was taken of it; the same was true of the more perfect physical mechanism, and Osler had aptly observed that a man often took less care of his body than he did of his motor. The average man or woman lived in an atmosphere of work and worry, taking insufficient thought of either physical or mental needs. Man presented a pitiful spectacle racing at top speed to gain wealth or position, staggering under the delusion that old age would bring rest and enjoyment, and, becoming enlightened too late, to find that his rest was disturbed by discomfort and enjoyment a memory only. Next to the strain of modern life came the acute infections and intoxications as causative agents. Among the poisons might be included lead and other minerals, alcohol, tobacco, tea, coffee, etc. Again sclerosis was caused by occupations which demanded great and continued physical strain, and in young men who kept up high and long continued tension through athletic sports. Their estimate of the blood pressure was gained through the medium of the touch in palpable arteries and by the employment of the sphygmomanometer. Hoover made the following observation: "Whether there were really different endovascular pressures in the several arteries or different degrees of hypertonus in the arterial walls which gave the results, the deduction remains the same; namely, that the blood pressure apparatus applied to accessible arteries does not give infallible information as to the aortic blood pressure, and as a consequence it is not safe to rely on routine measurements from the area as a guide to the employment of vasodilators in treating patients with a high arterial pressure." Daland had shown that the mere application of the pneumatic cuff in certain neurotic subjects often increased the blood pressure as much as 30 to 40 mm. The widest field for good lay in the prevention rather than in the cure of arteriosclerosis.

Urobilin: Its Clinical Significance.—Dr. RAY LYMAN WILBUR and Dr. THOMAS ADDIS of San Francisco, Cal., presented this communication and offered the following conclusions: (1) Simultaneous estimation of urobilin and urobilinogen in the stools and urine, after certain allowances were made for the state of the liver and intestinal peristalsis, permitted valuable approximations to be drawn as to the amount of hemoglobin broken down within the body. (2) Urobilinuria might be used as an early indicator of the failure of the liver to functionate normally in alcoholic individuals with enlarged and tender livers. (3) While in a jaundiced individual the persistent failure to obtain positive tests for urobilinogen in the urine by the present methods pointed usually to obscure closure of the duct, the presence of not inconsiderable amounts of urobilin in the stools of cases in which very little bilirubin (closure of the common bile duct) or no bilirubin (closure of the common duct and a biliary fistula) reached the intestine, seemed to indicate that the commonly accepted view that the only origin of urobilin was from the reduction of bilirubin in the intestine could not be correct. (4) The urobilinuria and urobilinemia of pneumonia deserved more study as the occurrence of urobilin as such in the blood was apparently, by the present methods, found during life only in this disease, and it might indicate that peculiar relations existed between urobilin and the factors accompanying cyanosis. (5) The discovery of a persistent urobilinuria should incite a careful study for all possible factors leading either to blood destruction or to parenchymatous or obstructive hepatic disorders.

Chloroma. A Clinical Study of Two Cases.—Dr. WALTER L. BIERRING of Des Moines, Iowa, reported in detail these two cases. This disease constituted a rare picture in human pathology. It was distinctly an affection of early life. Of the 73 cases gathered from the literature by Lehndorff, 50 occurred in the male sex. The disease apparently had very little relation to previous disease conditions, and usually was met with in healthy children of healthy parents. Trauma apparently had no relation to the disease. The characteristic pathologic anatomic changes in the form of lymphoid tumors and associated blood changes were a significant feature of the disease. The spread of tumors in the cranial and facial bones explained most of the characteristic symptoms. The exophthalmos was usually associated with pain because of the crowding of the bulb, and in this respect differed from other forms of exophthal[illegible] regard to general symptoms aside from those [illegible] directly attributed to the tumor formati[illegible] an early weakness in all cases, and the patient [illegible] became bedridden. The sensorium often remained [illegible] until the end. Since the work of Recklinghausen and [illegible] suggesting that chloroma was closely related to leukemia and generally accompanied by leucemic blood [illegible], greater attention had been paid to the study of the blood and the blood-making organs. Two distinct forms of chloroma were now recognized, the lymphatic and the myeloid, the former being much the more frequent. In both forms of chloroma the hemoglobin content was usually greatly diminished, the red cells became also variably reduced in number. The color index was usually minus. The anemia usually became more pronounced in the later stages of the illness and was often augmented by external influences as excessive hemorrha through epistaxis, hematemesis, hematuria, etc. Chloroma seemed to be specially characterized by the malignancy of its manifestations, the tendency to aggressive proliferation, giving it the character of leucosarcomatosis. The diagnosis was in most instances easily made at the first examination. The characteristic predilection of the tumors for the cranial and facial bones, exophthalmos, facial paralysis, visual disturbances, deafness, deformity of the skull, with the characteristic "frog-like" aspect, were so distinctive as to be recognized at the first glance. In the differential diagnosis malignant tumors especially osteosarcoma were to be considered. The prognosis of chloroma was like that of acute leucemia and similar processes where the hemotopoietic system was primarily involved in that the outlook was distinctly hopeless. Treatment could only be directed toward a relief of certain symptoms of the disease, particularly hemorrhage. In the light of their present knowledge the following conclusions would be proposed: (1) That chloroma was not a distinct disease entity. (2) That it belonged to the primary diseases of the blood-making parenchyma, and (3) that it was a generalized systemic affection of the lymphoid hemopoietic apparatus characterized by a tendency to malignant growth and heterotopic localization of its greenish pigmented infiltrations.

The Treatment of Leucemia and Pseudoleucemia with X-Rays.—Dr. ALFRED STENGEL and Dr. H. K. PANCOAST of Philadelphia presented this paper. They said that little had been added to their knowledge of the etiology or pathology of leucemia and Hodgkin's disease during the last few years. In a former discussion they called attention to the fact that so far as leucemia was concerned all recent investigations tended to prove that the bone marrow was the primary seat of the morbid process. A feature in the pathology of these diseases was the influence of the disease of the bone marrow on the formation of red blood corpuscles. The clinical study of the blood in cases of leucemia progressing unfavorably always showed advancing anemia, manifestly hypoplastic and hemolytic. All the evidences of the studies of the blood pointed to increasing imperfection in blood making and few of the signs of hemolysis. A matter of considerable clinical interest was the tendency to spontaneous recessions occasionally seen in leucemia.

Bacteriological Study of Streptococci in Milk in Relation to Epidemic Sore Throat.—Dr. DAVID J. DAVIS of Chicago read this paper and gave the following summary: The epidemic of sore throat in Chicago in the winter of 1911-1912 was caused by an organism belonging to the streptococcus group. In the exudates and in the body it was usually encapsulated, but not infrequently in the throats a capsule was not present. It was highly pathogenic for animals, readily producing arthritis in rabbits, and occasionally endocarditis. The cork of Capps and Miller showed clearly that the infection was largely milk borne and that an epidemic of mastitis in cows and sore throats in farmers prevailed during the winter in the vicinity of Batavia, Ill., the territory which supplied the contaminated milk. From a typical case of mastitis in a cow from a farm in this region a streptococcus was obtained pure which was pathogenic to animals, became encapsulated on animal passage and agreed in all essential respects to the human epidemic streptococcus. An identical coccus was obtained from a human case of tonsillitis and arthritis on the same farm. The relation of these streptococci to the common hemolytic variety was certainly very close. They might be identical, the differences noted being caused by environmental factors. The fact should be emphasized that streptococci which were pathogenic for animals, and which apparently were identical with streptococci causing human infections, might cause mastitis in milch cows.

The Relation of Aortitis to Syphilis and the Import-

ance of Its Recognition.—Dr. CLYDE L. CUMMER and Dr. RICHARD DEXTER of Cleveland presented this communication and made the following summary. From the cases reported by others and the work done upon them, together with the material upon which their paper was based, the following conclusions seemed justifiable. (1) That a large proportion (70-75 per cent.) of lesions of the aorta or aortic valve were syphilitic in origin. (2) That syphilitic aortitis was a definite pathological and clinical manifestation of syphilis, usually coming late after the disappearance of the early manifestations, after a long period of latency. (3) That aortitis occasionally was associated with luetic cerebrospinal manifestations. (4) That a complaint of pain in the chest and dyspnea should lead to careful examination of the thorax in the region of the aorta. In case of suggestive or doubtful physical findings an *x*-ray examination was desirable. (5) That after a diagnosis of aortitis had been made a Wassermann reaction should be performed. A positive reaction indicated the desirability of urgent mercurial treatment.

SECTION ON DISEASES OF CHILDREN.

Tuesday, June 4—First Day.

DR. ISAAC A. ABT IN THE CHAIR.

Chairman's Address.—Dr. ISAAC A. ABT of Chicago discussed the necessity for a more thorough study of gastrointestinal diseases. After thoroughly reviewing the history of the study of this condition from the very early literature of East India down to the present time, he urged retrospective study in order that studies already made might not be duplicated. He called attention to the very scientific classifications of these conditions made in the middle of the nineteenth century. He said that bacteriological research had failed to materially aid in the classification of disease, and that the improper use of designating terms had been a constant source of confusion, and that pathological conditions had been repeatedly assumed which did not exist. He called particular attention for division between the study of gastrointestinal diseases of infants and those of older children. He thought that the present danger was to drift too far afield, and that while bearing in mind the ground already covered, careful account should be kept of the progress being made.

The Ability of Women to Nurse Their Children.—Dr. J. P. CROZER GRIFFITH of Philadelphia read this paper, giving statistics to show the importance of breast feeding as compared with artificial feeding, and the influence which the latter had on the deathrate, and the subsequent later health of children. He said that in many instances the deleterious effects of artificial feeding might even be traced to adult life. He thought that probably over 60 per cent. of women would be able to nurse their children under proper instruction and care. He said that among the poor probably some artificial feeding was due to the women being compelled to earn their own and their children's living, but that even here partial breast feeding would be more general if its importance was emphasized by physicians. He believed that actual disability that could not be corrected by careful instruction existed to a very small degree, and that physicians were too ready to abandon efforts to establish breast feeding.

Supplemental Breast Feeding in Infants.—Dr. H. M. MCCLANAHAN of Omaha gave the general indications for supplemental feeding as follows: The better development of the infant, and the health and comfort of the mother. He said that the mother's milk being the natural food of the infant, it was more especially adapted, chemically, to the needs of the infant's body than any artificially modified milk could possibly be, therefore even a small amount was of value. He gave statistics from his own practice of 400 tabulated cases showing that in only fourteen cases was there real inability to nurse the child. His cases showed that even a small quantity of mother's milk enabled the child to assimilate the artificial food more fully, thus increasing the weight and general health of the infant. He called attention to the responsibility of physicians to teach mothers the necessity of breast feeding.

Dr. D. B. ENGLISH of Summit, N. J., said that in his experience nursing and feeding at the same time, putting the child to one breast, then to the bottle, then to the other breast, alternating until it was sufficiently fed, gave excellent results, the elements of the mother's milk, so necessary to the infant, thus being thoroughly mixed with the artificial food. He said that some preferred to give first the mother's milk and then the bottle feeding, or vice versa, but in his experience the practice of alternating the foods helped digestion, maintained the mother's supply, and kept the child in good condition.

Dr. CRAM of Milwaukee thought that often the scant supply of mother's milk was due to her not having had sufficient sleep, and that in his practice even such a measure as removing the infant for a short time produced good results.

Dr. SOUTHWORTH of New York said that one reason that babies did so much better on breast milk than any other food was because it did not require supervision. Bottle foods had to be constantly changed and modified to adapt them to the child's needs, but this was all done naturally when breast milk was fed. But even in view of this he did not think it would be well to give no supervision to breast feeding, because sometimes when the mother had plenty of milk the child did not do well. He did not believe there were many cases of actually bad milk, although there were many that were scanty on account of improper attention. He did not believe that too much dependence should be placed upon the analysis of milk, but that rather that the mother's physical condition should be looked after. He believed that too infrequent feedings tended to lessen the quantity on account of the lack of stimulation of the breasts. He thought that breast feeding was a safeguard to the health of the child.

Dr. SHAW of Albany thought that many infants' lives were saved by even one small breast feeding. In institutions where but one wet nurse was employed the mortality was much lower than before this measure was introduced. He criticised the statement that the pump did not stimulate the breast, stating that in his practice it had proven beneficial. He also disagreed wih Dr. Southworth's statement that the milk analysis was of no value. He had found it of distinct advantage.

Dr. CHURCHILL of Chicago said that at the Children's Memorial Hospital for some time one wet nurse had been employed during the winter and two during the summer with excellent results. He stated that their nurses were not allotted for the feeding of certain children, but that all the milk the nurses supplied was removed by means of a breast pump and divided among all the children so that each child had some. He said that one mother for a few weeks gave five quarts of milk daily, which seemed to disprove the statement that the breast pump was not of value in increasing the quantity. He said that careful records were kept and they knew that the quantity secreted was exact.

Dr. JOHNSON of Grand Rapids, Mich., said that in small towns difficulty was experienced in getting wet nurses, so that they had resorted to the practice of getting small amounts of milk from a number of nursing mothers, varying from an ounce to a pint, and that in this way they had had excellent results with infant feeding. In Berlin he had procured statistics showing that in mixed feeding (part bottle and part breast) the mortality was about 10 per cent., while the entirely artificially fed gave a much higher rate. He cited one group of thirty families among which there were eighty children, partly bottle fed and partly breast fed; at the end of the eighth year investigation of these families showed that all the bottle-fed children had died.

Dr. SCOTT of New York thought that psychic conditions had something to do with the disinclination of some women to nurse their children. That if they would appreciate the necessity for doing so there would be little difficulty in bringing the supply up to normal, or nearly so. He wished to protest against the practice of some obstetricians attempting to feed the child steadily from birth, allowing it to get into a poor condition and then handing it over to the pediatrist.

Dr. HARINGTON of Milwaukee said that the practice of putting the child first to one breast and then to the other was a mistake, because normally the mother had a rest of four hours between feedings, and with this practice she got only a rest of two hours to a breast that was not up to normal. He thought that no periodical nursing should be of more than ten to twelve minutes' duration, and that after the lapse of this time the needs of the child should be supplied with a bottle.

Dr. DOUGLAS of Detroit believed that every woman could nurse her child if she was correctly managed. He said that successful feeding was not merely a matter of getting a certain amount of liquid into the child; that the mother's habits of diet, exercise and rest should be regular so that the best results might be obtained. After this had been done, if the stool was still not in normal condition, he though that some readjustment of the method of feeding should be instituted. He emphasized the necessity for analysis of the breast milk that it might be known what the child was getting.

Dr. DENNY of Brookline, Mass., said that Dr. McClanahan omitted to state the advantages associated with giving

the child at an early period cow's milk, so that [illegible] weaning was necessary no serious disturbance occurred.

Dr. Zahorsky of St. Louis said that the main difficulty was the lack of definite knowledge regarding the whole subject of human lactation and infant feeding. He thought that if the causes of the unpleasant sensations which nursing aroused in some mothers could be discovered this knowledge would dispose of many cases.

Dr. Southworth wished to correct Dr. Shaw's impressions derived from the speaker's remarks. He said he did not intend to intimate that the analysis of breast milk was of no value, but to discourage immediate weaning upon the results of the first findings.

Dr. Brady of St. Louis thought that occasionally children were weaned because there was too much milk and they were overfed.

Long-Interval Feeding of Premature Infants.—Dr. J. C. Litzenberg of Minneapolis reported cases showing that a marked increase in weight occurred when premature babies had been taken from the short-interval feedings, so generally recommended, and had been fed at intervals of three to four hours. His charts showed an almost instant advance and no digestive disturbance. It had also the advantage of causing less disturbance to the child, permitting it to sleep for long periods.

A Plea for Longer Intervals in Milk-Feeding.—Julius H. Comrof of York, Pa., read this paper, showing that the average healthy infant received an excessive number of feedings during the first year. He thought that many of the signs of so-called insufficient nursings were more properly attributable to incomplete emptying of the stomach between feedings. He though that the advantages of longer intervals would be more complete gastric digestion; more complete emptying of the stomach; increase in quality and quantity of the milk supply in the breast fed; more rest for the infant and the mother. He thought that if the method were thoroughly tried out the present almost-universal rule of two-hour periods would become less common.

Dr. Lowenberg of Philadelphia said that his good results from short-interval periods would not justify him in changing. He criticised the reader of the paper for being as dogmatic in his plea for four-hour intervals as he had accused others of being in their use of the two-hour period. Statistics in the speaker's practice did not show that children fed at longer periods weighed more than those fed at short intervals.

Dr. Miller of Atlantic City had found, by use of the stomach-tube, that the child's stomach did not empty for at least four hours. He said that the results of past experience should, as a rule, be the guide, but when confronted with an infant with gastric indigestion, vomiting and other pathological symptoms he thought longer periods of rest would prove beneficial.

Dr. J. L. Morse of Boston called attention to the fact that usually the term "premature infant" implied a much weaker and feebler infant than those shown in the cases recited and that in these cases where often only a teaspoonful of food could be given at a time long periods were not possible or feasible. He called attention to the absolute necessity of adapting the feeding and the intervals between feedings to each individual case.

Dr. Royster of Norfolk, Va., said that a baby was not a laboratory, and that therefore there could be no hard and fast rule for its feeding: that it was one thing to measure the stomach of a child and another to enable it to take and absorb and digest the amount of food that could be put into such a sized stomach. He wished Dr. Litzenberg in closing to state at what time he put the child to the breast of the eclamptic mother, and what the toxic condition of the milk was.

Dr. Englis of Summit, N. J., said that infants could not be fed by a clock, that when their stomachs were empty they would make the fact known and that until they did they should not be fed. He thought that other measures than feeding should be tried when the infant cried and that if these measures failed there was time enough to feed it. He thought that not as much harm would come from eight-hour intervals between feedings if the child would stand it as from too frequent feedings.

Dr. Hess of Chicago said that he did believe it necessary to feed a large amount in order to make a premature child gain, but that it did seem, from his experience, that the premature would take more in proportion to its weight in order to gain than the normal infant. In his experience he had had infants weighing 1500 grams gain on 70 calories. He said he rarely fed at shorter than three-hour intervals, but kept up the number of calories by concentration of the food.

Dr. Southworth of New York [illegible] attention to the reaction from the recently widely recommended four hour interval in the German literature, the substance of which was that where milk was method to be scant there was not sufficient breast stimulation in four hour feedings to stimulate it.

Dr. McClevi of California had used the four hour intervals successfully in his practice. He said, in reply to the criticism of the dogmatic recommendation of the four-hour interval, that it permitted of just as much adaptation to individual cases as did two hour intervals. He called attention to the fact that modified cow's milk was the best substitute for mother's milk.

Dr. Zahorsky of St. Louis emphasized the fact that the general term "when an infant's stomach is empty" was only a relative one, depending entirely upon the amount of food taken, and that when only a little could be taken short intervals should intervene between feedings.

Dr. Litzenberg in closing said that he had not offered his method as a propaganda, but as a method to be tried in cases in which all other methods had failed. He said, in reply to Dr. Royster, that the child of the eclamptic patient was fed by another woman and not put to its mother's breast until the mother's condition was normal.

Dr. Comrof, in closing, said that the criticism seemed to come from those who had not tried the four-hour intervals, and who therefore were hardly in a position to speak authoritatively.

Intestinal Toxemia in the Newborn.—Dr. John Lovett Morse of Boston called attention to the almost uniform symptoms presented in these cases. Babies, normal at birth, became suddenly sick on the third or fourth day, were unduly quiet or markedly restless. The rise of temperature was moderate. The meconium was usually not all passed. He said that these symptoms were probably due to absorption of toxins of meconium occurring soon after birth. In his experience recovery was prompt when the intestines were thoroughly cleaned out. He recited several cases and showed the close resemblance to other infantile disorders.

Dr. Goodman of Jersey Shore, Pa., called attention to the clinical and laboratory research that had been done on this class of cases, stating that French physicians had inoculated guinea pigs with the watery extract of the contents of bowels in such cases, with the prompt death of the guinea pig; after treatment, they had again similarly inoculated guinea pigs with no harmful results. Inoculation with fluid from spinal puncture had also proven fatal to guinea pigs, showing the toxemia to be quite general.

Dr. Lowenberg of Philadelphia said that he had often looked upon these cases as instances of infection from the bronchi, or, as cases of simple pneumonia, and asked Dr. Morse if he had ever considered these possibilities.

Dr. Churchill of Chicago said his indications in this class of cases had not been so clear. He said that he always considered the possibility of pneumonia and that he had had a number of cases that gave a high leucocyte count.

Dr. Scott of New York said that there was undoubtedly some chemical combination between the sugar and proteid content of the mother's milk and the bacteria of the nipple that causes this condition.

Dr. McClanahan of Omaha said that if the condition was met promptly and immediately by a cleaning out of the alimentary canal the prognosis was good.

Dr. Morse, in closing, said that he had always used castor oil in these cases because of its quicker and more effective action. He said that he thought if all the indications of this condition were clearly in mind it would scarcely be confused with other conditions.

Pellagra in Children.—This paper was read by Dr. J. Ross Snyder of Birmingham, Ala. The paper embraced a brief history of the disease in the Southern States; the widely differing theories as to its etiology; the frequency of its occurrence in children; the symptoms presenting in children that differed from those in adults, and the difference in the mortality. The author summed up with a preliminary report of his experience together with that of the various physicians with whom he had corresponded, the substance of which was that while pellagra did occur in young children, it was more common after the age of eighteen months and that approximately 10 per cent. of all cases were children under the fifteenth year.

Dr. Butterworth of New Orleans called attention to the fact that Bass of New Orleans had fed chickens with spoiled corn and that the chickens developed unmistakable symptoms of pellagra, thereby seeming to establish the theory so common that the use of corn does have something to do with the development of the disease. He

said that the symptoms occur in order as follows: intestinal disturbances, the cutaneous eruption, and the nervous symptoms.

HOUSE OF DELEGATES.

Wednesday, June 5, 1912—Third Day.

Afternoon Session.

Report from the Board of Trustees.—This report stated in reference to the matter of giving support to small journals, that this course was already being pursued by the Association. The recommendation favoring a Health Journal had been submitted to them and they favored the establishment of such a journal which might be discontinued at any time on the request of the Board of Trustees in case they decided that such a course was advisable.

Report of Reference Committee on Sections and Section Work.—This committee reported that it had considered the resolutions asking for the formation of a Section on Physical Therapeutics, a Section on Proctology, and one on Orthopedic Surgery, and it had decided that it would not be expedient to establish the sections on the first two subjects mentioned but that it recommended the adoption of the resolution forming a Section on Orthopedic Surgery.

Dr. POPE said that the Section on Physical Therapeutics was desired by from 250 to 300 men and he thought the demand was reasonable. There was no doubt but that physical therapeutics had a place in medicine. Again, the profession had to deal with a great many quacks and impostors in this line and this class could best be eliminated by recognizing that branch of therapeutics and creating a standard for those using these methods. He hoped therefore that the house would consider this matter, as it concerned the wishes of many.

Dr. HORACE D. ARNOLD of Boston, Mass., said that the value of this branch of therapeutics was being more and more appreciated and it was going to become of far more importance in the future than it was at present. He thought they should have proper recognition from the Section on Therapeutics and Climatology.

Dr. C. E. CANTRELL of Greenville, Tex., said that they must not forget that the establishment of a section meant expense, time, and energy. If it was worth while to consider the subject he was sure it could be cared for in other sections. There were so many sections now that the Association was getting unwieldy. There was only one science of medicine and it was not a good thing to go after theories and dogmas. If they began this they would soon have a section on purgatives, one on opiates, etc. All therapeutic measures should go together.

Dr. PENNINGTON of Chicago said that he appeared before the House to speak in favor of the formation of a Section on Proctocology. The American Association of Proctologists had been formed fourteen years ago and it always met the day before the American Medical Association and in the same place; such an organization was no longer an experiment. As an instructor in post-graduate work he had been asked by rural physicians why they were not given the opportunity to know what the proctologists were doing.

The House adopted the resolution as recommended and refused to grant further hearing on the subject for the present.

Report of Reference Committee on Medical Education.—This committee reported that it desired to congratulate the Council on Medical Education on the continuance of its excellent work. They recommended that in the classification of medical colleges instead of Class A and Class minus A they should classify as follows: Class A plus, those that rank above 70 per cent. according to the scale of marking; Class A, those that have a general average of 70 per cent., though they might be slightly below in one or two subjects; Class A minus, those that might have an average of nearly 70 per cent, but fall off in three or four departments. They also recommended that the Council let it be known that they were ready to offer advice to any institution and to tell it how it might be brought up to the standard. They also recommended that the House of Delegates appropriate money for the proposed hospital investigation and classification.

The report of the Council on Education was adopted by a rising vote as a tribute to the excellence of the work it had done.

Report of Reference Committee on Legislation and Political Action.—Dr. W. A. EVANS of Chicago, Ill., in reporting for this committee said that they recommended that the House of Delegates appropriate $1,000 in accordance with the request of the committee, which had met in connection with the National Education Association, as the latter organization had pledged a like sum for carrying on a campaign of education and hygiene among school children. He recommended that the Committee on Public Health Education among Women be received, and called special attention to the good work done. Between July 1, 1911, and April 1, 1912, talks were given to approximately 3,342 audiences, not including 935 audiences of school children. The lectures had been so favorably received that it was impossible to restrict the work to women, as men had asked for talks and the requests could not be refused. In regard to the report of the Committee on the Prevention of Blindness and Ophthalmia Neonatorum, he said that they recommended that the secretary of the committee be requested to inform all State boards of health that ophthalmia neonatorum should be made a reportable disease, and also recommended that a resolution be sent to the Public Health and Marine Hospital Service requesting that this service undertake the investigation of trachoma, as relating to its cause, spread and control. He also recommended that the council be instructed by the House of Delegates to carry on a more definite and vigorous policy in regard to legislation.

This report was adopted as read, together with the above recommendations.

Reference Committee on the Nomenclature and Classification of Disease.—This committee reported that the report had been accepted by them as presented and they therefore recommended its adoption. The report stated that the copy for a practical nomenclature of diseases was completed and would soon be published. The Bellevue Hospital Nomenclature of Diseases and Conditions had been adopted and the differences in the Army, Navy and Philippine lists had been considered. Overtures had been made looking to cooperation with the Committee of the Royal College of Physicians and Surgeons of London to arrange for the fourth decennial revision of the fifth edition of the nomenclature that had been the authority in England for the past forty years.

Other Resolutions Introduced.—Dr. W. A. EVANS of Chicago introduced a resolution from the Section on Preventive Medicine and Public Health providing for the appointment of a permanent Committee on Industrial Hygiene to cooperate with the American Association for Labor Legislation. Also a resolution to the effect that the American Medical Association send a resolution to the Federal government urging the enactment of laws restricting the interstate traffic in opium, cocaine, morphine and other opiates not used for medicinal purposes, and that it take steps to restrict the importation of such drugs and to control their distribution in this country.

Dr. OSCAR DOWLING of Louisiana introduced a resolution providing for an inspection of doctors' and dentists' offices and the use of a score card that would classify them. He said that they should be required to come up to a certain standard. The unsanitary condition of many offices and the careless personal habits of some physicians demanded such a course. Dr. Dowling also introduced a resolution to the effect that whereas many physicians opened offices and practised as specialists in ophthalmology, otology, etc., who were by no means fitted for this work, provision should be made for the establishment of some standard or basis of determining the fitness of such practitioners and that the Council on Medical Education seek some means of supplying this deficiency by making provision for post-graduate work in such specialties and that State boards be enlightened as to the necessity of establishing a standard and permitting only those to practise a specialty who showed their fitness.

Dr. JACOBI said that as chairman he was not permitted to introduce a resolution, but that he wished to say that public opinion had been awakened to the necessity for conservation. After referring to the loss of life through automobile accidents, factory accidents, and floating palaces, he spoke of the loss of life and the suffering occasioned by the floods in the Mississippi which had permanently beggared many and created a desert which would not bloom again in a decade. This was because we had murdered our forests. We could not expect much from politics, but the American Medical Association was a permanent body and should take up the matter of rebuilding the forests, which could be done in the course of fifty years. Spain, Italy, Greece, and Palestine had been great because of their forests. He, therefore, urged that some one frame a resolution urging and compelling the government to take action in this matter and to follow it up persistently.

SECTION ON MEDICINE.

Wednesday, June 5—Second Day.

My Experience with Diabetes Mellitus Patients Living Ten or More Years.—Dr. ELLIOTT O. JOSLIN of Boston said it had been a gratifying surprise to him that sixty-seven of his patients with diabetes had lived or were still alive at least ten years after the onset of the disease. Eleven per cent. of all cases of diabetes which he had seen in private practice had had a duration of life of ten or more years. The duration of life in one case was thirty-five years and in five other cases twenty or more years. A study of his cases had taught him that the diabetic patients must be prevented from becoming fat. Three qualities of temperament constituted a reason why some of these patients lived so long. These qualities were common sense, courage, and cheerfulness. Heredity played an important rôle among the group. Twenty-five per cent. of the sixty-seven cases showed parents, brothers, and sisters, cousins, or aunts with the disease. Syphilis had existed in only five of his cases and he felt sure that as time went on the importance of this disease in this connection would receive more recognition. Every case should be scanned carefully for a possible connection with syphilis. The favorable outcome in a considerable percentage of cases could be attributed to early treatment, and, contrary to the rules, a certain number of cases became less severe as time advanced. Eleven of the cases were free from sugar before death occurred. So far as he was aware acidosis was absent in all of the cases. A contrast of the statistics in his cases with those of twenty years ago showed remarkable progress in the treatment of this disease.

Family Hematoporphyrinuria and Its Association with Chronic Gastroduodenal Dilatation and Thyreopathy.—Dr. L. F. BARKER of Baltimore reported a case of prolonged hematoporphyrinuria in a patient suffering from gastroduodenal dilatation with tetanus-like attacks. The autopsy findings showed dilatation of the stomach and duodenum, hemorrhagic erosions of the stomach, fatty degeneration of the liver, kidney, heart muscle, and pancreas, together with other serious pathological conditions. Two sisters of the patient suffered with the same condition and the father showed signs of Graves' disease. This change in the urine occurred in a variety of conditions, but he was inclined in this case to regard the toxemia as of gastroduodenal origin and the thyreopathy as an accompaniment. He especially emphasized the family character of the disease and thought that perhaps some vice of development had affected all three sisters and accounted for the gastroduodenal dilatation which led to the intoxication and hematoporphyrinuria.

An Analysis of Five Hundred Cases Showing High Blood Pressure.—Dr. THEODORE C. JANEWAY of New York read this paper. In the study of the history of some 500 cases of persons showing a high blood-pressure of 170 or over during the past eight years, it was found that approximately 150 had died. Of these 150 patients, accurate information as to the cause and time of death had been obtained. His clinical diagnosis of the primary underlying disease in these 100 cases in private practice was as follows: Chronic nephritis, 79; diabetes, 7; general arteriosclerosis, 4; coronary sclerosis, 4, and the condition of the heart which seemed to be the primary disease, 4 cases. The analysis of these cases gave evidence of the frequent association of cardiovascular and renal disease with diabetes in elderly individuals. In the younger cases of pure diabetes, high blood-pressure was not observed, but in individuals of suitable age it seemed to predispose to the development of those changes which produced hypertension. This series of cases was studied as regarded age incidence, sex incidence, immediate cause of death, the relation of the initial symptoms, the cause of death and the relation of prominent early symptoms to the cause of death. So far as conclusions could be drawn from a study of 100 cases, it seemed reasonable that—(1) The early occurrence of dyspnea whether on effort or of the paroxysmal type in a patient with high blood-pressure indicated marked danger of cardiac insufficiency. In such patients the disease should be treated as a cardiac disease, especially by safeguarding methods. (2) Anginoid pain, even of marked severity, occurring on exertion, did not make the prognosis any worse than did other cardiac symptoms in persons with high blood-pressure. Of course, every precaution must be taken to prevent over-exertion. The bulk of these patients would not die in an anginal paroxysm. (3) Complaint of polyuria, marked headache, or of visual disturbance by a patient with high blood-pressure, if that patient was below fifty years of age, should make the prognosis very guarded, since chronic uremia was a frequent mode of termination in such cases.

Immunization in Pneumonia and Other Pneumococcus Infections.—Dr. E. C. ROSENOW of Chicago presented briefly the results of immunization experiments in animals and the results of the treatment of lobar pneumonia in man with various products obtainable from pneumococci. The opsonic content of the serum in lobar pneumonia had been found to be below normal during the early part of the disease, and well above normal as the symptoms subsided. In those cases which died from overwhelming infection it remained persistently below normal. When highly virulent pneumococci were allowed to autolyze in NaCl solution there appeared at a certain period a highly toxic substance. This when injected intravenously in guinea pigs, rabbits, and dogs produced symptoms characteristic of anaphylaxis in these species and when injected subcutaneously in man produced a moderate increase in opsonins after a short negative phase, rather marked local reactions, leucocytosis, and some fever. These extracts called forth reactions in man similar to the heat-killed bacteria. For the treatment of lobar pneumonia the autolyzed pneumococci had been mostly used so far. A study of the statistical method during the past two years at the Cook County Hospital had shown a definite reduction in the mortality of the 130 cases treated. The number of cases treated was too small, however, to allow one to draw definite conclusions, but when they considered the patients that had been treated in this way belonged to the most unfavorable group, it looked as if this antigen really was of definite value.

Pleural Vomicæ with an Analysis of Sixteen Cases.—Dr. ELSWORTH SMITH of St. Louis said that if left to nature the destiny of pus within the pleural sac would be (1) absorption; (2) formation of a pleural vomica; (3) perforation of the chest wall, resulting in empyema necessitatis; and (4) perforation through the diaphragm into some of the abdominal organs or peritoneal cavity. Of these several results, all quite rare, that by way of formation of pleural vomica was probably the most frequent. Their series comprised sixteen cases, ten seen in private practice. An analysis of these sixteen cases developed some points of interest and value. Four cases developed in the course of pneumonia, one in appendicitis, one in an infection from the mouth, two in chronic bronchitis, three in empyema, three in abscess of the liver, showing that four sources were below the diaphragm. In not one of the sixteen cases were tubercle bacilli present. The important points in the diagnosis were the history of an etiological source for pus, septic fever, sudden, profuse and constant expectoration of pus, generally offensive and in large quantities, and above all in the localization of an area in the chest, giving the classical physical signs of fluid in the pleura, and on such findings had also to be based the differential diagnosis between pleural vomicæ and delayed pneumonic resolution, pulmonary tuberculosis, bronchiectasis, abscess of the lung, pulmonary gangrene, and the more rare conditions of new growth, lues, hydatid, etc. In conclusion he stated that pleural vomicæ belonged to a class of cases deserving far more attention than was accorded in the literature; that many a poor victim of this generally supposed curable malady was doomed to an untimely grave because believed to be suffering from such hopeless affections as advanced pulmonary tuberculosis, inoperable bronchiectasis, pulmonary abscess, or some of the more rare and fatal types of diseases of the respiratory tract; while, if the localized empyema was diagnosed before perforation or if every case of copious purulent expectoration were carefully studied and correctly appreciated, much untold misery and suffering might be averted and many lives might be saved.

A New Principle in the Treatment of Typhoid Fever.—Dr. WARREN COLEMAN of New York said that three years ago he brought to their attention a new principle in the dietetic treatment of typhoid fever, the principle of supplying the patient with sufficient food to diminish materially, and in some cases to prevent, loss of nitrogen and weight. The amount of food recommended exceeded that furnished by any diet hitherto employed in the treatment of the disease by 1,500 to 2,000 more calories per day. Though the number of cases thus treated was not large, something less than fifty, the results had been so striking that it seemed desirable to advocate the principle publicly. In the three years which had elapsed since the paper was presented the study of the effects of the diet had been steadily pursued, and the purpose of this paper was to present these results. The following foods had been given a thorough trial and were recommended for appropriate

ases. Apple sauce, one ounce; bread, average slice; butter, one pat (1/3 ounce); cereal, one heaping tablespoonful; crackers, one ounce; cream, one ounce; egg, two ounces; Lactose, one tablespoonful; milk (whole), one ounce; potato (whole), one medium; potato mashed, one tablespoonful; rice (boiled), one tablespoonful; sugar (cane), one lump; milk sugar, one tablespoonful; toast, average slice. The caloric values of these articles were based upon the tables of Atwater and Bryant, Schall, and Heisler. At present the foods which Dr. Coleman said he believed harmful were meat and its preparations, vegetable foods containing cellulose and fruits containing much cellulose and small seeds. The three objections brought against this diet were: 1. That the patient could not digest and absorb the amount of food recommended. 2. That the amount of fat would inevitably cause alimentary disorders and acidosis. 3. That, granting its absorption, patients did not require the amount of food which was advocated. The objection that patients could not digest and absorb the amount of food recommended was based upon the prevalent notion that typhoid fever caused serious impairment of the digestive powers. This belief was without foundation. Disorders of digestion depended not so much upon the quantity of food as upon the method of giving it. Sudden changes in diet and individual peculiarities were two factors that must be taken into consideration; these could be discovered only by testing the capacity of each patient for the foods allowed. In regard to the absorption of the large amount of food, investigations showed that the capacity of the typhoid fever patient to absorb large amounts of food was remarkable. The absorption of carbohydrate was practically complete, less than one-half of one per cent. being lost. The loss of protein was usually under 10 per cent. The loss in a normal man used as a control was 7.9 per cent. The objection that the amount of fat recommended would inevitably cause alimentary disorders and acidosis had likewise proven to be without foundation. The majority of patients had taken from 100 to 250 grams of fat a day without disturbance of any kind. Moderate diarrhea had occurred in a few cases, but had ceased upon withholding the cream. Instead of being harmful there was reason to believe that fat aided the digestion of carbohydrate. The third objection, that patients did not require the amount of food advocated should be considered from the clinical as well as the metabolic standpoint. In general, the more food a patient took the better his physical condition. Patients lost weight when an apparent excess of food was not given. The largest amounts which had been administered had been reached in the attempt to satisfy the patients' hunger. Though this was clinical evidence, it possessed considerable value, the ultimate test of any method being the effect it produced on the patient. The study of protein metabolism in typhoid fever had demonstrated that large amounts of food were required to keep a patient in, or nearly in, nitrogen balance. The total number of cases of typhoid fever treated at Bellevue during the five years previous to January 1, 1912, was 975 and the total number of deaths 157 or 16 per cent. The total number of cases on the diet treatment was 138, of which 44 were mild, 57 severe, and 37 very severe. The mortality rate for the series was 8.69 per cent. Both mortality rates were abnormally high because the worst types of the disease were admitted to the hospitals of the department, and many patients were brought in apparently only to die when treatment at home had proven unsatisfactory. Records of cases followed showing that under this diet the period of convalescence was materially shortened.

A Plea for the More Frequent Scientific Employment of Physical Therapeutics.—Dr. PHILIP MARVEL of Atlantic City, N. J., said that now physical treatment, too indefinitely directed, was given in a more or less routine manner, and was scientifically employed only in a few of the best sanatoria. Conditions, the outgrowth of a complex civilization, demanded the employment of mechanical and various other forces in the restoration of health. The public complainingly resented the failure of medical science properly to recognize the efficiency of this system of therapeutics in both anatomical and functional disturbances. There was a deplorable absence of physical therapeutics in the teaching curricula of medical colleges which was largely responsible for the growth and maintenance of cults and pathies. Knowing as well as they did the efficiency of massage, electricity, calisthenic exercises, and hydrotherapy when scientifically applied in correcting the undeveloped muscular system, functional deficiencies and tardy mental development not infrequently seen in childhood, it seemed astonishing that so many physicians so greatly needed the intelligent employment of these therapeutic agents. Fundamentally speaking there were three cardinal conditions that were directly concerned, as both contributing and causative agents, in various diseases that were accompanied by toxemia. They were intemperate food indulgence, indifferent muscular activity, and insufficient elimination.

Diagnostic Pitfalls Identified During a Study of 3,000 Autopsies.—Dr. RICHARD C. CABOT of Boston said that he wished to make three points: (1) That there was a goodly number of "classic" time-honored mistakes in diagnosis, which were familiar to all experienced physicians because they made them again and again. Some of those they could avoid, others were almost inevitable, but all should be borne in mind and marked on medical maps by a danger signal of some kind: "In this vicinity look out for hidden rocks," or "Dangerous, turn here, run slow." (2) That some common diseases were relatively inaccessible to diagnosis, no matter how carefully they were on the watch for them. From a study of 3,000 autopsies he had begun to work out a percentage or ratio of accessibility for the commoner diseases. (3) That beside the classic and well known pitfalls, there were some less familiar to the profession and needing all the more, therefore, to be marked "Dangerous." The following tables were of interest.

Percentage of Correct Diagnoses—Diabetes mellitus, 95 per cent.; typhoid fever, 92 per cent.; aortic regurgitation, 84 per cent.; cancer of colon, 74 per cent.; lobar pneumonia, 74 per cent.; chronic glomerulo-nephritis, 74 per cent.; cerebral tumor, 72.8 per cent.; tuberculous meningitis, 72 per cent.; gastric cancer 72 per cent.; mitral stenosis, 69 per cent.; brain hemorrhage, 67 per cent.; septic meningitis, 64 per cent.; aortic stenosis, 61 per cent.; phthisis, active, 59 per cent.; miliary tuberculosis, 52 per cent.; chronic interstitial nephritis, 50 per cent.; thoracic aneurysm, 50 per cent.; hepatic cirrhosis, 30 per cent.; acute endocarditis, 30 per cent.; peptic ulcer, 36 per cent.; suppurative nephritis, 35 per cent.; renal tuberculosis, 33 per cent.; bronchopneumonia, 33 per cent.; vertebral tuberculosis, 23 per cent.; chronic myocarditis, 22 per cent.; hepatic abscess, 20 per cent.; acute pericarditis, 20 per cent.; and acute nephritis, 16 per cent. One naturally asked "Whose diagnosis?" Whose success or failure did this represent? Where Smith and Jones failed they might have done better. He doubted it. The study of the details in these cases before and after death convinced him that, for the present and under the present limitations of diagnostic method, few of the mistakes tabulated above could have been avoided. This table represented the success-and-failure ratio of certain methods, rather than of certain men. Admitting that the man behind the gun (or the method) made a vast difference, he did not believe that these figures depended to any considerable degree on the possession or lack of special virtuosity in diagnosis. They mirrored the methods of an average up-to-date American hospital. Dr. Cabot concluded his paper by telling of the relatively unfamiliar mistakes.

Oration in Medicine: Prognosis in Chronic Heart Disease as Adversely Affected by Certain Medical Traditions.—Dr. CHAS. LYMAN GREENE of St. Paul, Minn., emphasized the contentions upon which this address was based as follows: (1) That an early diagnosis of cardiac insufficiency was absolutely essential to the patient's welfare. (2) That such early diagnosis necessitated a change in the general attitude of medical men with relation to the valuation of subjective symptoms and the determination of the symptomatic relationships of lesser cardiac dilatations. (3) That a large group of chronically diseased individuals usually classed as neurasthenics, while usually free from serious organic heart disease, were peculiarly lacking in heart muscle tonus and possessed extremely dilatable, symptom-producing hearts as a part of their fundamental and usually congenital defects in general bodily structure and function. (4) That so little basis now remained for the retention of the term "neurasthenia" as a description of a concrete disease, and such serious errors of omission resulted from its continued prominence in the field of chronic ailments, that it should be dropped from the literature of medicine, or be given its true valuation under a proper terminology. (5) That the term "perfect compensation" in heart disease was a misnomer, and that the pathological events in such cases made it evident that there was a constant, more or less gradual but progressive limitation of the field of cardiac response, and that periods must inevitable occur from time to time, long before the onset of emergent or gross symptoms, when appropriate therapeutic measures would support and aid the embarrassed and laboring heart, relieve suffering and prolong life. (6) That to make the symptom of extreme cardiac exhaustion one's only justification for active

therapy was both illogical and dangerous. (7) That recent studies of the causative agents and portals of entry in acute rheumatism a better knowledge of the nature and means of detection of syphilitic infection, and the introduction of new agencies and better methods for the intensive treatment of lues, made both the avoidance and permanent cure of these conditions easier, and indicated the possibility of greatly limiting the large group of myocardial and aortic lesions of which they were the causative factors. (8) That chronic disease in general, and cardiac disease in particular, were granted far less critical attention and direct control than was properly due them. (9) That chronic heart disease though incurable was wonderfully responsive to intelligent and properly timed treatment, and always benefited by such proper supervision and control as was indicated in the individual case and obtainable only through early diagnosis, tactful disclosure, and a well balanced optimism.

SECTION ON DISEASES OF CHILDREN

Wednesday, June 5—Second Day

DR ISAAC A. ABT OF CHICAGO IN THE CHAIR.

Use of Polycarbohydrates in the Diet of the Young Infant.—JULES M. BRADY of St. Louis showed that the usual milk modifications used successfully in private practice did not produce good results in asylums. He illustrated with this paper the favorable results obtained from furnishing the infant, in the first three months of life, the carbohydrate content of its milk mixture in the form of maltose, dextrin, cane-sugar, lactose, and barley, instead of the generally used seven per cent. lactose. From his observations he concluded that the possibility of rickets need scarcely be mentioned, so seldom had it been seen. From his experience in 170 cases, all of which were under control for six months and longer, he concluded that the asylum infant was materially assisted in its development by the use of liberal varieties of easily-assimilated carbohydrates.

Clinical Notes from the Willard Parker Hospital, New York; Intestinal Intoxication.—Dr. LOUIS FISCHER of New York showed that research into infant metabolism had proven many new facts, chief among which was that heretofore too much stress had been laid upon bacteria and too little upon fat, sugar, and casein. He concluded that sugar disturbed digestion in the large majority of cases, even causing fever in many. Fat he considered a very important therapeutic element, and the fact that casein curds, might be prescribed in febrile conditions, to lessen and modify intestinal putrefaction to distinct advantage had been demonstrated in his cases. He concluded that where there was metabolic disturbance with loss of weight there was no sugar to equal maltose but emphasized the fact that no food should be allowed to stagnate in the intestines.

A Series of Infants Fed on a High Percentage Albumin Milk.—FRANK C. NEFF of Kansas City, Missouri, presented a series of sixteen cases (with weight-chart illustrations) in which a modified *eiweiss milch* had been given. In his formula he increased the element of whey, and used all buttermilk as a diluent in place of half buttermilk and half water, as in the *eiweiss*. His cases represented infants ranging from 22 days to 5½ months old, all in institutions. They had not been gaining on the breast milk, but as soon as placed upon this modification gained steadily. Many of his cases showed gain on the high percentage albumin milk both before and after the addition of supplemental sugar.

Ileocolitis with Meningeal Symptoms.—A. L. GOODMAN of New York gave the history of several rather obscure cases in which meningeal symptoms were present, and yet spinal fluid, upon examination, proved to be sterile. He said that gastrointestinal autointoxication often gave rise to symptoms which might be confused with genuine meningitis and that a microscopic examination of the contents of the intestinal flora was oftentimes necessary to a differential diagnosis, but called attention to the misleading fact presented by such examinations because all the microorganisms found in pathological conditions could be found in the normal stool and the factor of the colon bacilli had not yet been definitely established. He called attention particularly to the confusing nature of the symptoms presented on account of their similarity to other conditions, but gave a favorable prognosis where purgatives were used early, the diet reduced, thus stopping the digestive irritation.

Dr. ZAHORSKI of St. Louis, discussing Dr. Brady's paper, said that he believed general conditions in asylums were so much improved that infants [illegible] dying with the rapidity which had obtained previously. Some years ago, he said, a mortality of 60 and 70 per cent. had not been unusual, while now, in the asylum with which he was connected, they had a mortality of only 10 per cent. and that all of the deaths had been among the bottle fed. He said that they had not used the carbohydrate diet mentioned, but considered it excellent. He thought that as long as their plan of half top-milk with sugar gave such a low mortality and such excellent results there was no necessity for changing. He deplored the lack of comparative tests of babies fed upon small amounts of fats and those in which it was the principal content of the diet. He thought that until these were supplied no one was justified in saying that young babies should not be fed fats.

Dr. WEEMS of Columbia, Texas, said that he had had several cases presenting such symptoms as Dr. Goodman had outlined which in the light of his presentation he concluded must be ileocolitis, but in view of the fact that the parents would not consent to lumbar puncture he was unable to say whether the fluid was sterile or not.

Dr. DOUGLAS of Detroit wished to know what, exactly, was meant by the general term "maltose," the use of the loose designation being misleading.

Dr. HESS of Chicago, discussing Dr. Fischer's paper, thought that unquestionably catharsis was of great benefit, both in elimination from the bowels and from the kidneys, but thought it possible to push it too far. He said that in his work he had never felt justified in giving a five-grain dose of calomel to a young child. He cited the experiments of Dr. Abt at the Michael Reis Hospital, where one grain of calomel, in divided doses covering a period of three days, showed blood in the stools upon microscopic examination, as did also magnesium sulphate, one gram, and castor oil, given in the same way over a like period. Some of the cases used for this series were normal children, in the hospital because the mother was confined there for some reason. He said that he considered most of the difficulties arising in the use of *eiweiss* milk were because it was not properly prepared, and that since Finkelstein had published more specific directions for its preparations he thought much better results would be produced.

Dr. MORSE of Boston expressed it as his opinion that the etiology of diseases of the gastrointestinal tract and their classification was in a transitional stage. He thought that German writers put too much stress upon the chemical side, and Americans, probably, upon the bacteriological, while the truth was between the two. He thought that any baby, from birth on, was able to digest a certain amount of starch, and that, where sugar was called for, lactose was the best form to give. He said that milk sugar would do harm to the intestinal tract, as shown by the large class of cases of intestinal disturbances that were due to fermentation from sugar. There were cases he said, in which lactose was the sugar of choice on account of its slow absorption, while in others maltose was preferable because of its rapid absorption. He had seen in his practice cases of meningismus in which there was increase in the mononuclear cells which would cause one to suspect tubercular meningitis.

Dr. ROYSTER of Norfolk, Va., also called attention to the necessity for differentiating between the institutional and the private-practice case. He thought that the cause for more trouble in institutions was lack of personal attention and too little fresh air. In the institution with which he is connected he said that they never had over ten babies; they had one graduate nurse, one student, and two ward attendants, which insured personal attention to each child, which went a good long way toward reducing mortality. In selected cases he used malt sugar with interesting results. Two infants did well for a while, and then began to retrograde. He then substituted dextrose with return to normal conditions. He reported that in a little series of cases he used a proprietary food rich in malt sugar, in another milk sugar, in the last dextrose malt. The infants on the proprietary food gained three ounces, milk sugar six ounces, and the dextrose malt one ounce. He believed it would not be well to keep them on any one diet continuously, that there came a time when a change was necessary to stimulate digestive functions.

Dr. SCHWARTZ of New York thought that ordinary results were better with malt sugar, and that chronic intestinal disturbance yielded better to it; that it was also one of the only preparations that reduced fatty acids to any appreciable extent. He said that the good results from *eiweiss* milk were due to the high percentage of protein. He stated that frequently a low percentage of sugar and increase of fats gave good results, and that in other cases

the reverse would prove beneficial, but that a balance should be struck between the two. In children with fever and intestinal disturbance he eliminated all food for twenty-four hours -or until the fever disappeared.

Dr. Southworth of New York had found, in his experience, that where there was disturbance a diluent of cereal nature produced good results. The use of starch he thought produced a chemical protection in the stomach by splitting the fats and the sugars. He considered dextrose a protection to the intestines much in the same way as starch. He said that if part of the sugar was given as maltose and part as dextrose it would be slowly split in the intestines and furnish further maltose during the time of absorption. He said that the dry preparations had a percentage of between 40 and 60 per cent: dextrin, while the liquid preparations have 50 or below.

Dr. Lowenburg of Philadelphia said that for eleven years he had been feeding top milk and cane sugar and had had such excellent results that he did not feel justified tin changing. During the summer months he pasteurized the milk. If the combined chemical and bacteriological etiology of the digestive disturbances were understood he believed that the treatment would be comparatively simple. He did not see any possible danger from the use of sugar, as all human milk contained it.

Dr. Dennett of New York called attention to the safeguard of boiling as a further preventive of digestive disorders.

Dr. Louis Fischer (closing the discussion) said that the dose of calomel he had recommended was not an infant's dose, but suitable for children (with scarlet fever) up to the fifteenth year; he however called attention to the absolute necessity for free elimination.

Dr. Johnson of Grand Rapids brought out the overlooked fact that *eiweiss* milk was for sick babies, not a diet for normal, and should in no instance be given for longer than six weeks. He said that in the Grand Rapids institution the death rate was but 10.8 in infants under one year.

Dr. Jules M. Brady in closing said that the chief factors in raising the mortality rate in asylums were the overcrowding of wards, insufficient help, etc. He thought that the fact that during the past year the ward temperature had been kept at 75°, instead of the usually prescribed 68° had helped to keep their infants in good condition. He said that their records showed undeniably that their best results were from small percentages of fats, their place being taken by carbohydrates. They were able to feed four ounces of one of their formulas to a new baby without producing vomiting. He drew particular attention to the necessity for watching the caloric requirements. He fed seven times a day at first, then as the fat was increased, decreased to five. He believed that the trouble experienced with *eiweiss* milk was due to the fact that it was not finely curdled. He believed that if flour were added to the feeding early there would be no necessity for adding maltose and dextrose preparations. His experience showed that infants under three months, even as early as three weeks, tolerated maltose very well.

Dr. Frank C. Neff, closing the discussion, said in answer to Dr. Hess that in his cases no gain had been produced until the malt was added. He believed that the sugar contained in milk varied greatly, so that cases where gain was shown when only milk was given were probably getting a high percentage of sugar in the milk. He put forth his formula simply as a method to be used in those cases where the other modifications did not produce good results, not as a routine.

HOUSE OF DELEGATES.

Thursday, June 6—Fourth Day.

Election of Officers.—The following officers were elected: *President*, John A. Witherspoon, Nashville, Tenn.; *First Vice-President*, Philander A. Harris, Paterson, N. J.; *Second Vice-President*, John Heffernon, Syracuse, N. Y.; *Third Vice-President*, H. H. McClanahan, Omaha, Neb.; *Fourth Vice-President*, Henry T. Fry, Washington, D. C.; *Secretary*, Alexander R. Craig, Chicago; *Treasurer*, William A. Pusey, Chicago; *Trustees*, M. L. Harris, Chicago; C. H. Dougherty, South Bend, Ind.; W. T. Councilman, Boston, Mass.; *Member of Judicial Council*, Frank Billings, Chicago; *Member of Council on Health and Public Instruction*, W. B. Cannon, Boston; *Members of Council on Medical Education*, James W. Holland, Philadelphia, and W. B. Hackett, Nashville, Tenn. The next meeting will be held at Minneapolis.

(*To be continued*)

New Instruments.

STOMACH SPRAY FOR THE LOCAL TREATMENT OF GASTRIC ULCER.

A PRELIMINARY COMMUNICATION

By ERNEST ZUEBLIN, M.D.,

PITTSBURGH, PA.

PHYSICIAN ALLEGHENY GENERAL HOSPITAL.

In Dr. Einhorn's string test and in his duodenal bucket we possess valuable methods for a more precise diagnosis of the ulcerated surface of the gastric wall. In treating cases of gastric ulcer by the ordinary methods (rest cure, diet, bismuth, alkalies, nitrate of silver, atropine, hot applications, etc.) and controlling the results with the string test I obtained in several instances a marked blood reaction. Even the disappearance of the subjective symptoms of gastric ulcer and a still positive brown discoloration of the string would indicate that the ordinary treatment of these pathological conditions is not in all instances sufficient. The question whether it would be possible to treat the ulcerated surface more

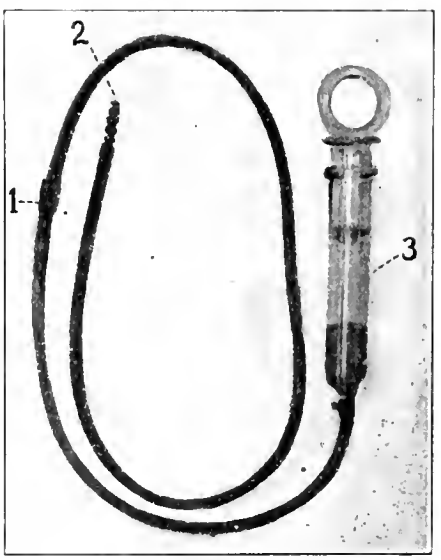

Fig. 1.—Tube for stomach spray: 1, guard-ring; 2, tip for spray with five lateral openings; 3, syringe.

effectively by local application seems very important. In many instances an operation is not accepted even if the former treatment was not successful.

As early as 1891 Einhorn recommended the appliance of a stomach spray, but the tube then used did not seem to me to answer well for the local treatment of gastric ulcer. The new irrigation tube which I have employed since October, 1911, consists of a thin rubber tube 3/16 inch in diameter, 30.1 inches long. Just above its closed lower extremity a series of fine openings allows the medicated fluid to escape in the form of a fine spray. A scale in inches on the outside of the tube denotes the level to which the tube has entered the stomach (distance measured from the dental row). The guard-ring fitting tightly on the tube and being caught by the teeth of the patient, prevents the compression of the tube and maintains it in a steady position, whereby the tickling sensation of the tube in the pharynx is reduced to a minimum, as well as the reflex movements of the pharynx. By suppression of the movements of regurgitation the change of the level corresponding to the ulcerated area of the tube is rendered less liable. The rubber tube can be

adapted either to Einhorn's outfit for duodenal feeding or it may be connected with an ordinary glass syringe (containing one ounce) filled with the medicated astringent solution.

The technique of the treatment may briefly be described as follows: The patient sits in an upright position. In a case of hyperchlorhydria where the string test has previously shown a marked brown discoloration with positive blood test at a level, for instance at 17 inches from the dental row, the guard ring is placed at 17¼ inches on the irrigation tube. The patient swallows the tube without difficulty, and bites on the guard-ring, so steadying the tube in this position. The glass syringe with the astringent solution is then fitted on, and by successive pressure the fluid is forced into the stomach at the level of the ulcerated bleeding surface. Then the tube is gradually withdrawn, the injection of the remnant fluid in the syringe being still continued until the cardia is reached. Then the whole tube is withdrawn. The patient then lies down in the right lateral position, and after a little while he swallows

Fig. 2.—Stomach spray in use.

a saline solution, in order to dilute the fluid in the stomach, which by a longer contact with the diseased part, might be injurious.

In order to try the treatment on a series of patients and to report later on a successful treatment by this method, I have delayed my communication up to the present time. So far as my observations on my cases are concerned this treatment has shown no disagreeable results or injurious effects. In regard to the clinical results the strength of the solutions used, the duration of the treatment, the experiments have still to be continued. For the present I can say that the string tests made some time after the treatment showed a marked improvement and the absence of blood. The patients were not only free from their previous subjective symptoms, and they did not object to the treatment at all, but also they said that the spray seemed to act directly on the spot, where previously they had remarked the pain.

429 Fourth Avenue.

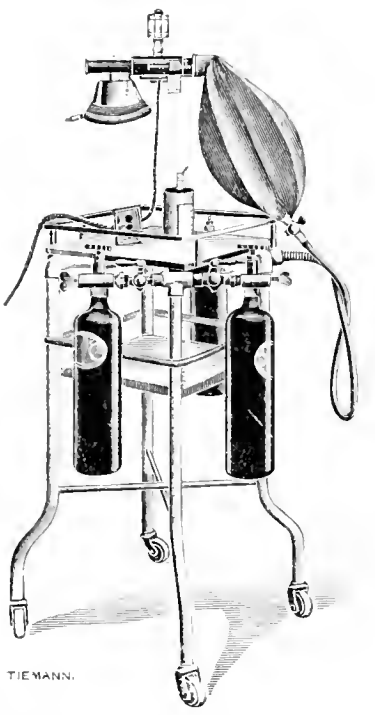
A NEW ANESTHETIST-CYLINDER STAND FOR HOSPITAL USE

By RAYMOND C. COBURN, M.A., M.D.

NEW YORK.

In the *Journal A. M. A.*, March 23, 1912, I described "A New Apparatus for Administering and Warming General Anesthetics" that was designed primarily for the administration of nitrous oxide-oxygen, with ether as an adjuvant. The stand for holding the cylinders in the apparatus therein illustrated is very light and portable. In the Medical Record, May 4, 1912, under the caption of "A Scientific System of Administering Ether" there were further illustrations of my apparatus, showing a folding stand mounted on casters. This stand occupies the minimum of space and is also light and portable.

The chief aim in designing a portable stand for the nitrous oxide and oxygen cylinders was that it should be light and compact, and easily and quickly assembled and taken apart. However, for hospital



use, lightness and compactness are not essentials, and so, in order to afford the most practical and convenient means for holding the cylinders and all other supplies of the anesthetist for this kind of use, the herein described and illustrated hospital stand was designed. Heretofore it has required one stand for the cylinders and another for the anesthetist's supplies, thus occupying a considerable amount of much needed space in the operating room, as well as causing unnecessary inconvenience in moving both stands about whenever the table is moved. In the anesthetist-cylinder stand I have combined the two stands into one, and, therefore, I believe this new hospital stand will fill a distinct and long-felt need, and this opinion is much strengthened by the fact that several of the largest and most progressive hospitals in this city have already added this stand and apparatus to their regular equipment, and they report that they are using them with entire satisfaction.

The stand consists of four legs mounted on small wheels. The top is made of thick plate glass,

twelve inches square, and one and one-half inches above is a light railing. About eight inches beneath the top is a shelf, also about twelve inches square; and above it is another railing. There is ample space for another shelf or two, if they are desired. At two opposite corners of the square stand are means for holding two cylinders each. When the cylinders are attached each one communicates with a fitting underneath the plate glass top at another corner of the stand. To this fitting is attached the small tubing that leads to the rubber bag.

The top is designed to hold the inhaler when not in use, and the supplies of ether, chloroform, anesthol and ethyl chloride, mouth gag, tongue forceps, etc., and on the lower shelf may be kept the supply of towels, gauze, hypodermic solutions, etc. The railings keep the supplies from being displaced when the stand is moved. As the stand is mounted on wheels it may be readily moved about with the cylinders attached, and all the supplies at hand for instant use in the anesthetizing room and during the transference of the patient, as well as in the operating room.

While the stand was designed for holding oxygen cylinders, a special fitting may be had for connecting with the regular oxygen tanks so universally used in hospitals.

The cost of nitrous oxide-oxygen anesthesia depends very much upon the method of its administration. The method of rebreathing and the intermittent supply of both gases, with the apparatus here shown, averages about $1.00 per hour, at the regular retail price of supplies, and, with the hospital discount, about $0.65 per hour. Where the hospital manufactures its own gas the cost is very considerably reduced, approximating that of ether by the open method.

Although the stand here shown was designed primarily for holding nitrous oxide and oxygen cylinders it may be advantageously used for holding a cylinder of carbon dioxide, or a mixture of carbon dioxide and oxygen, in the administration of all anesthetics, or for resuscitation in asphyxia from any cause. Provision for two more cylinders may be added without altering the design or changing the symmetry of the apparatus.

In my stands there is no breathing back and forth through any part of the stand conduits, and, therefore, all parts contaminated by rebreathing can be easily, quickly, and thoroughly cleansed and sterilized after each administration.

Hotel Bretton Hall, Eighty-sixth Street and Broadway

Treatment of Syphilis by Hectine and Hectargyre.—F. Dive presents his conclusions derived from the use of hectine and hectargyre in the treatment of syphilis in its various stages. Hectine is less toxic than the other derivatives of arsenic. It becomes localized in the muscles and skin, and hence causes the rapid resorption of cutaneous lesions. It may be applied subcutaneously in powder, or may be used in the form of an ointment. In pill form it is perfectly tolerated by the alimentary canal and acts well, being stable. It causes some pain when injected but no active inflammation. Injected in the thigh muscles it is generally painless. It increases the number of red and white blood cells, and the amount of hemoglobin. Its curative action is very rapid with respect to the chancre, the skin and mucous eruptions, the headache, gummata, scleroses, or ulcerations. It has little effect in paresis. When vision becomes affected the remedy should be stopped. Hectargyre may be advantageously combined with mercury. It is most used in malignant and precocious cases and in tertiary syphilis. It is well tolerated when taken by the mouth and when injected it causes neither induration nor infiltration, nor great pain. Injections should be made into the thigh muscles in the same manner as [illegible].—*Gazette des Praticiens.*

Medical Items.

Action of the X-rays on the Nervous System and Radiotherapy in Nervous Diseases.—U. de Luca has examined the literature as to the effect of the *x*-rays on the nervous system, has experimented on animals, and has employed the rays in a number of patients. He concludes that in no case has there been any harm done to the nervous system by the application of the *x*-rays. While the normal nerve elements remain unaltered the rays have a selective action on pathological nerve cells, since these are young tissue derived from pre-existing elements, such as the cells of the neuroglia, the ependymal cell, and the vascular and connective tissues, or consist of heterogeneous elements, as in the case of tumors. There is a special effect manifested by the *x*-rays on diseases of the spinal medulla, such as syringomyelia, in which the substratum is formed of gliomatous new-formed tissue with abnormal cavities. Here there is really a new formation, and on this the rays act promptly and specifically because they are rich in nuclein. There is an arrest of the degeneration and a diminution of the pressure of the new growth on the elements of the gray and white matter of the spinal medulla, and thus an improvement of the disturbances of sensibility and motility. Histories of appropriate cases are given.—*Rivista Ospidaliera.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended June 1, 1912.

CHOLERA

THE MANAGEMENT OF GONORRHEAL RHEUMATISM.*

By EUGENE FULLER, M. D.,
NEW YORK.

BEFORE making a special study of this subject, I felt—as I expect most of the profession now feel—that gonorrheal rheumatism was a direct complication which could be associated with the later or declining stages of an acute infection; although the symptoms might be most acute, still they were often subacute. I also felt that after the urethral discharge ceased and the urine became clear or free from inflammatory evidences directly associated with the gonococcus, the complicating rheumatic symptoms always eventually disappeared, although the period of convalescence might be very tedious; and should I have seen a patient suffering from rheumatism which he had had for years, in a constantly progressive or relapsing form, I should not have thought of connecting such a chronic condition with a gonorrhea of perhaps so many years before that the youthful indiscretion had been largely forgotten. On the therapeutic side, about all I did I know was that gonorrheal rheumatism was not at all favorably affected by the salicylates, uric acid eliminants, or various drugs having beneficial effects when administered in connection with other forms of rheumatism. On this account, the disease was looked upon as a professional bugbear, and as one liable to damage rather than enhance a surgeon's reputation for skill.

With my further knowledge of the subject, I can but feel the time-honored term, gonorrheal rheumatism, to be a very unfortunate one, for the following reasons. In the first place, just what rôle the gonococcus plays in the production of this complication has not been determined. There is a strong suspicion in my mind that its part is a secondary one, and perhaps not even that. Then, from a clinical standpoint, the term itself handicaps and embarrasses the surgeon, especially in dealing with the chronic forms of disease. Fancy, for instance, the results attendant on a diagnosis of gonorrheal rheumatism in connection with a gentleman past middle age who has been happily married for years, and who occupies an established social, political, or religious position. In such cases, I use the term "absorptive" or "toxic" rheumatism, explaining that the systemic symptoms depend on the absorption into the system of a toxic element which originates from a septic focus, the elimination of which will free the system of the poisonous element, thus ensuring a cure of the rheumatism.

The foregoing explanation has also the merit of being a definition of the affection in relation not only to the chronic but also to the acute cases.

*Read at the eleventh annual meeting of the American Urological Association, New York, April 3, 1912.

My active study of and interest in this subject covers a period of somewhat over seven years, dating from December, 1904. At that time, I found in my wards at the City Hospital a young man with a very marked acute suppurative gonorrheal seminal vesiculitis. Complicating this condition, there also existed a most acute and extensive gonorrheal rheumatism. The man had been bedridden for four months with the rheumatism. A detailed report of this first case, together with three other similar ones, will be found in the June, 1905, issue of the *Annals of Surgery*, the communication being entitled: "The Relation of Gonorrheal Rheumatism to Seminal Vesiculotomy." As I had already at that time opened and drained the seminal vesicles on numerous occasions with marked benefit, and as the pathological condition of the seminal vesicles in this case demanded drainage, I felt that it would be a matter of interest to watch and observe what effect, if any, this operation would have in relation to the rheumatic complication. I was greatly surprised in this case to find that all pain had vanished from the joints twenty-four hours after operation, while at the end of five days all of the extensive swelling had disappeared from the joints and limbs.

Later extensive experience in connection with acute gonorrheal rheumatism uniformly showed exactly similar results, the rheumatism disappearing in the same rapid and complete manner observed in the first instance, after performance of seminal vesiculotomy. Coincident with my first above mentioned report, Dr. John Rogers announced his experiments with antigonorrheal serum, administered with the purpose of curing gonorrheal rheumatism. The idea of curing the affection with a series of serum or vaccine injections was certainly far more attractive to the profession and to the patients than was my operative procedure. Any one could use serum, while for my operation one would require to be not only a surgeon but also one who had skilled himself in the special technique required. I was accordingly left to pursue my operative investigations quietly while the eyes and attention of the profession were directed toward serums. Although wishing to give serums a perfectly fair trial, I could not, even at that time, feel that they would at best prove more than sporadically efficient. It was evident to me that a patient afflicted with gonorrheal rheumatism harbored a pathological focus from which, constantly or intermittently, a systemic toxemia occurred, a result of which was the existing rheumatism. If the serums accomplished what their advocates claimed, and neutralized or removed existing systemic toxemia, I did not see how they could be radically efficacious unless they could also and at the same time cure the pathological focus, this preventing, as does my operation, future systemic toxemia. If a pathological focus, as not infrequently happens, ends in resolution, either spontaneously or as the result of palliative forms of

treatment, then, of course, there would be a corresponding termination of the resulting rheumatism.

It is not unlikely that serum or vaccine treatment with the latter class of cases would be of benefit in hastening the disappearance of rheumatic attacks. I understand from a mutual professional friend who has discussed this subject with him, that Sir A. E. Wright of London is in accord with my views, and that he ascribes the indifferent results from serum or vaccine treatment in these cases to the fact that there exists a systemic focus of infection which by its repeated reinfections more than counteracts the injections administered. If the time ever comes when mastoiditis, for instance, no longer demands operative surgery, the disease being under the complete control of vaccines or serums, then, I take it, gonorrheal rheumatism will likewise be found amenable to the same forms of treatment. Until then seminal vesiculotomy will hold its place as the radical method of cure.

My early operative experience was, as already stated, in connection with the acute cases of gonorrheal rheumatism, wherein the causative seminal vesiculitis was also acute and well marked, the organs being swollen, infiltrated, and surrounded oftentimes by periseminal vesicular edema, while an active suppurative process was in existence in the sac cavities. With further experience, cases of more chronicity came under observation, there being, perhaps, a stiff ankle, knee, wrist, or other joint or joints. These joints, as a rule, were involved in a hard inflammatory exudation. Such joints oftentimes presented an appearance closely resembling tuberculous conditions. On clinical investigation it would be found that a gonorrheal or urethral discharge had occurred, perhaps a year or so before. Such a discharge might soon have ceased or might still be persisting as a slight gleet. Perhaps there would be a history of an acute attack of rheumatism two or three months after the onset of the discharge, the present condition persisting, or perhaps there had been no such antecedent attack, the existing involvements having come on insidiously and slowly progressively, commencing, perhaps, six months or a year from the time of the urethral attack, and not, very likely, until long after the patient had supposed his urethral inflammation cured. In this latter class of cases the seminal vesiculitis accounting for the rheumatism would not be nearly so acute as that found in the preceding class.

Another peculiar point, and one which at first caused me to hesitate before operating on numerous occasions, lay in the fact that the extent and grade of an existing seminal vesiculitis bore no fixed relation to the grade and extent of the resulting rheumatism. Thus one might find a very severe and extensive seminal vesiculitis in a case where the rheumatic affection was not extensive or of a severe grade; while in another case, where the rheumatic symptoms were very extensive and crippling, the seminal vesiculitis might very likely seem mild in character, the lesion consisting chiefly of a sclerous thickening of the sac walls, there being but little periseminal vesicular involvement and but a minor degree of intraseminal vesicular catarrh. Then, again, there would be many cases wherein the grade and extent of the rheumatism seemed to correspond with that of the seminal vesiculitis. Experience has shown me, however, that the removal of an existing seminal vesiculitis through seminal vesiculotomy regardless of its apparent grade or extent, will be followed by the disappearance of the rheumatic complications, whatever they may be.

Then, finally, there comes a third and most interesting class of cases, the extent of which I have not yet fathomed, although I am actively studying the subject. These consist of cases in which neither a preceding gonorrhea nor a genitourinary complication has been considered, or probably even thought of, as having any relation to the existing disability. Hitherto few of these cases have come to me as a genitourinary surgeon, for the reason just referred to, that no one supposed they belonged to my department of medicine. For most of them I am indebted to my service at the City Hospital, where the courtesy shown me by those visiting in other departments, combined with the active assistance of an interested house staff, has enabled me to have transferred to my division material originally admitted to orthopedic or general surgery, to general medicine, to neurology, and sometimes even to ophthalmology.

Thus there might be chronically stiffened joints without any effusion, associated with contracted tendons and marked muscular atrophy. The spinal vertebræ and the associated muscles might be rigid and immovable, together with a fixation of the ribs, the classical picture of supposed arthritis deformans being presented. In such cases, oftentimes there was also a fixation of the cervical vertebræ, so that there was no rotation of the head. The jaws might be so fixed and locked that nothing but fluid food could be taken. The muscular atrophy might be so marked in connection with rigid joints and tendons that a diagnosis of progressive muscular atrophy or some other form of spinal lesion had previously been made. The joints, instead of being stiff and without effusion, might represent an opposite condition, there being great effusion and the joint capsule, especially the knee, having been thereby so stretched as to make it very loose and flail-like. Iridochoroiditis or some other insidious exudative process of the eyeball might exist, of so severe a grade as to cause or threaten blindness. A much longer recital of clinical conditions could be given to represent the pictures often seen illustrative of this affection in its multiple chronic phases. Still, the present recital ought to be sufficient to put the investigating surgeon on his guard.

In getting a clinical history in these cases one would very likely get a report of a gonorrhea perhaps twenty years before. In some instances there would be no history, or perhaps remembrance, of such a past condition. In one case which first came under my observation in its rheumatic incipiency almost twenty years ago, and which I have had under observation ever since, I am positive there never was a gonorrhea, the seminal vesiculitis being caused apparently by the streptococcus.

That the above described group of very chronic conditions really belongs to the same class as the acute rheumatisms already considered, I have proved, first by discovering the coexistence of seminal vesiculitis, generally in a most sclerous form, and then by curing the disorder through the performance of seminal vesiculotomy, thereby eliminating the focus of infection which caused the systemic toxemia. It is not to be expected that the same rapid and striking cure follows operation in the old chronic and severe cases as in the acute ones. Secondary muscular atrophy and joint adhesions are, of course, left after the chronic toxemia has been eliminated, and the surgeon has in the postoperative convalescent period of these cases

practically the same problems to deal with which he has in convalescence from fractures of long standing where there coexist like conditions of muscular atrophy and of joint and tendon adhesions. At a suitable period after resolution in connection with the fracture has taken place, massage and passive joint manipulation is prescribed. So in these postoperative rheumatic cases, there comes a time when massage and passive joint manipulation is most essential. Formerly, however, I inaugurated such postoperative treatment much sooner than I now do. I find it a mistake to make use of these treatments before the last fraction of the toxemia has been eliminated, otherwise an inflammatory reaction may ensue. Formerly, also, at the time of the operative anesthesia, or within a few weeks after operation, I forcibly manipulated stiffened joints and limbs, vigorously and with the use of considerable power, breaking down joint and ligament adhesions, thus restoring normal movements. Now, however, I consider such vigorous treatment during the toxic period to be inadvisable. I find it best to leave joints and muscles alone for a period of two months after operation, allowing the patient to make such progressive use of them as he may see fit. In cases not of the severe grades the progressive use of the parts made by the patient himself will very likely by the end of two months have been found to be all that was necessary. At the end of such time, however, manipulative treatment, if indicated, will do much in hastening the restoration of joint function. Such manipulations should not be too severe, especially at the start, and should be administered by one who has had training or experience.

In my early operative experience, much more frequently than at present, I noticed a month or thereabouts after operation some temporary rheumatic recrudescence of symptoms, all such evidences having promptly disappeared after operation. I found such recrudescences to correspond to the closure externally of the wound. It was evident to me that the closure in these instances had been premature and before all toxemia had been drained from the deeper parts. Consequently I made it a point not to remove my external drainage tubes for ten days or until such time as the deeper wound had thoroughly drained and granulated. Such conditions having been attained before the external wound is allowed to close, there will be no such recrudescence. The operative technique and management of seminal vesiculotomy will not here be considered. For such information reference is made to the author's article, "Relief of Urinary and Genital Conditions Through Surgery of the Seminal Vesicles," MEDICAL RECORD, October 30, 1909.

I have often been asked regarding the bacteriological findings in connection with the work now being considered. It would be of much interest and probably of value in determining the exact bacterial or toxic agency concerned in the causation of this form of rheumatism could there be an examination of smears taken from the intraseminal vesicular contents on the opening of the sacs. I have found this impossible of accomplishment except in a very few instances, for the reason that the seminal vesicles when opened are not exposed to view, the sense of touch being the guide, and, as the path of the wound is deep and narrow, the smear carrier introduced, guided by the finger, comes in such contact with blood and serum on its introduction to and withdrawal from the sac cavity that subsequent smear findings can, at best, be far from accurate or satisfactory.

Owing to the positive claims of cures which are just now beginning to appear from the use of electricity applied to the prostate or seminal vesicles, it seems necessary to give some notice to the subject. As there is no evidence at all that electricity in any of the multiple forms in which it has been applied has been found curative in any variety of sepsis, or has power to destroy germ proliferation or to free the natural cavities of the body of inflammations or their resulting exudates, it does not seem worthy of belief that this agency, on impartial investigation, will be found of potent or general value in this connection. This is not the first time that electricity has proclaimed herself a cure for a surgical disorder. She has done so, and loudly, many times, only to be many times discredited. Twenty-five or so years ago her champions announced that stricture of the urethra in all its forms could be quickly absorbed and cured by electricity. Very many wonderful statistics of cures were published to support these claims. Investigations thoroughly discredited these as well as similar claims made some years later of cures by the Fort method. Then, in the early stages of gynecological surgery, in connection with ovarian tumors and extrauterine pregnancy, the claim of electricity, supported by the usual array of cures, was again raised. Now anyone trying such treatment for such disorders would, to put it mildly, be considered most unethical. Again, in the early days of prostatectomy, the Bottini method was resurrected as a simple cure free from danger and far preferable to prostatectomy. Here again the claim has been found wanting and the method has been discarded. Seminal vesiculotomy is a new procedure, and, while the profession are considering it, it seems only natural that electricity should do as she has done so many times before under similar conditions, namely, put in her claim of ability to beat the knife. Electricity, barring possibly the *x*-ray, in her attempts to displace surgery, has run a poor second to Christian Science. Electricity as an aid to surgery has done much in the direction of the *x*-ray, in illuminating spaces otherwise inaccessible to sight and in allowing a cauterization of similar parts. I have, of course, profound respect for the accomplishments of electricity in the field of therapeutics.

In the article already referred to, which appeared in the MEDICAL RECORD October 30, 1909, I reported my first 126 cases of seminal vesiculotomy. Of these 35 represented cases of rheumatism. Since then I have performed seminal vesiculotomy 125 more times, so that at present my total operative cases number 251. Of these last 125 cases 87 represented rheumatism. With most of these the rheumatism, acute or chronic, was of a very severe grade, and it was for the relief of the rheumatism only that seminal vesiculotomy was performed. A minority of the cases had other clinical symptoms due to seminal vesiculitis coexisting with rheumatism as a reason for operation. In this last series a much larger proportion represented rheumatic conditions than pertained to the first series. This is largely because rheumatism is the clinical symptom of seminal vesiculitis which usually, by incapacitating an individual, brings him to hospital, and in my experience at the City Hospital, when those suffering from rheumatism see the rapid

cures resulting with little postoperative discomfort in those who have been subjected to seminal vesiculotomy, there is such a scramble for operation that no time has to be wasted in persuasion. Out of 251 cases there has been no mortality, so argument against the operation on that score cannot be very impressive. In my last series the results with rheumatic cases have been uniformly good. I attribute the better results in the second series to a more thorough performance of the operation and to improved postoperative details. I expect shortly to prepare a paper in which more attention will be given to certain features, especially clinical ones, that I have not here had space to include.

252 Lexington Avenue.

FACTS OF MODERN SCIENCE AND THEIR VALUE IN THE PREVENTION AND CURE OF DISEASE.

By HERMANN HILLE, Ph.D.

CHICAGO, ILL.

HON. MEMBER S. W. MISSOURI MEDICAL SOCIETY.

Strange as it may appear, there are well-established facts in modern science which seem to be almost completely ignored not only in the estimation of food values and the manufacture and preparing of foods, but also in the prevention, alleviation, and cure of disease. I have reference to the facts about the mineral constituents of food and of the human organism, and their functions in the processes of life.

In the middle of the last century a number of investigators of more than average ability, among them Justus v. Liebig, F. W. Beneke, Jakob Moleschott, Carl Voit, and others, recognized and emphasized the vital importance of the mineral salts in physiology and pathology of living organisms. For the benefit of those who have not access to the writings of these methodical and profound thinkers, I take the liberty of quoting a few passages from their writings.

Liebig: "The indispensable agents of the organic processes are the incombustible constituents or the salts of the blood. If it be true that these substances take a conditioning and necessary part in the processes of transforming the constituents of food into constituents of the body, then it is self-evident that no food, in which these materials are lacking, can sustain life; that all foods in order to possess full nutritive value must contain these materials in the proportions favorable for the formation of blood, and that we can deprive food of its blood-making power if we deprive it of these agents. In all processes in the animal organism, digestion, blood making, respiration and metabolism, the mineral* constituents, or the salts which are constant components of the blood, the muscles, the tissues and all of the organs, as well as of food, take a very essential, in many cases a directing, part; only by their co-operation do the nutritive elements of the foods of man, and the fodder of animals, receive the faculty to serve for the sustaining of the organic processes, and therefore they ought to be taken into account in the explanation of these processes."

F. W. Beneke, a distinguished clinician and pathologist of Marburg, in his celebrated book, "Grundlinien der Pathologie des Stoffwechsels," writes: "The mineral constituents, which through the food are supplied to the organism and enter into the composition of the body building material, up to a short time ago, have been so underrated in their importance and even at the present time are still so little taken in account, that one cannot forcefully enough draw attention to the fault which lies in this neglect. Just as these constituents are of the most far-reaching importance for all formation and growth in the vegetable kingdom, so too for the animal organism they are partly the most necessary conditions of all growth, partly the most indispensable agents of the processes of life. Without the presence of phosphates and sulphates no proteins are formed in the vegetable kingdom, and in an unsuspected way the phosphates take part even in the dissolving of the plant proteins; without the presence of alkali carbonates no vegetable acids, no sugar, no amylum are formed. In the animal organism, however, a large portion of the mineral constituents of the vegetable is utilized in the formation of the skeleton and the soft cellular structures, and another portion serves essentially as agents for all those processes which include the nutrition of the existing and the gradually retrograding metamorphosis of the introduced food constituents.

"It is almost trivial to remark that the bony structure of man cannot be formed without the supply of a certain quantity of earth phosphates, and still it often appears as though in medical practice this fact were never given any thought. Without potassium phosphate no blood corpuscle is formed, without the presence of alkaline bases the oxidation of vegetable acids in the organism is but partially accomplished, without the presence of sodium chloride the processes of diffusion in the body would be entirely different from what they really are; without phosphoric acid as highly important a combination as the glycerinophosphoric acid could not possibly be formed. But notwithstanding the indubitable certainty concerning these things, they are but to a small extent taken into account in medical practice. Powerful agents, like iodine, arsenic, mercury, quinine, etc., are extensively used as remedies, but the fate of the organism so far as it depends upon the integrating mineral constituents is apparently left entirely to benevolent Nature, without considering that she, too, notwithstanding all her benevolence, through certain conditions is limited in her ability to act, and that oftentimes one can accomplish the most rational cure by eliminating those conditions, namely, in our case, *by endeavoring to* reestablish mineral equilibrium.*"

Jakob Moleschott in one of his books, entitled "Der Kreislauf des Lebens" (Circle of Life), says, as nearly as I am able to give it in English: "The fabric and the life sustaining powers of the organs are dependent upon the necessary quantity of the mineral constituents. Real bone is as impossible without calcium phosphate, as gristle is without cartilage salts, blood without iron, or saliva without potassium chloride."

*In most publications the mineral elements and their combinations in the vegetable, animal, and human organism are designated as the "inorganic" components of the system. This entirely arbitrary and misleading expression is contrary to the facts of Science, and I have, therefore, taken the liberty of substituting "mineral" for "inorganic" in all of my translated quotations. While it is true that at the present time chemistry is unable to distinguish between inorganic and organic forms of elements and their combinations, the time is not distant when this distinction will be clearly made and defined.

*Literal translation from the German text: "bring back into the correct proportion the disturbed equilibrium of the mineral constituents."

Much corroborative evidence might be quoted from other sources, and all that these men have so ably expressed thirty and more years ago applies with equal force to-day, so far as personal observation and statements of contemporaneous authorities go.

Of the most recent and modern authors, Drs. Albu and Neuberg of the University of Berlin, in their highly recommendable little book, "Physiologie und Pathologie des Mineralstoffwechsels," Berlin, 1906, write as follows: "As little as scientific medicine at the present time acknowledges the importance which the salts deserve in the physiology of nutrition, just as little does it appreciate also the role which they play in the genesis and evolution of disturbances in nutrition and of anomalies in metabolism. * * * *Let us draw attention to the far-spread error that the small quantities in which the mineral substances occur in the organs, the blood and tissue juices, make them of little importance in the economy of the body. This is a fallacy!* That smallest quantities of the same are often capable of producing quite characteristic physiologic and pathologic effects upon the organism, is sufficiently known from the experiences in human and experimental pharmacology! Although from the small percentage of minerals in the body a small need may rightfully be deducted, nevertheless the importance of this need must not be underestimated, and just as erroneous, therefore, is the far-spread, quite arbitrary assumption, which may be found in almost every text-book, that this relatively small need of minerals is usually in the food of man not only fully met, but even surpassed. In the case of a healthy person this certainly is true; it is the very reason why he remains healthy. But disturbances in the metabolism of the minerals occur as frequently as those of organic substances, and the former are of no less influence upon the vital processes than the negative balance in the metabolism of proteins, fats and carbohydrates. Were the supply of mineral salts always sufficient there would occur no anomalies in mineral metabolism, of which there are so many different and often very grave ones. To-day it must therefore be taken as fact that with otherwise fully sufficient nutrition a grown organism perishes within a few weeks if the supply of mineral salts in the food is insufficient. After quick elimination of the circulating salts the body forcibly, as it were, retains but a minimum, which, however, does not suffice to retard death from 'mineral starvation.' How much the organism suffers from mineral starvation has been clearly illustrated by experimental observations with starving animals and above all by the well-known experiments with the professional fasters Cetti, Breithaupt, and Succi, on whom the very considerable changes of mineral metabolism were well observable. The designation of the mineral salts as 'Nutritive Salts' received its full justification through the fact that the renewed supply of salts in the food is capable of preventing death from mineral starvation, or of removing the already inaugurated health-destroying consequences of salt deficiency. From another recently acquired point of view the physical conception of the processes of nutrition and metabolism, and of the physiological functions in general, the salts of food, in an indirect sense, possess absolutely a 'Nutritive Value.' It has been shown that the salts are by no means unessential and passively carried along accompaniments of the organic foodstuffs; on the contrary, they play an eminently active role in the assimilation of the total food and especially the organic foodstuffs. Although in a quite different way from the latter the salts too are carriers of energy which in the body is transformed into motion. This knowledge is one of the ripest fruits which the application of modern physical chemistry in physiology and medicine has produced."

It would fall outside the scope of this paper to enter into an explanation of the laws of modern physical chemistry, therefore suffice it to say that the osmotic pressure of salt solutions is one of the forms of energy stored up in the minerals, and that the osmotic analysis of the blood, body juices and liquid foods, as well as of the secretions and excretions of the organism, has shed additional light upon the functions of the internal organs and the processes of metabolism.

If this subject prove of sufficient interest to my audience I shall take great pleasure in making the laws underlying and governing osmosis, and the methods employed in osmotic analysis, the subject of another paper.

For the purpose of this paper it is sufficient to quote again Albu-Neuberg as follows: "The absorption of the nutritive salts into the circulation represents a labor which is in direct proportion to the difference of the osmotic pressure between the food contents of the digestive tract on the one side and the blood and lymph on the other. These differences must be adjusted in order to keep constant the tone of the blood, the immutable physiological magnitude of which has been proved necessary for the conservation of life. This equalizing of the differences in the osmotic tension can be accomplished in no other way than through currents of motion in the liquids coming in contact with each other. By no means can all motions of liquids, which occur in the animal organism, for instance in resorption and secretion, exclusively be referred to osmotic processes. But the latter in almost all physiological processes of the organism take a greater or smaller part, which we are able to determine far more accurately than other physical and physiological forces which are active in the organism like 'diffusion' and 'filtration,' and above all the 'vital force,' which appears to regain a larger space in the views of modern physiology."

In briefly stating the total present knowledge of their physiological importance, the minerals apparently have to perform in the body the following tasks: (1) They are cell and tissue builders; they take part in the formation, growth and reconstruction of all tissues of the organism in different degrees. (2) They bring about the osmotic tension in the cells and tissues, in the blood and other body juices, and thus are indirect carriers of energy. (3) They act as "catalysers" in a large number of chemical processes in the organism. They, for instance, act as carriers of oxygen in the processes of oxidation. They cause those transformations of proteids in the cell protoplasm which are inseparably connected with their functions. (4) They are the agents of the autochthonic toxin and anti-toxin forming processes which unceasingly are going on in the living protoplasm, balancing each other by their partial antagonism. (5) They probably bring about a large portion of the so-called intermediary processes of metabolism, particularly in the glandular organs. Everywhere they regulate disintegration and assimilation of organic substances."

In Hammarsten's Text-Book of Physiological Chemistry, fifth American edition, New York, 1908,

we find the following: "Those bodies are designated as food which have no injurious action upon the organism and which serve as a source of energy and can replace those constituents of the body that have been consumed in metabolism or that can prevent or diminish the consumption of such constituents. We have learned by direct observation and a wide experience that besides the oxygen, which is necessary for oxidation, the essential foods for animals in general, and for man especially, are *water, mineral bodies, proteins, carbohydrates,* and *fats.* The food may be quantitatively insufficient, and the final result is absolute inanition. The food may also be qualitatively insufficient or, as we say, inadequate. This occurs when any of the necessary nutritive bodies are absent in the food, while the others occur in sufficient or perhaps even in excessive amounts."

Russell H. Chittenden, Professor of Physiolog. Chemistry, Yale University, in "The Nutrition of Man," page 3, writes: "Indeed, electrolytes are perhaps the substances that put life into the proteids of the protoplasm and it is truly important for the integrity and functional power of living cells that the proportion of mineral constituents therein be kept in a constant condition of quality and quantity."

Dr. Hans Köppe of Giessen in his paper, "Die Bedeutung der Salze als Nahrungsmittel" (The Importance of the Salts as Food), read at the 68th meeting of German Naturalists and Physicians in Frankfort o/M., said: "On the contrary, we have to consider the salts as food, indeed, for through them, or their solutions, the organism is supplied with *Energy,* which, thanks to van t'Hoff's theory of solutions, can be measured, and whose effects in the organism can be studied. We now know that under favorable conditions a solution of mineral salts can render considerable labor because of its 'osmotic pressure.' This labor, however, is of a different kind from that of the proteids, carbohydrates and fats; while the energy of these materials, measured in calories, is transformed into heat, the energy of salt solutions expresses itself in modes of *Pressure* and *Motion,* and is measured in terms of atmospheric pressure."

Part of the Energy with which we supply the body through the salts, is used for the absorption of food.

"In a totally different light appear now the mineral waters when viewed with regard to the laws of osmotic pressure: Not only do they deserve our attention as carriers of a specific energy, but especially on account of the presence and the relative proportions of the large number of *different* salts. Even though they occur only in very small quantities, they are nevertheless the cause of highly important qualities of the mineral waters. The action of mineral waters is due to their contents of neutral, *i.e.* not dissociated, molecules on the one hand, and the number and kind of the dissociated Ions on the other. One must not forget that the cause of a disease can rarely be traced to one single agent, or to the lack or altered metabolism of one mineral alone. Therefore the application of that one substance alone cannot cure the disease. All of our natural food products, vegetable or animal, contain a large number of elements. So do all of our mineral waters, in some of the best known of which have been found as many as 26 elements."

"The mineral constituents of the human organism and of foods occur in two distinct forms: (1) One portion of the salts is firmly combined with the combustible substances of the body in the organized structures and as integral portions of the blood and juices. Those are the real body salts. (2) Another, very much smaller, portion is simply dissolved in the juices. These are the salts which are either set free by the disintegration and oxidation of the combustible substances in the organism, or have combined with the products of decomposition."

Experimental proof of the vast importance of the "Nutritive Salts" for the organism has been furnished by a large number of investigators, a few among whom are J. Forster, C. Voit, Bunge, Kemmerich, Hofmeister, Hardy, Pauli, E. Overton, Hamburger, Köppe, Bredig, Loeb, Grützner, Russell, E. Voit, Hober, Goldberger, Heidenhain, Wallace and Cushny, Schade, v. Noorden, etc. Above all, the classical and celebrated animal experiments by Forster, deserve mentioning here, because they so clearly demonstrate two most significant facts, viz.: (1) Animals cannot live with an insufficient supply of "mineral salts." (2) Death occurs sooner in mineral starvation than in complete starvation. Or, in other words, proteins, carbohydrates, and fats not only cease to be food when deprived of the mineral food salts, but become actual poisons.

Animal tests have also demonstrated the fact that *inorganic* minerals, added to demineralized food, cannot take the place of the food minerals; while they retard death, they are unable to prevent it.

Much more corroborative material could easily be added, but the foregoing would seem to represent abundant evidence for the purpose and the scope of this paper.

FACTS

Briefly recapitulating, modern science has established these facts:

1. Of all the vital processes and activities of the human organism, not one is possible without the mineral constituents.
2. The mineral elements and salts are generators of Energy.
3. The nutritive salts are of equal importance with the other essential constituents of food, viz., oxygen, water, proteins, carbohydrates and fats.
4. The mineral elements and salts in true organic form are indispensable foods without which the human organism cannot exist.
5. Mineral Starvation causes serious disturbances in the vital processes and activities of the human organism. Or, expressed in simple language, Mineral Starvation causes disease and death.
6. Mineral Starvation causes death in a shorter time than does complete starvation.
7. Most diseases are caused by the lack, or altered metabolism, of more than one mineral.
8. All natural foods and mineral waters contain a large number of elements. In some as many as 26 elements have been found.
9. By far the larger portion of the mineral constituents of the human organism and of foods are in organic form.

CONCLUSIONS

The foregoing facts of modern science, if they have any meaning at all, compel to far-reaching conclusions, viz.:

1. The primary cause of disease, from a purely physical viewpoint is chiefly mineral starvation.
2. Minerals in inorganic form cannot be utilized by the human organism as directly and effectually as can true organic minerals.
3. Foodstuffs not only lose their food value, but become actual poisons in proportion to their loss of mineral bodies. Or, in other words, the more we

deprive natural foodstuffs of their mineral portion, the more do we deprive them of nutritive value and convert them into poison.

4. Mineral starvation causes disturbance in the vital processes and activities of the human organism, reduces the supply of vital energy, pollutes the blood, body juices and tissues, and thus prepares a soil in which the omnipresent parasites thrive and multiply with little interference.

Unfortunately for the well-being and health of the individual and the human race, the manufacture of foodstuffs, as well as of medicines, has been tending more and more to isolation of chemical entities and our modern methods of "refining," "purifying," and "improving" the foods, which Nature so abundantly furnishes, deprive the natural, wholesome food products of most of their mineral constituents and thereby reduce their real food value to a minimum. The human organism receives but a small fraction of the nutritive salts which Nature evidently intended it to have, and the inevitable result is mineral starvation and its dire consequences in the shape of malnutrition, general debility, anemia, indigestion, tuberculosis, rachitis, pernicious anemia, decayed teeth, gout, carcinoma, appendicitis, and other "modern" diseases.

A few examples will be sufficient to demonstrate this incontrovertible fact: The average grain of wheat contains 1.75 per cent. of mineral bodies. The finest patent flour contains only 0.44 per cent. of mineral bodies, which is only one-fourth of the quantity contained in the whole wheat. Unhulled rice contains 4.41 per cent. minerals, while polished rice, the kind we buy in every grocer's store, contains only 0.39 per cent., or less than 1/11 the quantity. Raw, brown sugar contains 1.97 per cent. minerals, while the most refined sugar contains 200 times less, viz., 0.01 per cent. In view of these facts is it any wonder that disease is the normal condition of our age and civilization, and that perfect health is the very rare exception?

Application.—1. The food minerals can no longer be ignored wherever the health and well being of the individual and of the human race are concerned, for our health depends as much upon a sufficient supply of mineral bodies as it does upon a sufficient supply of pure air, fresh and pure water, proteins, carbohydrates and fats.

2. A rational, scientific estimation of the value of foodstuffs, and the needs of the human organism, must take into account *all* of the "necessary nutritive bodies," viz., air, water, mineral bodies, proteins, carbohydrates, and fats. The now prevailing calorific standard of food value, which measures only the heat units produced in the combustion of proteids, carbohydrates, and fats, and completely ignores the mineral bodies, is not only woefully inadequate in the light of modern science but constitutes a menace to the health and life of the human race.

3. Rational scientific therapeutics can no longer ignore the mineral bodies. In the cure, as well as the prevention of disease, they must be given a more prominent place. To be consistent with the facts of modern science the physician can no longer be content with combating the outward, or secondary expressions of disease alone. He must also remove its primary cause, viz., *mineral starvation*. Prof. Albert Robin, a clinician of Paris, France, years ago, has drawn attention to the fact that mineral starvation is the primary cause of tuberculosis. His findings have been corroborated by Gaube, Ader, Dimitropol, Boureau, and, in this country, by Dr. John F. Russell of New York City, who is treating cases of tuberculosis with marked success upon the basis of mineral starvation.

4. One of the most important duties of chemistry at the present time is to find a rational and scientific distinction between inorganic and organic forms of matter.

The foregoing facts of modern science, and the conclusions to which these facts compel, are illuminating the path along which a reformation of existing conditions in the manufacture of food, in the standard of food values, in therapeutics, and in chemistry must and will eventually be accomplished.

THE PRACTICAL VALUE OF THE WASSERMANN REACTION.

By D. M. KAPLAN, M.D.,

New York,

Director of Laboratory, Neurological Institute; Serologist to the Montefiore Home.

In reviewing the Wassermann reaction I shall dwell first on its theoretical development; second, on facts that justify its classification among phenomena of an immune nature in accordance with the side-chain theory of Ehrlich, and third, from the technical viewpoint and that of the practicing physician. In 1901 Bordet and Gengou discovered the phenomenon of complement deviation. As is well known, today a specific cause of disease such as the cholera, typhoid, or diphtheria bacillus is known as the antigen of the respective disease. The word has been used to designate the fact that the microorganism in question is capable of stimulating the susceptible infected animal to react specifically by producing in the serum of the said animal certain demonstrable substances called antibodies. In other words, the name antigen means antibody generator. It is needless to emphasize the fact that the specific qualities of the cholera antibody are entirely different from the specific reactions of the diphtheria or typhoid antibody, facts readily demonstrable in the testtube. From the teachings of Ehrlich such antigens and antibodies have certain positive chemotactic properties, in that they are capable of fixing complement (guinea-pig serum) when present in the same testtube under certain favorable circumstances. The chief requirement is that the same antibody present is to have the same specific antigen. The conception of a lock and the proper key for diagrammatic purposes can be easily remembered by those who make use of the phenomenon in a theoretical way only. The lock supposedly represents the antigen, and the key the antibody that will fit it. In order to lock such a system it is absolutely necessary for the key to fit. If it does not fit, no amount of power will cause the wrong key to lock. The amount of power required to turn the key and cause the system to lock is represented in the Wassermann reaction by one unit of complement (guinea-pig serum). In other words, in the process of locking, a definite amount of power is used up in the turning of the key; this same power in the form of one unit of complement is also used up in the process of binding or deviation experiments. In case the antigen and antibody do not fit each other, the introduced complement or, as in the lock and key experiment the power to turn it, is not used up, and when another antibody is introduced with an antigen that fits it, prompt union in the latter takes place. Figuratively, power is left over to lock systems that fit one another. In testing the serum of a patient we are looking for the key that will fit a known lock; the lock in this instance is a liver extract called antigen, the key corresponding to the antibody. Whether it will fit will be shown by the presence or absence of complement for systems that are known to fit one another. We assume that the syphilitic fetal liver extract is equivalent to the extract of *Treponema pallidum*. In case the patient's serum in question does contain the key or antibody we are looking for, the antigen or luetic extract will bring about a consumption of complement.

If the patient's serum does not contain the required antibody to fit our antigen no complement will be used up and it will remain in the testtube ready to act when a well fitting antigen-antibody mixture is introduced. This consideration closes the first part in the performance of a Wassermann reaction. The second part can be named "the search for uncombined complement." To ascertain this we make use of an indicator such as a hemolytic amboceptor capable of laking red blood corpuscles when complement is present. The red cells in this instance are sheep corpuscles and correspond to the antigen in the Wassermann reaction in the second part of the experiment. I have stated before that a substance is introduced which acts as an indicator; this is precisely what takes place when complement is present to complete the action of the subsequently introduced hemolytic amboceptor and sheep cells. The complement is in such an instance available for the completion of hemolysis, the red cells in the tube are laked and the mixture becomes transparent, signifying that the reaction is negative and that the complement was not used up in the previous test. Where there is no complement left over as in the case of syphilis, the red cells do not become transparent or hemolyzed, and the result is a positive Wassermann reaction. From a theoretical point of view the exposition of the Wassermann reaction as described seems to be in accord with the laws of phenomena as formulated by Ehrlich.

It is my object to render clear the incompatibility of certain practical facts with some of the theoretically fundamental laws that govern the Wassermann reaction. These incongruities are still defended by ingenious explanations of theoretical enthusiasts who are loath to accept the just criticisms

of practical workers. It is nevertheless a fact that many seemingly correct applications of the principles involved in the Wassermann reaction, critically and practically considered, have nothing in common with the laws governing immune processes. To begin with, if we are to consider the substance present in the serum of a luetic individual that is responsible for the deviation of the complement as a specific result of the invasion of the *Treponema pallidum*, we must compare it also with specific antibodies of other known diseases. Does the antibody of syphilis behave in as specific a manner as for instance the antibody of diphtheria or cholera? Again, is it possible to obtain complement deviation with diphtheria antigen (diphtheria bacilli) and sera obtained from patients suffering from a disease other than diphtheria? It is an established fact that this is impossible. Can the same be said regarding the biological principles of the Wassermann reaction? Considered critically from many personal observations and from the literature we find that the extracts from syphilitic organs that serve for want of something better as specific antigens, will cause the same phenomenon of deviation of complement with three or four diseases other than syphilis. Sleeping sickness, leprosy, scleroderma, certain jaundices, etc., all may cause the deviation of complement, i. e., positive Wassermann reactions. The contention that it is better to work with extracts from syphilitic human organs is also no longer defendable. The author and numerous other workers have used with satisfactory results extracts from beef livers and hearts as well as extracts from guinea-pig hearts. In clear cut cases of recent untreated lues I have rarely reported negative Wassermanns. As far as old syphilis is concerned, it might be advanced that there is no extract obtainable that will give more than about 60 or 70 per cent. of positive results with the Wassermann test. These facts clearly prove, first, that not only syphilis but other diseases as well are capable of giving rise to a positive Wassermann test, and second, that in order to get good working antigen it is not essential to use extracts of syphilitic fetal livers, nor extracts from human organs at all. In other words, the reaction considered from the standpoint of a specific antibody or antigen is not specific.

To explain the *modus operandi* of the Wassermann reaction from what has been said before, it is permissible to state that in syphilis of recent infection and less so in remote lues, as well as in some other diseases, substances of an unknown nature develop and circulate in the serum which are capable of preventing the laking (hemolysis) of the red cells in a hemolytic system. For the complete inhibition of hemolysis another substance is necessary which has been classed among antigens. This so-called antigen chemically considered belongs to the fatty acids or lipoids. I prefer to speak of this substance as the inhibitory extract. Neither in the patient's serum nor in the reagents used in the Wassermann reaction are we dealing with a biological test whose mechanism, as far as its relation to the teaching of Ehrlich is concerned, is only a conjecture and a lucky find. This closes the theoretical consideration of the Wassermann reaction.

In analyzing the practical side of the question laboratory men may be reminded of some peculiarities of a technical nature. It is very easy to discuss technicalities by memorizing text book expositions and literary descriptions. There are very few stumbling blocks with this very interesting and important test to those who are uninitiated or freshly graduated or who are only theoretical workers. The theoretical worker is the most dangerous adviser a practical physician can select. The greatest amount of harm hails from following the suggestions of men who do not possess sufficient bedside experience. These men working in experimental laboratories schedule results and come to conclusions from hearsay evidence, and are frequently substituting testtubes, chemicals, and animals for the history, symptoms, and the clinical course of a disease in human beings. It is very sad but nevertheless true that the opinion and verdict from such onesided workers is held in high repute by the physician who is too busy to work experimentally. These workers are scientists and therefore their opinion ought to be regarded as of greater significance than the bedside opinion. I wish to impress upon those who do serological work that it is not the putting together of the reagents that counts in the make-up of the experienced serologist, but his ability to judge the resulting end reaction. This degree of proficiency cannot be imparted by teachers, but must be acquired individually by the performance of very many tests, by making ever so many mistakes, and finally by cooling down in judging the value of the entire test for clinical purposes. It is well to remember in doing the test that the complement ought to be free from cells and not older than twelve or fourteen hours; the vessel collecting the blood should be clean and dry; and when the carotid of the guinea-pig is severed the esophagus should not be injured, as the gastric contents mixed with the serum will markedly diminish its complemental powers. The patient's serum should be observed critically for traces of a yellow color. Such sera often give a positive Wassermann reaction without the patient having been infected with lues.

The serum is best analyzed twelve to forty-eight hours after venepunction. If it is older than this positive results are plentiful, especially if the worker is using the Noguchi method. The standardization should be done the same day as the test. One should use three units of amboceptor instead of two, especially on rainy days, as during such weather hemolysis is very slow. The inhibitory extract should be used in one-quarter unit doses only. A genuinely luetic serum will inhibit even if four units of amboceptor are added, and will require often no more than an eighth of a unit of antigen. Finally, the confusing or uncertain end reaction should always be reported negative, bearing in mind that the clinicians were in the majority of instances capable of diagnosing syphilis without any laboratory tests. In our days, however, a syphilitic patient has a very poor chance for escaping detection. If the patient denies or if he does not know that he has syphilis, the physician finds many clues that tell him the cause of the trouble. If the physician is in doubt, the laboratory is sometimes helpful in deciding the question. That all three factors entering into the analysis of a patient should give no definite clue to the real cause of the disease is extremely rare indeed.

It is very important to be able to report correctly where the patient denies an infection and the doctor is unable to find vestiges of lues. I therefore advise extreme care in the interpretation of end reactions and to submit reports that are the result of a critical reading of Wassermann tests. It is in such instances that the serologist helps most and often harms most. Beginners will give a positive report when hemolysis is incomplete, and the experimenter who sends the verdict as weakly positive leaves the

doctor in the same position as before. I wish to call attention to the Noguchi modification. The only advantage I can see is the greater stability of the amboceptor. It must be borne in mind, however, that it takes four or five injections of human blood in order to produce it in the rabbit in sufficient strength, and that there are very few patients who will permit the withdrawal of their blood. This is an important item, as I had to ascertain for myself. Had it not been for the kindness of a few hospital directors I could not have performed comparative studies with this modification of the Wassermann test. It is not out of place to mention here the fact that the Noguchi reaction performed *lege artis* gives positive results in a not inconsiderable number of non-luetic patients. In a number of cases of chancroids and other clinical states this reaction was found to be positive, whereas the Wassermann was negative. Had it not been for this control these patients would have been innocently carrying the burden of a luetic treatment, and in subsequent illnesses, the fact that they were treated in a specific manner would influence the therapy of the prescribing physician. This exposition is made with the intention of conveying an idea as to the relative value of negative and positive Wassermann reactions. In view of two controls, such as the patient's history and the clinical status, a negative report can never do the harm that a positive result may cause in a similar case. In using the antihuman system this danger is too frequent to justify the use of this test without the use of the original Wassermann reaction as a control. It should be remembered by those who work with the Wassermann reaction that the sheep cells should not be older than twelve hours. The end reactions should not be read until the antigen interference control is completely hemolyzed. When submitting reports of a positive nature one should not include anything that is not unquestionably, completely inhibited. In case the laboratory knows that the patient has has syphilis reports of weakly positive if such be the case are permissible. Under no other circumstances is the serologist to report in such a manner, as he may stigmatize an innocent person, bearing in mind, as has been stated before, that a negative report in a luetic individual is by far not so serious an error as a positive report in a non-luetic individual. In the former sooner or later luetic signs will be discovered, whereas the latter, in view of the faulty analysis, has to suffer ever afterward. Eliminating all factors that can give rise to a positive Wassermann report, the laboratory worker in himself is by no means a negligible quantity. He very often indeed is not sure as to the meaning of a certain test, and very often is confronted by the clinician who recites a score of facts that make the positive report very shaky indeed. Then the laboratory genius parades the various causes for a positive result in non-luetic patients as a sort of repartee, but is far from admitting that he made a mistake. The intricacies of the Wassermann reaction are rarely discussed at medical meetings. It seems that workers in this line prefer to remain silent on this very important topic. Many serologists of small or large experience when speaking of the Wassermann reaction rarely obtain less than 100 per cent. of correct interpretations and with pride relate the wonderful disclosures their work has accomplished.

One need not emphasize the fact that in the laboratory there are no infallible methods, a fact which is most glaringly true of the Wassermann reaction. I make this statement, taking for granted that the worker is experienced. What a beginner is capable of reporting may be easily judged. I can recount an experience in which the same serum divided into three portions and analyzed by three different workers resulted in the following reports: The serologist with least experience said it was positive; next came the maturer worker who was not sure of its being positive or weakly positive; the last report was that the result was negative. As a matter of fact a very well known syphilographer made a negative diagnosis. Such instances are of daily occurrence and depend entirely upon the man who does the work. There is only one interpretation that the mature worker considers as important, and that is an unquestionable positive result; all other designations of weakly positive, or plus minus, or negative, carry no diagnostic significance.

In my own work I must say that many negative results were obtained in the case of individuals who had lues. This brings one to the practical side of the paper. This extreme was necessary to eliminate the chances of having non-luetic patients treated for syphilis. Even with this precaution and the careful report of results, about one-half of one per cent. of patients in whom lues could be excluded have been reported as positive. On the other hand it is not at all to be considered an error or poor technique when one reports negative result in cases of old tabes, treated cerebrospinal lues, and other meta or paraluetic affections of old standing, cases which have had prolonged antiluetic therapy. Such patients as a rule as a result of organic changes in their body fluids of autogenous origin, or as a result of treatment, give a negative Wassermann.

These results are plentifully reported in the literature in which one finds from 30 to 50 per cent. of negative results in tabes. This is not a technical fault but is to be considered as one of the peculiarities of the test. The same argument applies to the positive reactions obtained in leprosy and scleroderma. To defend the statement that a positive Wassermann reaction is impossible with scarlet fever is unscientific, and the result of enthusiasm and lack of conservatism. The serological worker instead of defending hypotheses ought to champion facts, and on suitable occasions when necessary admit his ignorance instead of speculating with unknown hypothetical quantities and qualities. This, however, need not diminish one's spirit for research; but unless something more palpable than the theory of the Wassermann reaction is obtained one ought to deal with facts and not with what a reaction is supposed to do. These facts should come from the clinicians, even if they prove to be contrary to the findings of the experimental worker. In the treatment of tabes the nature of the syphilitic process should be taken into consideration before therapy is instituted. In case the Wassermann reaction is negative it is best to leave the patient alone. Only when signs of an exudative nature are present should mercury or other antisyphilitic remedies be prescribed. The futility in treating the degenerated posterior columns in a tabetic needs no emphasis. It is my firm belief that the clinician is more often correct in making a diagnosis of syphilis than the laboratory, and only when he is unable in some rare instances to do so should the laboratory's verdict be taken into consideration. And then great caution will have to be exercised in accepting the result, especially when the result is positive; the reason for this skepticism has been given before. It must also

not be forgotten that a negative Wassermann reaction is perfectly feasible with a frank history of syphilis. This in the majority of instances is due to recent therapy and not at all infrequently to the recuperative and negativating forces of the organism. The remoter the initial lesion the less strong the resulting test, of course with the exception of paresis or other very persisting paraluetic conditions. It is self evident that before the patient is sent to the laboratory for a Wassermann he ought to be looked over as to his physical improvement, for reaction in very many instances becomes negative much earlier than the disappearance of the physical signs. If a patient presents himself at the office of a physician to ascertain whether he is free from lues, he can be assured only after a thorough clinical examination, resulting in negative findings, and a negative Wassermann in the blood.

It is not at all rare to hear of chancres cured with placebos without the subsequent development of secondary manifestations. The subjects of these mysteriously cured initial lesions giving a negative Wassermann reaction critically considered may never have had lues and bear the odium of this disease unjustly. I am sure many will recall instances of such a nature. I recall a case in which the patient related a history of having had some twenty years ago a suspicious sore on the glans. He showed absent knee jerks and mild sensory disturbances in the legs. The present complaint was uncertainty in walking and pains in the legs. The diagnosis made upon this superficial examination was tabes. The blood Wassermann was negative. The Wassermann reaction in the cerebrospinal fluid was also negative. There were no excess of globulin and no increase in the number of cells. Fehling's solution was promptly reduced. These laboratory data made the examining physician reconsider his original diagnosis, and a more thorough analysis of the physical status revealed that the patient suffered from multiple neuritis. He admitted drinking on an average twenty or more glasses of beer daily, being a beer brewery employee. This fact, however, was lost sight of in view of the history of a sore on the penis. It is quite possible that the sore was not specific. There are many who give similar histories, and become neurasthenics, simply because one who was not very well versed in the recognition and differentiation between specific and nonspecific ulcers diagnosed a chancroid as specific, and unwittingly made a syphilophobe out of a susceptible individual.

The trouble begins when such a neurasthenic in view of the symptoms and the history of a sore is diagnosed as a general paretic. The crowning feat to such a diagnosis is the positive Wassermann from a beginner. It is fortunate indeed that we have laboratory findings aside from the Wassermann reaction that tell us whether a patient has or has not paresis. Thanks to the stimulus of such workers as Plaut and Nonne we have been able to differentiate not only between luetic and non-luetic nervous affections, but between the different paraluetic nervous diseases with more than gratifying constancy. It seems to me that the dermatologist is the wisest manipulator of the Wassermann reaction, using the test 99 times out of a 100 as a therapeutic indicator only. The mystery surrounding the etiology of many nervous affections causes many unnecessary Wassermann tests to be performed, and as a result of faulty laboratory work or interpretation more than one individual has been wrongly stamped syphilitic. In the Wassermann reaction the stumbling blocks are many and can be overcome by experience and patience only. The beginner makes many nonluetic sera positive, the theoretical worker does the same to a lesser extent, and the mature worker fails to report many syphilitic sera as positive. The confidence that the general practitioner places in the Wassermann reaction makes the former two a menace to his patients and jeopardizes the doctor's private practice. The harm done by the experienced worker is comparatively mild, as sooner or later the clinician will find the true cause of the trouble. It is by far less harmful to err with a negative report on a luetic serum than render an innocent person uncomfortable with the knowledge of having been made syphilitic by the laboratory. In the pre-Wassermann days of some six years ago the physician in doubt would as a rule carefully reconsider his case, and if no diagnosis could be arrived at would consult a colleague who had an extensive experience in such cases. Today it is quite different. First, the commercial laboratories begin to manufacture the biological reagents necessary for the Wassermann test. Second, rapid, simple methods are being substituted, for the original Wassermann reaction, on the just-as-good plan. Third, inexperienced workers spring up like mushrooms after a rain and report what their limited knowledge tells them. The result is that an innocent person is often treated for syphilis and an insufficiently treated syphilitic is neglected. All this is due to the widespread fact that there is a test in the laboratory that can detect syphilis if present no matter how long ago, or when absent, that can exclude it. For the reasons above stated I am convinced that much harm has been done in the name of the Wassermann test, and it will take many papers of this nature before the patient and physician will rid themselves of the conception that the Wassermann test is the final court of appeal. To recapitulate:

1. The Wassermann reaction from a theoretical standpoint has very little in common with the side-chain theory of Ehrlich.

2. Technically, only unquestionably positive results are to be taken into consideration by the laboratory and by the clinician.

3. Practically, one should not consider a Wassermann reaction without obtaining a good history and a complete physical examination.

MERCURY IN SYPHILIS.

By WALTER S. REYNOLDS, M.D.,

NEW YORK

LATE CHIEF OF CLINIC AND INSTRUCTOR IN GENITOURINARY DISEASES, COLLEGE OF PHYSICIANS AND SURGEONS (COLUMBIA UNIVERSITY); FORMERLY PROFESSOR OF VENEREAL DISEASES, MEDICAL DEPARTMENT, UNIVERSITY OF VERMONT.

The remarkable effect which salvarsan has in causing a very rapid disappearance of some of the manifestations of syphilis has been abundantly demonstrated. But that mercury, so long considered the only specific for this disease, may act with equal promptness in some instances should not be overlooked. There are cases where salvarsan for some cause is contraindicated and where it is important to bring about a resolution of the lesions as promptly as possible; it is in such cases that we have in the older remedy a drug which, properly administered, will seldom fail in its results. It must be remembered, however, that if a rapid action is desired mercury must be administered in sufficiently large quantities, and the question as to the best method of introducing it into the system in sufficient quantity, and at the same time to obviate any bad effects,

is a question which is sometimes most perplexing.

There are a number of ways in which the absorption of mercury into the system can be brought about. Nearly every method has its advantages and at the same time some disadvantage which may render that particular mode of administration inapplicable in some cases. It is important, therefore, that everyone who is called upon to treat this disease should be familiar with the various ways of accomplishing the desired result and be able to select whichever form of administration seems most desirable. Not only are there a number of ways of administering mercury, but there are also many combinations of mercury with other chemicals, the majority of which, with the exception of arsenic perhaps, have no effect on the syphilitic process, but which render the mercury applicable to the various forms of administration. We have, therefore, not only to consider the method in which mercury is to be used, but also which particular preparation of mercury is best adapted to meet the indications.

The oldest method of using mercury is by inunction and is, in the estimation of many at the present time, one of the best ways in which it can be introduced into the system. In this method metallic mercury is employed, the official ointment being rubbed together with lard until the mercury is in a fine state of division. Other substances have been used in place of the lard, as cocoa butter, soap, etc., and in some instances are useful, but the ordinary mercurial ointment is generally used.

The objection most generally raised against the use of mercury in this way is that it is an uncleanly method and that it is uncertain how much absorption takes place. It has seemed to me that these objections are rather theoretical than real, for I have never had a patient object to this method when I have advised it, and I have been told by some that they enjoy the rubbings. It is always best to have the inunctions given by some one who understands how to rub the ointment properly into the body, but when this is not possible the patient can be instructed how to rub himself fairly well.

The amount of mercury which different individuals will tolerate varies greatly. It is, therefore, of the greatest importance that it should be prescribed in such a way that definite amounts are used for the rubbings each time. In beginning treatment 30 grains of the 50 per cent. ointment can be ordered in paraffin papers and one of the packages may be used every night or every other night. The amount can also be easily increased by adding a certain amount from one of the packages and in this way definite quantities are used each time.

In cases of generalized manifestations it is best to divide the body into regions according to the method of R. W. Taylor, each region being taken for successive rubbings, so that at the end of the course nearly the entire body has been covered. It is important that the area to be rubbed should be thoroughly freed from dirt and grease, otherwise absorption does not so readily occur and there is much more likelihood of dermatitis being set up. It usually requires from 20 to 30 minutes of vigorous friction to get the ointment well rubbed in, and if this is done only a faint grayish film remains on the locality where the ointment was applied.

In using inunctions great attention should be given to the condition of the mouth and teeth, as this will aid in the prevention of salivation. I prefer a tooth paste containing chlorate of potassium such as Bierdorf's. This is used with a soft brush two or three times a day. Attention to the condition of the bowels is also of great importance.

The following case—although a mistake occurred in the quantity used—illustrates the rapidity with which mercury may control the disease. A young man 24 years of age was referred to me on February 5 by Dr. S. Brady. There was an indurated lesion at the preputial opening, causing phimosis, and another mass could be felt on the inner surface of the prepuce. He stated that they had developed about December 20. There were no signs of a rash on the body and the inguinal glands were not markedly enlarged. Although no spirochetes could be found a diagnosis of chancre was made and he was placed on subpreputial irrigations of bichloride of mercury, 1 to 2000, as there was no indication of destruction going on under the prepuce, and a wet dressing of the same solution was kept applied externally. On February 12, or 54 days after the lesion developed, a rash appeared on the body. The initial lesions were healing and the prepuce could be partly retracted. He decided that he would prefer not to have salvarsan used, and he was therefore ordered twelve packages of 50 per cent. mercurial ointment containing 30 grains each, with explicit instructions as to the method of use, and he was also given a slip with the printed directions of the regions and the method of using the ointment. The following morning he returned with his entire body covered with the ointment and stated that he had used eleven of the 30-grain packages, or 330 grains in all the previous night. He was immediately ordered a very hot bath and a good scrubbing with soap, and the bowels were flushed out with a saline cathartic. On February 16 the rash had entirely disappeared. The gums were slightly tender, but there was no marked salivation, and he was feeling much better than he had previous to the appearance of the rash.

Intramuscular injections of various salts of mercury have been largely employed in the last few years and afford a very satisfactory way of administering the drug, many preferring it to other forms of administration. In some instances it may cause considerable pain, generally lasting for a comparatively short time. The pain is not always due to the form of mercury employed, for while using the same solution and in the same manner I have sometimes had patients complain of considerable pain and at other times of none at all.

The frequency with which the injections are given will depend upon the form of mercury used. If the bichloride of mercury (a soluble salt) is employed, the injections may be given two or three times a week and from one-eighth to one-quarter grain used for each injection. If a physiological salt solution is used as a menstruum the pain of the injection is considerably lessened. Salicylate of mercury is a favorite with many for intramuscular injections. It is an insoluble salt and is given suspended in an oily liquid. From one-half to two grains may be given about once a week. The above are the two salts of mercury probably most frequently used for intramuscular injections.

The advantages claimed for the use of mercury in this way are the certainty and promptness with which it can be introduced into the system and the fact that it is less objectionable to patients than the inunction method. The objection to the soluble salts, which are more rapidly eliminated, is that they must be more frequently administered. With the insoluble salts absorption is less rapid and there-

fore it is not necessary to repeat them so frequently. If salivation or other toxic symptoms should occur where the insoluble salt is being used this would be a decided disadvantage.

The injections are best given in the gluteal region, using a hypodermic syringe with a needle about one and one-half inches in length and of sufficient calibre to allow the fluid to flow freely. The site of the injection should be varied, alternating the right and left side at each injection as well as the point at which the needle is inserted. All precautions should be taken in regard to cleanliness and asepsis. Personally, I have never seen an abscess or any bad result follow this method of administration.

The internal administration of mercury alone has been largely superseded by the two former methods of administration. In the form of mixed treatment it is still undoubtedly employed to a large extent and is of considerable value. The disadvantage of this form of administration is that the amounts of the ingredients cannot be so easily varied, which is of considerable importance in many cases.

In the form of pill or preferably tablets, on account of their being more soluble, several compounds of mercury are employed. Given in this way and in full doses it is more likely to cause gastrointestinal disturbances than other forms of administration. It is necessary, however, in some cases to resort to this method of administration, but usually only as a temporary expedient.

We have two forms of mercury in combination: the mercurous salts, which are sparingly soluble and therefore less likely to act as poisons; the mercuric salts, more soluble and more active poisons. The hydrargyri iodidum flavum, mecurous iodide or protoiodide, may be given in one-fifth to one-quarter grain doses three or four times a day. This is the form most commonly employed. Hydrargyri iodidum rubrum, red mercuric iodide or biniodide, is given in doses of one thirty-second of a grain and increased gradually in amount. Tannate of mercury in one-half grain doses has been considerably employed by some with good results.

For internal administration in combination with potassium iodide, for the so-called mixed treatment, either biniodide or bichloride is used in doses of one thirty-second to one-sixteenth grain, with five to twenty grains of potassium iodide. Syrup of sarsaparilla compound, tincture gentian, or some of the digestive solutions, such as essence of pepsin, may be employed as a solvent. The following is a common formula:

℞ Hydrarg. biniodidi, 1/32 to 1/16 grain.
Potass. iodidi, 5 to 20 grains.
Syr. sarsaparillæ comp., q.s. ʒj.

The methods of administration by fumigation, by the rectum in the form of suppositories, by inhalation, by baths, and by introduction immediately into the blood current have all been used and in some instances may be employed, though these modes of employment are rarely necessary.

At the present time the treatment of syphilis is being more carefully studied than it has ever been heretofore, and this will undoubtedly result in great changes in many of our conceptions previously held.

With the discovery of the *Spirochæta pallida*, the recent cultivation and inoculation experiments of Noguchi, demonstrating conclusively that this organism is the cause of syphilis, the introduction of salvarsan in the treatment of the infection, and the Wassermann test as a method of diagnosis and for the purpose of determining the effect of treatment on the course of the disease, we must expect ultimately to be able to see a great improvement in our knowledge regarding the most efficient method. In the past we have been able to judge of the effect of treatment only by the clinical manifestations, but at present with the great advantages which these discoveries have placed within our reach we should be able to treat our syphilitic patients in a much more scientific and intelligent manner.

It is almost universally conceded that treatment early in the course of the disease is much more likely to bring about a cure, and there seems to be no reason now why treatment should not be begun as soon as a positive diagnosis is made. This is now possible in many cases of initial lesions by the aid of the dark field apparatus, the presence of *Spirochæta pallida* being proof positive of the nature of the lesion.

66 West Seventy-first Street.

MYOSITIS TRAUMATICA.

By MARK I. KNAPP, M.D., LL.B., LL.M.,

NEW YORK.

The case I am about to report is typical of a large number of cases which go the round of physicians and are the despair not only of their medical attendant, but also, and chiefly, of their own family. They suffer and suffer at times very violent pains without ever responding to any of the drugs praised and valued for their anodyne effect. Useless to say, that all sorts of diagnoses are made, ranging from malaria, nervousness, and rheumatism to even, as in the case here reported, a sclerosis of the spinal cord, for which the actual cautery was applied for an extended period and, this failing to effect any relief, an operation was actually urged in order to remove the supposed materia peccans from somewhere in the spinal cord. The stumbling block in these cases is the fact that they begin to misbehave just when, according to all our medical logic, the patients ought to feel most comfortable. Their misery, nay, agony, begins to appear some time after they have gone to sleep, and, while they get up with pain of varying intensity, such pain loosens up after a time and, as the day advances, they feel comparatively comfortable, only to go to bed to renewed misery. That paradox of pain during resting hours and comparative comfort while laboring, might have given impetus to some fanatic to expostulate sinful idleness and to exhort the propriety of constant labor. Now it is the back that hurts so much and is worse in the night and on getting up, and again it is in the shoulder or the nape of the neck or the muscles of some other part of the body. The almost natural and instinctive diagnosis made by the physician is muscular rheumatism, which diagnosis has in fact already been made by the patient himself, and who, as a rule, prides himself upon his intuitive medical skill. The positiveness with which many a "knowing" patient makes his assertion is, unfortunately too often, concurred in by the physician. In support of the rheumatic theory, the patient unhesitatingly states that he is verily a living barometer and that he can foretell the oncoming storm with unerring precision. Such about is the general picture of the malady. Internal and external medication is prescribed, and various remedies are tried until the patient becomes a wreck, justly decrying the medical art which failed to give relief.

The picture here drawn is unquestionably known to a great many of the profession who have battled with but have not conquered the apparently intricate problem.

The subject of this report is a male patient, 42 years old, a Russian, who came to this country some seven years ago and began to suffer soon after his arrival here. At home he was employed at the horse trade; here he is a presser. He complained of excruciating pain which was centered somewhere in the dorsolumbar region of the spine. He came to me through a friend of his, whom I had cured of a gastrointestinal disease; this friend supposed that all this patient's trouble likewise came from dyspepsia. As a matter of fact this patient did suffer from insufficiency of the pylorus and organacidia enterica. But, although organacidia enterica does mostly give pain in the lumbar region, which pain is due to the pulling of the distended intestine upon the mesentery and which latter in turn pulls upon where it is attached, the spine; yet the severity of the pain did not warrant the conclusion that it was entirely of intestinal origin. The pain in his spinal region began some two hours after he had gone to sleep, became of an excruciating character and of a severity which prompted the patient to qualify it as "cramps." He could not remain in bed and had to assume a semireclining position in bed or on a chair and get as much sleep in such awkward position as he could. During the day his pain eased up somewhat, notwithstanding his arduous labor as a presser. Thus he suffered for seven long years. At first he was treated for a cold, and, after suffering for one and a half years, he thought, or he was made to think, the New York air was not up to Russian standards, and, as for reasons of his own, he did not wish again to come into the fond embrace of the Muscovite, he went to England to be under the protecting wing of his brother. But he came back, as he could not be reconciled to the idea of an operation, which was advised him in England. After his return he was treated for neuralgia, for consumption of the spine, for kidney trouble, for a sprain, for nervousness, and finally for rheumatism, and was treated with the actual cautery. When he came to me he was suffering quite severely and was despondent. Yet, notwithstanding his very long suffering, he was quite well the fourth day after I began the treatment. That miraculous cure was accomplished by a very novel treatment, a treatment which suggested itself to me then for the first time. I simply had the patient remove his mattress from the bed, put it on the floor, and had the patient sleep on the floor instead of in the bed. Having worked such wonders in this case I applied the same heroic (!) treatment to several clinic patients, who had their pains located variously in the back, shoulder, etc. My students, who are present in the clinic with me, were somewhat nonplussed as to an explanation for such curious procedure, but I held them in suspense for an explanation of the peculiar therapy until they heard of the excellent result from the patients themselves at their subsequent visit to the clinic, or, possibly, at the visit following. As a rule, the patients came with the diagnosis of long-standing rheumatism or neuralgias of some sort. Of course, in order to impress the patient I had to resort to some local applications without which I doubt whether the patients would have followed my advice. So I gave the first patient some soap liniment locally; to the other patients I gave whatever happened to occur to me at the moment.

And now, what is the cause of the suffering? The peculiarly heroic treatment applied by me and the almost instantaneous cure at once preclude the assumption of the presence of any very severe pathological condition. Yet those patients had suffered, suffered severely, and in the first case, here reported, the patient had suffered for seven long years. The cases of which I speak here are not the only cases I have seen of this type, but these are the first cases in which I applied floor sleeping as a remedy.

My view is that the pain is caused by hyperextension, or by prolonged extension, or by both, of the muscles severally involved, whether the muscle involved be the sternocleidomastoid, or the trapezius, or the longissimus dorsi, or the quadratus lumborum, or any other muscle of the arm or leg. This hyperextension and prolonged extension of the muscles is produced by faulty posture in bed, whether due to the faulty arrangement of the pillows or the sagging down of the cheap bedspring under the weight of the gluteal region of the patient. In any of these conditions the corresponding muscles are put on the stretch for a long time and, as I assume, a myositis results. The assumption of a myositis being present is, I believe, justified, although I hardly think that it could ever be pathologically demonstrated by section or autopsy, as this condition is not fatal. There are present the pain, subjective and objective, and the diminished movement of the respective muscles, which, I hold, justifies the diagnosis of an inflammatory condition. One may experiment on himself the effect of extreme and prolonged extension. Let him attempt to keep his arm fully extended and at right angle to the body and he will soon find out how long he could keep it up; I doubt if it can be done by any one for fifteen minutes. Whether we attempt to stretch the muscles voluntarily and fail to keep it up because of the pain, or whether the muscles are put on the stretch for some hours involuntarily by faulty posture during sleep, the result is the same pain—pain due to over and prolonged stretching of the muscles; it is a trauma which produces the pain, the resulting myositis is of a traumatic origin. It is not systemic, it is not constitutional, it is not due to any infection nor to continuity of an inflammatory condition of a neighboring organ; the pain is due to violence and, it is immaterial whether the violence is intended or not; we are dealing not with an active but a passive traumatism.

After the first patient got well, but still sleeping on the floor, he came to me one day again complaining of pain. On questioning, I found that his wife had taken pity on him and put an extra pillow under the small of his back. He felt better the next day after the pillow had been removed.

Of course, we can easily understand that such traumatism, persisting for any extended period, is bound to leave some bad effect upon the sheath of the muscle or the muscle itself. However, with the disappearance of the cause the effect gradually disappears.

The therapy consists in finding out the specific faulty posture and in correcting it. If the pain is in the lower portion of the spine, and the bedspring is at fault, then order another, unyielding bedspring; and if the patient cannot afford it, have him remove his mattress to the floor or put wooden boards into the bed and remove the bedspring. If the nape of the neck is affected, the chances are that the head is very much flexed upon the chest during sleep by

a faulty arrangement of the pillows under the head or by too many pillows under the head. Arrange the pillows so that the head is not flexed during sleep. In case the shoulder joint is affected, remove some of the pillows from under the joint, allowing the arm to fall down slightly during sleep. Pain in the hip, knee, or ankle joint may likewise be due to overstretching of the corresponding muscles, which also will be cured magically by readjusting the posture.

Whether the patient may be intrusted with the actual diagnosis immediately or at all depends entirely upon the intelligence of the patient. An intelligent patient will appreciate the correct diagnosis so much better if the treatment is first instituted. He can be intrusted with the actual facts after a few days, when he is beginning to get well and will have gained confidence. The non-intelligent patient is always a study and can rarely see, much less understand, the relation between cause and effect. Reasoning is excluded here, but he will obey a mandate if sufficiently peremptory in its character.

Under no condition must we forget the local applications; we must have the psychical adjuvant. It makes no difference what is used, but something must be used. We are in duty bound to delude the patient for the patient's welfare. The patient does not understand pathology and will not at once be able to follow medical reasoning.

616 Madison Avenue.

WHAT SHOULD THE GENERAL PRACTITIONER KNOW ABOUT DISTURBANCES OF MOTILITY OF THE EYE?

By JOHN R. HICKS, M.D.,

NEW BRIGHTON, STATEN ISLAND, N. Y.

To answer this question in the words of the opthalmologist would be to explain one of the most, if not the most intricate and scientific chapters in medicine and surgery. It not only comprises what one may study about the eye, but it covers almost the entire field of medicine and surgery of the brain. Without the assistance of the ophthalmic surgeon, the location of all brain tumors, and the diagnosis of brain disease in general are often difficult or nearly impossible, a hasty diagnosis often leading to serious consequences both to the patient and the physician. It is my intention to present to the general practitioner a description of the conditions which are met with in your daily practice, in regard to which the practitioner frequently says to the parents of the unfortunate child: "Don't worry about your child's eyes; the eye just turns in a little bit and the child will outgrow it after a while." That "after a while" in nearly every case never comes, and the physician has left upon his hands and conscience a most disfiguring affection, one which destroys the usefulness of the boy and the beauty of the girl, and one which interferes materially with the whole development of the child from birth to adult life. The child grows, it is true, but with the "cross eye," it becomes shy, wants to be alone, and is teased and jeered at by other children, until life becomes a burden. Added to this is the inevitable lack of development which results, and the attendant backwardness in school work due to bad sight and the general effect on mind and body. Blind children develop slowly and the nearer the child approaches to blindness the less developed in mind and body will it be. One need not refer to the disastrous effects of ophthalmia neonatorum upon the eye and to its prevention. At the present time the physician is thoroughly versed on the subject of its prevention as well as of its treatment. I shall deal solely with "squint," known as "cross-eye," "cock-eye" and other names. I propose to try to show various sins of omission rather than sins of commission. For example, one may be dealing with a boy, small of stature, with rather large head, pale, more or less anemic, and although nine years of age, not even knowing his letters. One will notice at a glance that there is a marked squint in the left eye. This cross-eyed boy exemplifies the remissness on the part of many family physicians in that they are too eager to make light of this affection at its beginning. He often fails to realize the seriousness of this defect in a child until the sight may have been lost in at least one eye. Often these patients lose the sight in one eye when the other is defective, from not being able to focus upon the object with the affected eye, hence learning to disregard the image of the object and to become blind as a result. Nowadays we hear a great deal about the degenerative effects of adenoids and enlarged tonsils upon the child, while the presence of "cross-eye" goes unnoticed, although it is one of the most potent reasons for retarded development. Another example is seen in a boy who is now about 15 years old. Two years ago he was badly nourished, badly developed, shy and rather effeminate; backward in his studies, though naturally of good mind as subsequent events have shown. Now, after operation he is a bright, rather sprightly boy and is able to hold his position among his associates. There is no serious operation that the child consents to submit to so cheerfully as to this one for cross-eye, because he has so continuously experienced on account of this condition mortification at the hands of his companions. What girl would not submit to operation if approached properly? However, I have one family of seven (on my books), father, mother and five small children; the mother and three of the children are cross-eyed; she does not want them treated, to say nothing of an operation, because her family physician told her some years ago "the children's eyes will come around all right," though she herself has been cross-eyed since early childhood. Few deformities are worse, particularly in a girl. It is particularly important that our children both in school and before the school age should be examined for eye defects, and especially for different forms of squint. The examination of the eyes of children in the schools is most to be commended, for here often a defective vision with a resulting squint begins.

Turning to the anatomy of the eye, I need only call your attention rather crudely to its extrinsic muscles, as these are the ones most involved in the production of the manifest muscular anomalies. These comprise the several varieties of squint, namely, convergent or cross-eye, divergent, cock-eye or wall-eye, or that form in which the eyes goes outward, and vertical squint, or that form in which the eye turns upward or downward. The muscles concerned in the movements of the eye are four straight and two oblique. Roughly, the superior rectus moves the eye up and its action increases as the eye turns up and does have subsidiary action, as do some of the other muscles of the eye. The inferior rectus moves the eye down and its action increases as the eye turns out. The inferior oblique moves the eye up, adducts the eye, and moves it on

its vertical meridian out. The superior oblique moves the eye down, adducts it, and rotates it on the vertical meridian in. But in this paper I shall confine my remarks to the action of the external and internal rectus muscles, as these are the ones with which general practitioners have to deal. The external rectus muscle arises by two heads from the outer margin of the orbital foramen, from the ligament of Zinn and from the lower margin of the spheroidal fissure. It passes forward near the outer wall of the orbit to be attached to the sclerotic coat about three or four lines from the margin of the cornea on its outer side. The internal rectus arises from the inner margin of the optic foramen, the inner and lower parts forming a common tendon called the ligament of Zinn; from this origin it passes forward to be attached to the inner side of the sclerotic coat by a tendinous insertion about three or four lines back of the margin of the cornea. The internal rectus, with most of the other muscles of the eye, is supplied by the third cranial nerve, while the external rectus is supplied by the sixth cranial nerve. It is seen from the varied actions of these extrinsic muscles of the eyes that when they are interfered with, some form of squint must result. This at first may be latent but there often comes a time when Nature refuses to overcome this defect and there results a permanent squint (The non-hygienic surroundings of the child often combine to bring about this condition.) It is certain that we see cross-eye more often in poor, badly fed, badly nourished children than in the children of the well-to-do classes. There must be more reason for it than the mere fact that they have a congenital predisposition to it or that they are born far-sighted. Coordination of the muscles in the eye must take place just as it does in the muscles of the other portions of the body, or imperfect results will follow. Lack of proper nutrition of the muscles of the eye acts just as it does in the case of other muscles of the body. One muscle being better supplied with blood than another will have more perfect action. So, too, lack of nutrition and improper hygiene disturb the action of the nerves and nerve mechanism, leading to lack of development. It also affects the quality of action of the muscles and nerves of the eyes, which in turn affect the other organs and functions of the body.

While I have not made a thorough investigation of the association of adenoids and enlarged tonsils to the predisposition to squint, I believe that there is an indirect connection between them and a consequent interference with development. These points are interesting to consider from a specialist's standpoint, if not from that of a general practitioner. The association of eye movements, according to the necessities of the case, is regulated by association centers of a higher order than the nerve nuclei which enervate the muscles; they enervate certain muscles or a group of muscles of one eye simultaneously with those of the other. The internal rectus of one eye may be set in action synchronously with that of the other eye so that a movement of convergence takes place, or it may act in conjunction with the external rectus of the other eye, so that both eyes turn in the same direction. If these muscles do not act simultaneously and with the same power some form of squint results, with double vision, confusion of objects, and resulting deleterious effects upon the child's development and advancement. Orientation is the ascription of objects seen to the place where they actually belong. The objects in the external world form images upon the retina and by being transferred to the normal brain by normal tracts definitely enable us to locate objects in the outer world arranged side by side just as their images are upon our retinæ, but only in reverse order. This process of determining the place of external objects which is learned by experience is called projection of the retinal images outwards. We are thus informed with certainty in regard to the position of objects in relation to each other; and also we can assign the object to its correct position in space. Not until we do this can we have any conception corresponding to the real state of things; we must also have a true conception of the position of objects with reference to our own body and of the position which the eyes occupy in the body. This orientation then is accomplished by virtue of the sense of equilibrium, by muscular sensations which originate in the muscles of the eye and which inform us of the relation of the position of our eyes to that of our body. By orientation we are able to recognize the absolute position in space of any object we see. It is not necessary to point out the importance of this in the development of a child, as one of the first signs of development and intelligence is the determination of the position of objects in space and the nature of the object as determined first by sight and after by a sense of feeling, perception, muscle sense, etc. As a result of correct orientation we see with both eyes at once but one object, as the image is made in symmetrical points upon the retina and by projection is located upon the same point in the outer world; hence, are seen single, giving binocular single vision. Suppose there is interference with this normal single vision, then we have binocular diplopia which appears when one eye deviates from the object of fixation. If the eye deviates inward, then there is a convergent squint forming two objects instead of one; hence diplopia results. With one eye the object is seen in the right place, but with the squinting eye it is seen in the wrong place, giving either two objects or leading the patient to conclude that the object has been displaced to the left, so that in this case the orientation is not correct and the whole mosaic of retinal images (if the left eye is the squinting eye) is located in space too far to the left, because the patient is misinformed in regard to the position of the eye in his head. One can readily imagine that when a child sees double images he either stops trying to see or else learns to suppress the vision in the squinting eye, which leads to blindness in that eye because the image from the squinting eye is less distinct and more easily disregarded. One can readily see the effect of defective vision from muscular defects, nerve defects, or errors in refraction which often accompany these defects of muscle movements and actions.

The causes of squint are numerous, periostitis of bones, birth injuries, fractures, gunshot wounds, various poisons, etc., but it is not the purpose of this paper to discuss these causes, as they lie rather more in the domain of the general practitioner. It is in my province to correct the squint as much as is possible. In these cases of squint other manifest symptoms occur which lead to their recognition and correction. Those beginning in young children without manifest cause, and developing in school children during the periods of development, are the ones to which I have specially called attention. However, I wish to sound the warning that in older people the most frequent causes of paralytic squint are syphilis and diabetes. I may add alcohol and

rheumatic conditions. The causes of these squints which begin in early childhood may be mentioned and are spoken of as disturbances of equilibrium of the muscles, in contradistinction to paralytic cases of squint. Among these causes are feebleness of one of the pairs of muscles, which may depend upon anatomical conditions, such as the size of the muscle, whether feebly nourished from bad or insufficient food; the way the muscle is inserted; the size of the eyeballs and their distance from each other. Myopic eyes are usually large and more difficult to move, hence, during the early school days divergent squint often follows myopia or nearsightedness. Children are not born with myopia or nearsightedness; they develop it as the result of improper methods of living. Kindergarten work and too close application at school are among the most frequent causes, and, given a child, the shape of whose head and the position of whose eyes favor myopia, it requires only the above conditions to develop the latter, followed by a divergent squint. This is an important reason for the examination of the eyes of school children. Enfeeblement of the muscles of the eye may follow any of the exhausting diseases, including rickets and infantile scurvy.

The functional causes of these non-paralytic squints in the young are very important for practitioners to remember; they arise from abnormal innervation of the muscles occurring in the above-mentioned conditions, or from the relations between accommodation and convergence. These two functions go hand-in-hand in the normal eye, but if an eye is in an abnormal condition of refraction, either myopic or hyperopic, the amount of accommodation changes accordingly, and while the eye may adapt itself for a while to the changed conditions, this often is not the case, and one or the other forms of squint may result, greatly to the detriment of the child. It is these cases we most often have to deal with as practitioners of medicine. How can one recognize these disturbances of the muscular power of the eye before the actual cross-eye or squint begins? Muscular asthenopia begins at some stage of these disturbances, and if we pay attention to the beginning symptoms, whether one or more, we are apt in a short time to find our diagnosis correct, as evidenced by a squint or tendency to backwardness of the child at school, or by the fact that the child does not want to go to school. In reading the eyes hurt or there is a headache, or there may be an attack of vomiting which is often attributed to indigestion. Objects grow indistinct and often the child tells the teacher she is unable to see them, but when examined for distance vision on the card she may read at 20 feet the normal line, or even better than normally. In this case the teacher may rebuke the child, or the family physician may tell the mother "there is nothing the matter with her eyes; she is only nervous and she will outgrow it after a while." Nevertheless, the child will continue to complain of headache, indistinct vision or double vision, and a burning sensation in the eyes. She will have red lids, and will suffer from nausea and vomiting. She will fall behind in her studies and will finally develop a hatred of school and near work, with resulting squint, to be followed by bad effects upon the mind and body and loss of vision in the squinting eye. For these reasons blind eyes are very often found to deviate out or in. Sight is diminished in these eyes even before the squint begins, so one should not wait for the latter. I may add in the words of Fuchs, one of our greatest authorities: "In exceptional cases it happens that children with strabismus gradually cease to squint as they grow up, and lose their strabismus about the age of puberty. But the eye that previously deviated is left with its sight permanently weakened and accurate binocular vision is never restored."

Now, these conditions may be prevented, as follows: (1) One should pay attention to the child's complaints of its eyes and head and heed other symptoms which one cannot account for. (2) One should attend to the complaints of the mother or older members of the family and not look upon them too lightly. (3) Eye examinations of all school children should be made at stated intervals, for this year a child may have normal vision, but next year a squint, or an error in refraction may occur. (4) Particular attention should be paid to the school room as to light, position of child when studying and distance from the blackboard; and to the nourishment of the child while attending school, the kind of food and its quantity. (5) Hygienic instruction at home should be given to the mother and child. (6) The child should be referred for treatment when necessary by one skilled in this work. It is not in the province of this paper to mention and describe the operation or the special treatment for the condition known as squint or cross-eye. I believe if more attention is paid to this important matter by physicians and those with authority over children, one of the most difficult subjects in medicine will be made simpler, at the expense of one of the most interesting conditions with which the specialist has to deal. At the same time there will be eliminated to a large degree one cause for backwardness and degeneracy in our school children, and the children who cannot or do not go to school. But if the defect is once acquired, whether the child shows degeneracy or not, no surgical procedure is accompanied with better results to the patient and more satisfaction to the specialist, than the operation for curing strabismus.

50 Westervelt Avenue.

EXOPHTHALMIC GOITER, WITH REPORT OF A CASE.*

By M. B. GORDON, M.D.,

BROOKLYN, N. Y.

On September 22, 1910, I was called in emergency at midnight and found the patient, Mrs. S. M., age 38, with a temperature of 99°, respiration 36, pulse 130, irregular, intermittent, barely perceptible. I gave hypodermic injection of nitroglycerin and digitalin gr. 1/100 of each and ordered tincture of strophanthus ♏iv, sparteine sulphate gr. ¼ by mouth every four hours, ice bag to the precordium, and absolute rest. In about an hour, I was called again and found the pulse worse, breathing shallow, dyspneic, and patient in a semi-comatose condition. Her pulse responded to stimulation and gradually became stronger and the intermittences became fewer, breathing improved, and precordial pain diminished. Further examination showed anixous facies, dry coated tongue, pulsation in vessels of neck, bruit heard. Goiter on both sides of neck, exaggerated on left side due to presence of a sebaceous cyst. Heart sounds irregular, murmur obtained with both sounds and heard all over the chest, tachycardia present. Lungs negative except for harsh, rapid, shallow breath-

*Read before the New Utrecht Medical Society Feb. 2, 1912.

ing. Slight exophthalmus present with Dalrymple and Stellwag's signs. A history of exophthalmic goiter for the past seven months was obtained, the patient being under thyroid treatment and accounting for her acute attack by her having taken two thyroid tablets instead of one as directed by her physician. Uranalysis made the next day showed specific gravity 1021, amber, turbid, large amount of sediment due to urates and phosphates, sugar absent, albumin present to slight amount. No microscopical examination was made.

The patient was kept in bed and put on a fluid diet with plenty of water, stimulation was given when necessary, and in a few days the albumin had disappeared, the urine was clearer, heart sounds were regular, and a systolic murmur at the apex which was transmitted to the left could be made out.

On October 6 she came to my office and complained of having had cold sweats for about a week. This was amenable to belladonna treatment. The thyroid had not been given since her attack and she was instructed to continue with the strophanthus and tincture of nux vomica. I did not hear from the patient from this date up to August 10, 1911, when she called at my office very much improved in appearance, stouter and looking more robust. She complained, however, of a choking sensation in her throat, her pulse was 120, of high tension, heart beat regular and murmur still present, while the murmur in the neck was more marked than previously. I put her on a diet and advised rest and recommended the simple life; she, however, did not take my advice, for on August 27, 1911, she was seized with an acute attack of cardiac palpitation caused by her walking against the wind and by her having taken a swim in Rockaway. She rallied from this, but on September 8 she said that she had had fever every evening for the past week, accompanying diarrhea and vomiting. On examination, her temperature was 102° (os), pulse 120, fairly good quality, lungs negative, abdomen negative except for a tenderness on left side, no headaches. This condition continued for a week without improvement and it was decided to send her to the Jewish Hospital of Brooklyn.

I am indebted to Dr. William Lintz for the following data of her stay in the hospital. Patient entered on September 17, 1911. Her condition was as outlined above, her temperature was on admission 101°, this never rising above 102°, and coming down to normal for the first few weeks, after which it became septic in nature, showing fluctuations between 104° and 100°. Pulse at the start was between 92 and 112 and occasionally higher, at one time running up to 130. Respirations were between 20 and 30. In a few days after admission her extreme abdominal pain was gone, but she complained all the time of cardiac palpitation, headache, anorexia, weakness, and extreme nervousness. Blood pressure was generally between 130 and 140, though at one time it came down to 90. Several blood examinations were made, but they all were found normal—there was no leucocytosis at any stage of the disease. Urine showed traces of albumin at times, otherwise normal except for a few white blood cells which were found microscopically and which were probably due to an existing leucorrhea.

She was given codeine sulphate, gr. ¼ t.i.d. Atropine sulphate, gr. 1/100 t.i.d., then thyroidectin antithyroidin, and Rogers-Beebe serum were tried in turn, but were of no avail. The nervous condition was becoming worse, patient being irrational for days at a time. The temperature assumed a septic type and it was decided that surgical interference was called for. Dr. William Linder operated, ligating the thyroid artery on the left side, this being followed by an amelioration of the symptoms for about two weeks, when the pulse and temperature shot up, the irrational condition became exaggerated, languor and stupor set in, and the patient finally died in coma, on November 10, 1911.

Although exophthalmic goiter was described as far back as the eighteenth century by Morgagni, it is still a condition that pathologically we know comparatively little about and of which we have still a good deal to learn. It has also been called Graves' disease and Basedow's disease, following the description of the condition by these men. The name exophthalmic goiter is not pathologically correct, as the condition may exist without either the goiter or the exophthalmos. Hyperthyroidism has been suggested by Charles Mayo, but this also is not correct, as in some stages of the disease, hypothyroidism exists.

The etiology is obscure, due to its relation to the pathology. It has been traditionally accepted that fright, worry, and a preexisting nervous state are etiological factors. This may be explained in that the severe mental shock has produced a change in the nervous system, this exciting the condition which was latent up to that time. Iodine medication will sometimes have the same result. Infectious diseases predispose toward it. Some observers think that it is frequently found in tuberculous patients. Though cases have been observed in families, the consensus of opinion is that heredity and family history play no part in the etiology. Climate and locality may have some effect, as may sex, for it is found to be more frequent in women than men in the proportion of eight to one. The age limit is between 16 and 40, though cases have been reported in childhood.

The modern opinions as to etiological factors are dependent upon the ever-increasing pathological knowledge of the thyroid gland and its function. Beebe seems to think that the condition is due to a pathological degree of activity stimulated by a hormone which is furnished by the thyroid gland. Marine believes that "hyperthyroidism is induced by a lack of some essential secretion of the thyroid, considered as a complex substance, and in the effort to restore this, an excess of some component part of the secretion is produced to a toxic degree."

I shall not go into the minute pathology of the disease, as the theories expounded by different men vary in many particulars, but it has been definitely accepted that the thryoid gland during the disease is the seat of a parenchymatous activity in which there is an increase in the number of cells in the alveoli and also in the number of alveoli. This may or may not be accompanied by an increase in the size of the gland itself. There is an increase in the cell secretion, with resulting symptoms of hyperthyroidism. This process may lead to a degenerative change in the parenchyma with loss of secretion or hypothyroidism shown by myxedematous symptoms, or as MacCarty has shown, it may revert to a simple goiter with an amelioration of the symptoms. This may occur at any stage of the disease; in fact, a diseased thyroid shows both processes occurring in different portions of the gland, so that hypothyroidism and hyperthyroidism may be had at the

same time. With the stage of hypothyroidism there are generally secondary changes in the heart, kidneys, and liver.

All who have investigated the thyroid during the disease agree that the amount of iodine in the gland is less than normal, but then Reid Hunt claims that there is more iodine in the blood, as its elimination is slower than usual.

The symptoms vary from cases in which all the classical symptoms are seen to those in which just two or three are manifested. According to Mayo there are two groups (1) those of a simple goiter without any symptoms of hyperthyroidism, and (2) those in which hyperthyroidism symptoms are the main features. The general symptoms are sweating, anemia, emaciation, vomiting, diarrhea at times.

Tachycardia is a cardinal symptom, palpitation and arrhythmia are seen in advanced cases. Goiter is not always present. When it is, it may be either unilateral or bilateral. Exophthalmos is not a constant symptom. The other eye symptoms are:

Dalrymple—widening of the palpebral fissure.

Stellwag—staring without winking.

Graeffe—lagging of the lids with eye movements.

Möbius—insufficiency of accommodation at near point. These may or may not be present, they are not pathognomonic of Basedow's disease, as they are found also in myocardial changes and in chronic Bright's disease.

Tremor is a characteristic symptom; nervousness, neurasthenia, even mania, may be present. Stupor and coma are usual terminal conditions.

The temperature is generally normal, but in acute cases it may assume a septic type, running between 104° and 102°—this is probably due to the toxemia produced by the overacting thyroid.

Occasional albuminuria and a transient glycosuria are often found. The blood is practically normal, though a mild anemia may be shown. Pigmentation of the skin and increased perspiration are prominent symptoms.

The diagnosis is difficult in mild cases or in those which present one or two symptoms. Tachycardia, increased perspiration, rapid emaciation, characteristic tremor, are warning signs, and, associated with eye symptoms, are practically pathognomonic.

Formerly this was considered a purely medical disease, but the work of Kocher, Ferguson, and the Mayos proclaims it as one of the future fields of surgery. Some surgeons claim that surgery is the best treatment. This may be true in the early cases, but when symptoms of hypothyroidism are present and secondary changes in the heart, liver, and kidneys are manifested, surgery obviously cannot be of much benefit. Surgery, according to Zapffe, of Chicago, is contraindicated in cases associated with cardiac lesions and in long-standing cases with extreme nervous disturbances.

The operation consists in either ligating the superior thyroid vessels or extirpation of the gland, depending upon the condition of the patient and the stage of the disease.

C. Mayo in mild cases, and in severe cases with secondary changes, does a simple ligation of vessels, nerves, and lymphatics at the upper pole, using linen ligature. This may be followed by the removal of one lobe and the isthmus later if deemed necessary. He thinks three-fifths of the gland may be removed without any untoward effects. Others think that more than one-half the gland should be removed in severe cases only. In ligating the superior thyroid artery, the vascularity of the gland is limited and the amount of poison taken into the system is reduced. Mayo uses ether as an anesthetic preceded by morphine sulphate gr. 1/6-1/4, atropine gr. 1/120, twenty minutes before the operation. Where ether is contraindicated, cocaine is used locally, this being preceded by scopolamine gr. 1/200 fifty minutes before the operation. Mayo's results are 70 per cent. cured, the mortality with ligation 3.7 per cent., with extirpation 3.9 per cent. Kocher had a mortality of 3.5 per cent. in 3,460 operations; all of the surviving patients were benefited, 83 per cent. being cured. These figures compare very favorably with the results following medical treatment.

The medical treatment consists in drugs and organic therapeutic agents in addition to hygienic measures. Physical and mental rest is absolutely essential, but it is difficult to enforce this rigidly in the present strenuous mode of life. The patient should be encouraged to have as much sleep as possible, taking a two to three hour afternoon nap when practicable. Exercise should be interdicted in those cases where cardiac lesions are present; in the milder cases it may be permitted, the amount being regulated and dependent upon the effects on the system. The diet depends upon the individual, overeating should not be indulged in, but enough should be taken to prevent underweight. Hydrotherapy is of some benefit. The heart condition should be watched and where a stimulant is necessary, strophanthus or strychnine may be given, as they have been found to be preferable to digitalis, due to the latter's effect on the stomach. For the sweating belladonna is very efficacious. Iodine and the iodides have been used in the treatment; the *x*-ray, electricity, and mental suggestion have also been tried.

In organotherapy, the thymus gland has been given, due to the belief that the thymus enlargement found in exophthalmic goiter is compensatory. Thyroid gland and thyroid extract are given in both stages—in hyperthyroidism to lessen the need for compensatory hypertrophy of the thyroid and in hypothyroidism to make up for the lessened secretion. Preparations from the serum and from the milk of thyroidectomized sheep are given. They all act in the same way, by neutralizing the excess of thyroid secretion in the system. Beebe and Rogers use a serum which is obtained by injecting the nucleoproteid and thyroglobulin from thyroids removed at operations, into rabbits. Time alone will tell of the efficiency of this class of remedies.

Iodine Fumigations in Gynecology.—Reynes states that this method gives excellent results in all uterine affections which may be treated per vaginam, like ulcerous metritis of the cervix, cervicitis, or granulomatous metritis. It is also useful for the disintegration of uterine cancers, after scraping the superficial layers of the tumor. Iodine vapors may also be introduced directly into the uterus. The author is employing this treatment with success in cases of postabortal metritis. The modus operandi is very simple: After carefully swabbing the vagina and cervix, the author introduces into the vagina a small pledget of cotton wool dipped in iodoform, which has been passed in the flame of a spirit lamp, candle or match. The combustion of the cotton wool is instantaneous, and the heat of this combustion is sufficient to set iodine free, so that iodine vapors fill the vagina, which has been previously dilated with a speculum. A deposit of iodine soon takes place in the vagina and on the cervix. Another method consists in heating the tube of an insufflator, insufflating iodoform, and bringing free iodine into contact with the diseased part. None of these methods requires any special apparatus.—*Progrès Médical.*

SEWAGE POLLUTED WATER SUPPLIES IN RELATION TO INFANT MORTALITY.

AT first thought there does not appear to be any close connection between water contaminated by sewage and infant mortality. When, however, the matter is given more earnest attention the relationship between polluted water and certain diseases to which infants are especially prone is obvious. Many infants are fed artificially, most of those, in fact, whose mothers work in factories or at other forms of labor away from home. Cow's milk is then the staple food of the infants, and in places in which there is a polluted water supply the milk will not long escape contamination, and infants may be expected to suffer from diarrhea and enteritis.

Dr. Allan J. McLaughlin, Passed Assistant Surgeon, Public Health and Marine Hospital Service, is the author of a paper in Public Health Reports for April 26, 1912, in which he invites attention to the excessive prevalence of diarrhea and enteritis of children in certain cities and towns which have a polluted water supply. He also points out that there is generally a parallelism between the curves for typhoid fever and enteritis in the winter months, suggesting that water is a factor in the prevalence of both. McLaughlin hopes that attention called to these conditions will result in the cooperation of practising physicians and local health officers and will effect two things, viz., (1) Investigation of deaths in the group classified as diarrhea and enteritis; (2) a wider use of municipal laboratories, especially in the diagnosis of typhoid fever and dysentery. A study of the intestinal discharges of children presents more features of importance in the problem of infant mortality than any other branch of investigation. McLaughlin concludes that statistics seem to show that the reduction in the general death rate, which has been called the Mills-Reincke phenomenon, when present, is due in greatest measure to the reduction in those diseases which are grouped under the heading of diarrhea and enteritis of children. To what extent an improved water supply is a factor in the reduction of the general death rate it is difficult to say. However, this much can be safely affirmed, that in practically every instance, in addition to a lessened number of deaths from typhoid fever, the substitution of a safeguarded for a polluted public water supply results in the saving of many lives from diseases which are not reported as typhoid fever. It certainly must be more than a coincidence that the death rate among infants from enteritis rises *pari passu* with the degree of contamination of a water supply, and points to the inference that the winter and spring mortality from the complaint is due to the water.

The subject is a fitting one for close investigation, and as McLaughlin says, the best way to probe the matter thoroughly is by the wider employment of municipal laboratories by practising physicians, especially in the diagnosis of typhoid fever and examination of the discharges of sick children. It is possible also that typhoid fever itself, and particularly the paratyphoid affections, attack infants with greater frequency by far than is generally believed. In recent years typhoid fever has been diagnosed on several occasions in infants and, perhaps, one or other of the paratyphoid fevers, if carefully looked for, would be found to be even more common. The relationship between infant mortality and sewage polluted water supplies is undoubtedly close.

THE TUBERCULOSIS SANATORIUM.

A COMMITTEE appointed by the Chancelor of the Exchequer to report on the preventive, curative, and other aspects of the tuberculosis problem, in order that the Government and local bodies in the United Kingdom might be guided in making or aiding provision for sanatorium or other treatment, has made an "interim report," which should be of equal interest in this country. Sanatoria have now for many years been building among us; and *pari passu* there has been much controversy over these institutions and some opposition to them.

This interim report is emphatically in favor of the tuberculosis sanatorium, insisting only that buildings erected or adapted for this use shall be unpretentious, and economical as regards both construction and management. It is not to be inferred that the committee means all consumptives should be confined in such institutions. On the contrary, it is recognized that the treatment of many patients in their homes and by their family physicians is not only possible, but oftentimes preferable. What is insisted on is that *all* persons afflicted with tuberculosis shall have treatment, to which end sanatoria shall be provided; herein we find but a paraphrase of the slogan of the New York State Charities Aid Association, "No uncared for case of tuberculosis after 1915."

One must indeed realize that sanatorium treatment is impossible for even a great number of consumptives. Those now in existence can accommodate but five per cent. of the present sufferers from this disease. Obviously the rest have to be treated in their own homes and by their own physicians, and very many among those who seek advice early and are obedient patients do recover in their own homes. The committee urges also that dispensaries be provided, not only for the prevention and the cure of tuberculosis, but also to serve as receiving houses, centers of diagnosis, for the education of physicians and as general information bureaus. It is recognized in this interim report that sanatorium

treatment has not always fulfilled expectations. Reasons for disappointment are that cases are not early enough diagnosed; that the public is ignorant of the significance of the incipient symptoms, and of the need of prompt treatment; that unsuitable cases are admitted and given continued treatment to the exclusion of favorable cases; that the patients do not get proper care after leaving the sanatoria; that the sanatoria are not always manned by physicians expert in this special work. The abatement of these objectionable conditions should largely increase the efficiency of the sanatorium.

LITERARY GENIUS AND MANIC-DEPRESSIVE INSANITY.

The insanity of genius is a phenomenon of which the literatures of every country and of every epoch have furnished abundant examples. So eminent have been the names inscribed in the literary hall of fame and of madness, that apparently no writer can dare to aspire to literary distinction without running the risk of submitting to psychological dissection by the alienists. In many instances it is no longer a question as to whether a certain genius was insane or not. The modern query is: "From what form of insanity did he suffer?"

In a thesis on the manifestations of manic-depressive insanity in literary genius, Eva Charlotte Reid (*American Journal of Insanity*, April, 1912) presents an interesting study showing that this type of insanity was the form most common among literary geniuses. The alternations of elation and depression, of frenzy and despair, of mania and melancholia, are frequently discerned in the writing of some of the most illustrious contributors to the world's literature. Among these are mentioned Goethe, Alfiere, Lucretius, Rousseau, George Sand, Tasso, Samuel Johnson, Chatterton, De Quincey, Swift, Keats, Charles and Mary Lamb, Coleridge, Cowper, Ruskin, Burns, Parkman, and Poe. Evidences of mental degeneracy in the antecedents or of abnormal mental manifestations in early life are cited in connection with allusions drawn from the works of these writers to show that they were victims of manic-depressive insanity. The author seeks to explain that this very infirmity was the motive force that impelled them to devote their lives to literature. "With an emotional instability which raises him to the pinnacle of exaltation one day and plunges him into the depth of despair the next, his industry must be spasmodic." He is unable to adapt himself to his surroundings. "In his literature he finds an outlet for all his abnormal feelings and passions. Here he pours forth, under various guises, his rapturous joys and fears, his dreams of bliss and his dread of impending calamity. The manifestations of his abnormal mental condition, which are denied him in actual life, find an outlet in poetry and fiction, under the guise of literary and poetical inspiration."

CATTLE TRYPANOSOMIASIS.

So far as modern medical research is concerned the greatest progress has of late been made, perhaps, in the field of tropical medicine. We have frequently noted that the conquest of the tropics by the white man has been really the conquest of tropical diseases. When malaria was the scourge it formerly was, certain parts of the tropics were more or less uninhabitable by white people. The same may be said of yellow fever to a lesser extent. Both of these dread diseases have been so greatly eliminated and robbed of their terror by methods of prevention founded upon a correct knowledge of their origin, that they no longer deter persons of the Caucasian race from living and living in health in regions near or in the Torrid Zone. Investigations as to the cause of other tropical diseases have resulted in an accumulation of facts on the subject that augur well for their ultimate extermination. F. M. Sandwith, in the first of the Gresham lectures delivered in London in February, 1912, and published in the *Medical Press and Circular*, April 3, 1912, deals with cattle trypanosomiasis and the early history of sleeping sickness. It appears that since the days of early travelers in Africa the tsetse fly has been a menace of the greatest magnitude to natives and white men alike. The tsetse fly and its ravages were referred to frequently by David Livingstone who, as a skillful and highly intelligent medical man, was one of the first to give an accurate description of the fly, the manner in which it injected its poison, the symptoms of infection of domestic animals thereby, and the post-mortem appearances. Major Bruce's later investigations proved that cattle trypanosomiasis is caused by the trypanosomes he found in the blood of the affected animals, and not in healthy ones, and that this trypanosome is conveyed by a particular tsetse fly, either from wild game, in which the trypanosome occurs as a comparatively harmless parasite to domestic animals, to which it is deadly, or from sick to healthy animals. However, although the means of dissemination has been discovered, as yet there has been no practical result from these investigations. No preventive measures have been devised and no certain cure for the disease has yet been found.

THE VALUE OF MEDICAL STATISTICS.

Undoubtedly the value of medical statistics is greatly overlooked by the average military or civilian surgeon. From all points of view and especially from that of public health and preventive medicine, vital statistics are desirable and even necessary. In the *Military Surgeon*, May, 1912, First Lieutenant Sanford W. French, Medical Corps, U. S. Army, draws attention to this fact. He points out that medical statistics in general, and venereal statistics in particular, do not appear ever to be taken seriously by either military surgeons or civilian practitioners. In the Army, according to this witness, there seems to be a great lack of uniformity in the method of properly recording all cases admitted to treatment or the sick list. This lack of uniformity is to some extent due to the fact that it is a matter for pride so to conduct the medical department of a regiment as to show as small a loss as possible from sick and wounded, but for comparison and the formulation of statistics, uniformity is necessary, which seems only obtainable by more stringent regulations in regard to the admission of sick and wounded and the recording of all cases unfit for duty. A similar condition is said to exist as regards venereal statistics. At some posts all venereal cases which come under observa-

tion of the medical officer are recorded, whether the patient is retained in the hospital for treatment or is treated while performing his duties. At other places men are treated for venereal diseases and their cases are not recorded unless their condition actually requires them to be in bed in the hospital. French argues that if statistics are to be of any value whatever, they should show the actual state of affairs in all cases, at all times and at all places. Obviously, statistics are worse than useless if they are cooked, or if they are not kept accurately and uniformly. That medical statistics are valuable when properly kept requires no argument in proof, and thus the plea made by French for such statistics is both cogent and timely.

The History of the Sleeping Sickness.

In the Gresham Lecture delivered in London in February (*Medical Press and Circular*, April 3, 1912), F. M. Sandwith gives an interesting history of the early accounts of the sleeping sickness. The earliest mention of this disease is in a book by one John Atkins, a naval surgeon who wrote of the "physical observations on the coast of Guinea." This work was published in London in the year 1742. Dr. Winterbottom, a colonial surgeon, was the next to write on the matter in 1803; he gave his experience of the disease as he saw it along the Bight of Benin on the west coast of Africa. Another colonial surgeon, Robert Clarke, wrote a fuller account in 1840 from observations he had made at Sierra Leone, and since then many English and French physicians have written concerning the malady. All were agreed that the disease was confined to certain areas. Dr. Corré a French naval physician, wrote regarding his observations in 1876, attributing the disease to a kind of ergotism or scrofula and to the moral condition of the people Corré, like all the earlier writers, asserted that none but blacks ever had the disease. Dr. C. Mense, a German author reported in 1906 that the number of deaths from sleeping sickness in the Congo within ten years amounted to at least half a million. The first scientific commission sent from Europe to investigate sleeping sickness was sent by the Portuguese Government. It is believed that Europeans have been mainly responsible for the spread of the malady. Henry Stanley is thought to have unwittingly helped to carry sleeping sickness from the center of the Dark Continent to districts where it had never beetn known. Now it is to be found in various regions of Africa and has actually decimated parts of the country which before had been healthy and prosperous—Uganda, for example. Recently much has been learned with regard to the disease, but it is as deadly as ever, and is undoubtedly the worst scourge of Africa at the present time.

The Senile Heart Again.

The death by heart-failure of General J. W. Duncan, commanding the Department of Texas, again brings up the question of overstrained hearts. He was only 58 years old, and had been apparently in perfect health. He was sick only a few days but did not have heart power to resist it. If many more such deaths occur, they will raise apprehension that all the experienced army officers will collapse or die in the first few weeks of an actual war. The situation will be rather serious if not alarming. They are national resources which deserve conservation.

News of the Week.

Cancer Research.—A fresh impetus has been given to cancer research in New York recently and broader fields have opened up for the workers on that baffling problem. The appointment of Professor F. C. Wood to be director of Cancer Research in Columbia University, working under the George Crocker Special Research Fund, as announced last week, will permit the observation of cases in St. Luke's Hospital where Dr. Wood has a special service for scientific study and the laboratories of which are also under his directorship. The opportunities for clinical study have heretofore been quite inadequate, and this combination of forces will be sure to be advantageous. This need of clinical study has also been recognized by a "well known scientist" who prefers to remain anonymous, in his gift of $100,000 to the General Memorial Hospital as an endowment for the maintenance of twenty beds for cancer patients. These beds have been placed at the disposal of the workers under the Collis P. Huntington Fund of Cornell University Medical College, who will thus have an unequaled opportunity for the bedside study of the disease. Three volumes of the results of laboratory experimentation have already been issued by the Huntington Fund, and it is to be expected that this larger opportunity will lead to correspondingly greater returns.

Deaths from Plague.—From Tien-Tsin, China, comes a report of two deaths from plague, the cases having the pulmonary symptoms which marked the serious epidemic in Manchuria last year. The international conference at Mukden which investigated that epidemic decided that while this form of the disease was invariably fatal within six days, its spread could be successfully checked by isolation of the victims.

Cartwright Lectures.—Prof. Dr. Ludwig Pick of the University of Berlin who will deliver the Cartwright lectures of the College of Physicians and Surgeons, New York, on November 7, 8, and 9, 1912, has announced the following subjects: 1, Some pathological-anatomical findings of hypophysis diseases and their practical value. 2. Modern views of the tumors of the nervous tissue. 3. Pathological anatomy of true and false hermaphroditism in man. The lectures will be given in the New York Academy of Medicine.

American Medical Editors' Association.—The forty-third annual meeting of this association was held at Atlantic City, June 1 and 3, 1912. Papers were read as follows: "Science in Personal Journalism," by T. D. Crothers, Hartford; "The Province of the Editor in Medical Journalism," by W. B. Snow, New York; "Commercialism," by C. F. Taylor, Philadelphia; "Research Work in Life Insurance Medicine," by Frederick L. Hoffman, Newark; "Shifting Medical Conditions Confronting Medical Journalism," by E. A. Ayers, New York; "Medical Journalism from a Disinterested Standpoint," by Albert E. Stern, Indianapolis; "What Doctors Read and Write," by Erwin Reissman, New York; "Independent Medical Journalism and the Task of the Independent Editor of To-day," by W. J. Robinson, New York; "Differential Diagnosis Between the "Write-up" and an Honest Article on a New Remedy," by H. S. Baketel, New York; "Book Reviews," by Arnold Snow, New York; "Subscription Getting," by G. Strobach, Cincinnati; "How the Medical Press can Cooperate with the Manufacturers for the Proper Introduc-

tion of New Materia Medica Science and Brands of the Same to Commerce," by F. E. Stewart, Philadelphia.

The following were read by title: "The Advisability of Newspapers and Magazines Having Medical Editors on their Staffs," by Edgar A. Vander Veer, Albany, N. Y.; "False Values in the Practice of Medicine," by H. Edwin Lewis, New York; "Eugenics in the Medical Magazines," by C. H. Hughes, St. Louis; "The Medical Editor of a Daily Newspaper, His Duties and His Educational Opportunities," by A. S. Burdick, Chicago; "Medical Expert Testimony," by R. B. H. Gradwohl, St. Louis; "State Board Examination Questions and Answers in Medical Journals," by Hills Cole, New York; "Laboratory Experiments versus Clinical Experience as a Method in Determining the Therapeutic Value of a Remedy," by John W. Wainwright, New York; "Anonymous vs. Personal Journalism," by Charles A. Wingerter, Wheeling, W. Va.; "Medical Journalism in Years Gone by," by W. A. Young, Toronto, Canda.

The election of officers resulted as follows: *President,* Thomas L. Stedman, New York; *First Vice-President,* Edgar A. Vander Veer, Albany, N. Y.; *Second Vice-President,* G. Strobach, Cincinnati; *Secretary and Treasurer,* Joseph MacDonald, Jr., New York.

The annual banquet was held at the Marlborough-Blenheim on the evening of Monday, June 3. Dr. Walter M. Brickner of New York was toastmaster, and addresses were made by Dr. Abraham Jacobi, President of the American Medical Association; Dr. Rupert Blue, Surgeon-General U. S. Public Health and Marine-Hospital Service; Mr. F. L. Hoffman, Statistician of the Prudential Insurance Co. of Newark; H. H. Snedeker, Esq., of the New York Bar; Dr. George E. Butler of Chicago, Dr. E. A. Ayers of New York, and Dr. James P. Warbasse of Brooklyn.

New Tuberculosis Ward.—The new ward for tuberculosis patients at the City Hospital, Providence, R. I., was formally opened on May 28.

To Combine Relief Work.—The Association of Infants' Milk Stations in New York is preparing a plan for the formation of a central society to be known as the Baby Welfare Association, in which shall be combined every organization in the city having anything to do with infants, all the regular milk stations, the hospital dispensaries, the day nurseries, etc. In this way it is hoped that all overlapping of effort and consequent waste of money will be avoided.

Doctor Fined.—A physician of Montclair, N. J., was recently fined $180 by the Montclair Department of Health for failure to report nine births at which he had attended.

Dog Famine.—The Provost of the University of Pennsylvania has complained to the Mayor of Philadelphia that the Medical Department of the University is unable to obtain dogs for class demonstration purposes because of the stringent regulations which have been enforced by the Women's Pennsylvania Society for the Prevention of Cruelty to Animals. Some of the class demonstrations toward the end of the year had to be omitted because of the impossibility of obtaining animals.

Smallpox at Quarantine.—The steamship *Kursk* which arrived at the Port of New York recently was found to carry two cases of smallpox, and was detained at Quarantine. The patients were both children, one in the cabin, and one in the steerage. A large number of passengers were removed to Hoffman Island for observation.

Shaw on Vivisection.—At the annual meeting of the Anti-Vivisection Society of London, England, recently, Mr. Bernard Shaw made a violent attack upon vivisection and vivisectors. He likened the claim that it was necessary to experiment on dogs in order to discover the cause of distemper to a possible claim that in order to discover the cause of the foundering of the *Titanic* several ships must be loaded and sunk in the Atlantic, apparently overlooking the fact that if the causes of that disaster were as obscure as are the causes of distemper, certain of his fellow countrymen would now be in a more enviable frame of mind.

Ambulances Wrecked.—An ambulance of St. John's Riverside Hospital, Yonkers, N. Y., was struck by an automobile while answering a call recently, and the surgeon in charge, Dr. Pratt, was seriously injured, the driver slightly injured, and the ambulance badly smashed. On June 4 an ambulance of the Harlem Hospital, New York, was struck by a Third Avenue car at 112th Street, and considerably damaged. Surgeon Charles McKinley suffered contusions of the shoulder and shock.

Gifts to Charities.—By the will of the late Edwin B. Foote of Brooklyn, N. Y., the New Haven Hospital of New Haven, Conn., and the Presbyterian Hospital of New York each receive the sum of $153,575. The bequest to the former institution is made in memory of the testator's father and is to be known as the Edwin Foote Memorial Bequest for the Endowment of Free Beds in Perpetuity. The New Haven Home for Aged and Destitute Women receives a like sum in memory of the testator's mother, Julia A. Foote.

Sir William Bennett of London, England, has placed at the disposal of the London School of Tropical Medicine the sum of £10,000 bequeathed to him by the late Lord Wandsworth for the purposes of medical research.

By the will of the late Thomas E. McVitty of Bryn Mawr, Penn., the sum of $5,000 is bequeathed to the Children's Seaside Home at Atlantic City, N. J., and the sum of $5,000 to St. Christopher's Home for Children in Philadelphia.

By the will of the late Helen B. Roberts of Philadelphia the sum of $5,000 is bequeathed to the Polyclinic Hospital, for the endowment of a free bed in the name of her husband, Caleb C. Roberts, a former trustee of that institution. It is stipulated that the bed shall be used for patients of her son, Dr. John B. Roberts. The sum of $1,000 is bequeathed to the Aid Association of the Philadelphia County Medical Society.

Fire in Flushing Hospital.—A fire in the two-story brick annex used as a kitchen for the Flushing Hospital, New York, on June 7, was extinguished by the nurses and orderlies on night duty before the arrival of the firemen. But little damage was done to the building and none of the patients were alarmed.

Death Rate Low Again.—During the week ending June 1 there were in New York City fewer deaths than during any other week of this year. The total number was 1,275 and the death rate per thousand was 12.86, while in the corresponding week of 1911, the total number of deaths was 1,334 and the rate was 13.96. Of the entire number of deaths, 94 were due to violence, 170 to heart disease, and 166 to tuberculosis. The other causes were as follows:

measles, 22; scarlet fever, 21; diphtheria and croup, 15; whooping-cough, 6; typhoid fever, 4; cerebro-spinal meningitis, 7; digestive diseases, 154; influenza, 3; bronchitis, 12; lobar pneumonia, 92; diseases of the kidney, 80; diseases of the nervous system, 55; all other causes, 431.

Martyr to Science.—Professor Lanfranchi of the University of Parma, Italy, who for the last four years has been conducting experiments on animals in the effort to obtain a cure for sleeping sickness, has himself contracted the disease and is reported to be in a serious condition.

School Medical Examiners in Philadelphia.—Dr. Walter S. Cornell, chief of the School Medical Examiners of Philadelphia, in a report to Director of Public Health and Charities Neff, states that the quality of the medical examinations made in the public schools in that city has improved greatly during the past year, while the cost of the work has been somewhat diminished. The number of defects discovered in pupils during the year has increased to 15,500. The number of nurses assigned to the schools has increased from 8 in 1911 to 22 in 1912, and the number of schools covered by nurses from 42 to 113. While 487 school visits were made in 1911, 1,325 were made in 1912, and the home visits increased from 551 to 1,042. Investigation has shown that about 35 per cent. of the children in the public schools are for one reason or another over the age of the grade in which they stand, and that 90 per cent. of these begin to advance and take their position with normal children as soon as they are fitted with proper glasses.

Jefferson Medical College.—Dr. William M. Sweet has been elected clinical professor of ophthalmology, and Dr. Hiram R. Loux, professor of genitourinary diseases in succession to Dr. Orville Horeait, who recently resigned.

Dr. William M. Walsh, formerly of the United States Public Health and Marine-Hospital Service, has been appointed superintendent of the Philadelphia Hospital for Contagious Diseases, succeeding Dr. Willard Morgan, resigned.

Dr. John F. Winn of Richmond, Va., who for several years has filled the chair of clinical obstetrics in the University College of Medicine, was recently elected professor of obstetrics by the board of trustees of that institution.

Dr. Philip L. O'Hanlon of New York, for the last fifteen years a coroner's physician in this city, was appointed a police surgeon by Commissioner Waldo on June 6.

Dr. Harvey W. Wiley has declined the office of chairman of the Board of Health of Boston offered him by Mayor Fitzgerald of that city.

The Medical Staff of the Jewish Maternity Hospital gave a dinner on May 25 to Dr. A. J. Rongy in honor of his appointment as attending gynecologist to the Lebanon Hospital, New York

Graduation Days.—The College of Physicians and Surgeons of New York on June 5 graduated eighty-five students with the degree of doctor of medicine, the exercises being held in common with the other departments of Columbia University on the University grounds at 116th Street. The address to the graduates was delivered by President Nicholas Murray Butler of the University, who also bestowed the degrees.

On the same day at the annual commencement exercises of the New York University, eighty students of the University and Bellevue Hospital Medical College received the degree of doctor of medicine. The following prizes were awarded: Valentine Mott silver medal to Francis Arthur Glass of New York; bronze medal to Harry B. Eisberg of New Jersey; Glover C. Arnold surgical prize to Cornelius John Tyson of New York.

The commencement exercises of Cornell University Medical College were held in the college building in New York City on June 7, when President Schurman of the University conferred degrees upon eleven graduates. The following prizes were awarded by the Dean: Whiting prizes in otology, first, to David Nye Barrows of New York; second, to Robert D. Schrock of Decatur, Ind.; John Metcalfe Polk Memorial prizes, first, to Chester H. Waters of Clinton, Iowa; second, to Robert D. Schrock; third, to Edwin S. Ingersoll of Rochester.

On May 29 diplomas were awarded to thirty graduates of the Women's Medical College of Philadelphia at the annual exercises, the address to the graduates being delivered by Dr. J. J. Walsh, dean of the Medical Department of Fordham University, New York.

Sixty-four students were graduated from the Medical College of South Carolina, Charleston, on June 3, at the eighty-third annual exercises.

The Medical School of the University of Texas bestowed the degree of doctor of medicine upon forty-six graduates at the exercises held in Galveston on May 31, and twelve students in medicine were graduated by the Wisconsin College of Physicians and Surgeons of Milwaukee on May 25.

At the Army Medical School, Washington, graduated thirty-eight physicians in Memorial Continental Hall on May 31, the graduates receiving the grade of first lieutenant in the United States Army Medical Reserve Corps. First honors were awarded to William B. Meister of New York, who received the Hoff memorial medal.

At the Boston University School of Medicine eighteen students were graduated on June 3.

At the commencement exercises of Jefferson Medical College held June 3 the medical degree was conferred on 148 graduates. The valedictory address was delivered by Dr. Thomas McCrae, recently elected Professor of Medicine, who spoke on Post-Graduate Education. The Degree of Doctor of Science was conferred on Dr. W. W. Keen, emeritus professor of surgery in Jefferson, and on Dr. J. W. Holland, emeritus professor of chemistry; that of Doctor of Laws on Dr. J. Solis-Cohen, honorary professor of laryngology, and that of Doctor of Public Health on Dr. Joseph S. Neff, director of Public Health and Charities of Philadelphia.

At the annual commencement of Hahnemann Medical College of Philadelphia on June 6 the Degree of Doctor of Medicine was conferred on thirty-five graduates.

At the annual commencement of Temple University of Philadelphia on June 6 the Degree of Doctor of Medicine was conferred on twenty graduates and the Degree of Doctor of Laws was conferred on Dr. J. Solis-Cohen, honorary professor of laryngology in Jefferson Medical College.

The medical degree was conferred upon seventy-one graduates at the commencement of the Medico-Chirurgical College of Philadelphia on June 7. The oration was delivered by Dr. Louis C. McMurtry, professor of abdominal surgery in the University of Louisville.

Philadelphia Medical Club.—A reception was given on June 7 to Dr. Abraham Jacobi, president of the American Medical Association; Dr. J. A.

Witherspoon, of Nashville, president-elect; Dr. Alexander R. Craig, of Chicago, secretary, and Dr. James Tyson, president of the Medical Society of the State of Pennsylvania.

American Dermatological Association.—At the thirty-sixth annual meeting of this association held in St. Louis on May 23 to 25, the following officers were elected for the ensuing year: *President*, Dr. Isadore Dyer, New Orleans; *vice-president*, Dr. D. W. Montgomery, San Francisco; *secretary treasurer*, Dr. James McFarlane Winfield, Brooklyn. The next meeting of the association will be held in Washington, D. C.

South Dakota State Medical Association.—The largest convention in the history of the association was held in Mitchell on May 24 and 25, when the following officers were elected: *President*, Dr. Charles E. McCauley, Aberdeen; *vice-presidents*, Dr. Frederick A. Spafford, Flandreau, and Dr. Fred Treon, Chamberlain; *secretary-treasurer*, Dr. Robert Douglas Alway, Aberdeen. The next meeting will be held in Vermilion.

State Medical Society of Wisconsin.—At the annual meeting held in Wausau on May 21 to 24, the following officers were elected: *President*, Dr. Arthur J. Patek, Milwaukee; *vice-president*, Dr. Charles Allen Armstrong, Boscobel.

Ontario Medical Association.—The following officers were elected at the meeting held in Toronto on May 22: *President*, Dr. Charles F. McGillivray, Whitby; *vice-presidents*, Dr. A. T. Shillington, Ottawa; Dr. Alexander Taylor, Goderich, and Dr. W. T. Parke, Woodstock; *secretary*, Dr. F. A. Clarkson, Toronto; *treasurer*, Dr. J. H. Elliott, Toronto.

Franklin County (Vermont) Medical Society.—At the annual meeting in St. Albans on May 29 officers for the ensuing year were elected as follows: *President*, Dr. Stephen W. Paige, St. Albans; *vice-president*, Dr. G. S. Clark, Montgomery Center; *secretary-treasurer*, Dr. Waldo J. Upton, St. Albans.

Minnesota Homeopathic Institute.—The following officers were elected at a recent meeting: *President*, Dr. A. E. Booth, Minneapolis; *vice-presidents*, Dr. L. A. Williams, Slayton, and Dr. E. L. Mann, St. Paul; *secretary*, Dr. Ethel E. Hurd, Minneapolis; *treasurer*, Dr. Margaret Koch, Minneapolis.

California State Homeopathic Medical Society.—At the meeting held in Sacramento on May 22, the following officers were elected: *President*, Dr. W. J. Hawkes, Los Angeles; *vice-presidents*, Dr. C. L. Tisdale, San Francisco, and Dr. Mary M. Cronemiller, Sacramento; *secretary*, Dr. Guy E. Manning, San Francisco; *treasurer*, Dr. T. C. Low, Los Angeles.

Manitoba Medical Association.—The annual meeting was held in Winnipeg on May 21 and 22, when an interesting clinical program was presented. The election of officers resulted as follows: *President*, Dr. J. S. Matheson, Brandon; *vice-presidents*, Dr. S. C. Bier, Brandon; Dr. T. R. Ponton, Macgregor; *honorary secretary*, Dr. Joseph Halpenny, Winnipeg; *honorary treasurer*, Dr. R. F. Parke, Winnipeg; *executive committee*, Dr. A. F. Walkey, Portage la Prairie; Dr. W. Bigelow, Brandon, and Dr. James McKenty, Winnipeg.

Missouri State Medical Association.—The annual meeting, held in Sedalia, ended on May 23 with the election of officers as follows: *President*, Dr. Robert M. Funkhouser, St. Louis; *Vice-Presidents*, Dr. J. S. Wallace, Brunswick; Dr. Harry S. Crawford, Harrisonville, and Dr. J. N. Baskett, Hannibal; *Secretary*, Dr. Edward J. Goodwin, St. Louis; *Treasurer*, Dr. J. Franklin Welch, Salisbury.

Harvard Medical School.—Class day exercises were held by the 1912 class of the Harvard University Medical School on May 25. The class, consisting of fifty graduates, is the first to complete the whole course of four years in the new college buildings on Longwood Avenue, Boston.

Certify Druggists.—The New York County Medical Society at a recent meeting authorized its president to appoint a committee of ten to meet a similar committee from the New York Pharmaceutical Association and confer on a plan for certifying pharmacies in the city.

Heaviest Man Dead.—Chauncey Moran, reputed to be the heaviest man in the world, died recently in Elwood, Indiana, aged 45 years. Up to his last illness Moran weighed 853 pounds, and had been for many years an attraction at Barnum & Bailey's circus.

Rabies Warning.—Commissioner Huson of the Department of Agriculture has issued a statement showing that in New York State ten towns and one village are now under quarantine for rabies, and that the disease is prevalent to a marked degree in Erie, Genesee, Wyoming, and Queens Counties.

Illinois State Medical Society.—The following officers were elected at the annual meeting held in Springfield on May 22 and 23: *President*, Dr. Charles Joseph Whalen, Chicago; *Vice-Presidents*, Dr. Samuel E. Munson, Springfield, and Dr. Watson H. Curtis, Wilmington; *Secretary*, Dr. Edmund W. Weis, Ottawa; *Treasurer*, Dr. A. J. Markley, Belvidere.

Obituary Notes.—Dr. William M. Gay of Talladega, Ala., a graduate of the Georgia College of Eclectic Medicine and Surgery in 1881, and a member of the Alabama State and Talladega County Medical Societies, died at his home on May 25, after a long illness, aged 65 years.

Dr. J. S. Heflin of Locust Grove, Ga., a graduate of the Oglethorpe Medical College of Savannah in 1870, died at his home on May 9, aged 65 years.

Dr. Thomas B. Rider of Hot Springs, Ark., a graduate of the Atlanta Medical College, Georgia, in 1887, died at Rye Patch, Nev., on May 19, aged 53 years.

Dr. Josiah R. Bromwell of Washington, D. C., a graduate of the University of Maryland, School of Medicine, Baltimore, in 1871, and a member of the American Medical Association and the Medical Society of the District of Columbia, died at his home on May 25, aged 69 years.

Dr. Mark T. Dodge of Troy, Me., a graduate of the Medical School of Maine, Portland, in 1891, and formerly a member of the State Legislature of Maine, died at his home after a long illness on May 18, aged 61 years.

Dr. Alvan J. Rosenberry of Benton Harbor, Mich., a graduate of the University of Michigan, Department of Medicine and Surgery, Ann Arbor, in 1880, and a member of the American Medical Association and the Michigan State and Berrien County Medical Societies, died at his home recently, aged 61 years.

Dr. William M. Hoff of Farmersville, Mo., a graduate of the Missouri Medical College, St. Louis, in 1884, died at his home on May 20, aged 60 years.

Dr. Elmer Ellsworth Briggs of Santa Rosa, Cal., a graduate of the New York Homeopathic

Medical College and Hospital in 1893, and a member of the American Medical Association and the California State and Sonoma County Medical Societies, died suddenly while performing an operation in the Santa Rosa Hospital, on May 15, aged 51 years.

Dr. Elizabeth J. T. Gould of East Orange, N. J., a graduate of the Woman's Medical College of the New York Infirmary for Women and Children, New York, in 1873, died at her home, on May 24, aged 69 years.

Dr. Aquilla Nebeker of Philadelphia, Pa., a graduate of the Eclectic Medical College of Pennsylvania in 1870, died at his home, on May 27, aged 69 years.

Dr. Albert Moore Shoemaker of White Haven, Pa., a graduate of the University of Pennsylvania, Department of Medicine, Philadelphia, in 1900, and a member of the American Medical Association and the Pennsylvania State and Luzerne County Medical Societies, died at his home on May 18, aged 34 years.

Dr. George Weisle, retired, of Williamsport, Pa., a graduate of the University of Pennsylvania, Department of Medicine, in 1864, died at his home of apoplexy, on May 20, aged 68 years.

Dr. Lewis C. B. Yorgey of Pottstown, Pa., a graduate of the University of Pennsylvania, Department of Medicine, in 1873, died at his home of apoplexy, on May 21, aged 61 years.

Dr. Ernest W. Pinson of Cross Hill, S. C., a graduate of the Louisville Medical College, Kentucky, in 1890, and a member of the South Carolina State and Laurens County Medical Societies, died at his home after a long illness, on May 18, aged 43 years.

Dr. John Arthur Irwin of New York, a graduate of the University of Dublin, Ireland, in 1875, and of the Royal College of Surgeons, England, in 1876, and a member of the British Medical Society, the London Obstetrical Society, the Royal Medical Society of England, the New York Academy of Medicine, and the Medico-Surgical Society, died at his home of cirrhosis of the liver, on June 1, aged 59 years.

Dr. Chester Rowell of Fresno, Cal., a graduate of the Cooper Medical College, San Francisco, in 1870, and a member of the California State and Fresno County Medical Societies, mayor of Fresno, a regent of the University of California, State senator for three terms, and a former member of the State Board of Health, died in Los Angeles on May 23, aged 67 years.

Dr. Beverly MacMonagle of San Francisco, Cal., a graduate of the Harvard Medical School in 1876, a member of the American Medical Association, the California State and San Francisco County Medical Societies, the American Gynecological Society, the American Surgical Association, and the Western Surgical Association, and formerly chief surgeon at the Children's Hospital, San Francisco, died in Paris, France, where he had gone in search of health, on May 22, aged 57 years.

Dr. Carey Fenton Marshall of Lynn, Mass., a graduate of the New York University Medical College in 1879, died at his home on May 31, aged 57 years.

Dr. Thurman L. Wagner of St. Louis, Mo., a graduate of the University of Illinois, College of Medicine, in 1903, died at the home of his parents in Wabash, Ind., on May 28, from the effect of *x*-ray burns, aged 35 years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

KING OPENS THE ROYAL SOCIETY OF MEDICINE'S NEW BUILDING—TROPICAL MEDICINE—MEDICAL SOCIETY'S ANNUAL MEETING AND ORATION—SELECT COMMITTEE ON PROPRIETARY MEDICINES.

London, May 24, 1912.

The King, accompanied by the Queen, opened the new building of the Royal Society of Medicine on Tuesday afternoon. That event has been the leading topic of talk among doctors all the week. Fine weather favored the occasion and set off the façade of the society's new home. At a quarter to four exactly the sound of cheering from the dense crowd outside, mingled with the strains of the national anthem, announced the arrival of their majesties. They were received by the president (Sir H. Morris) and other officials and conducted to the great hall, which is named after the late Dr. Robert Barnes and is capable of seating 500 persons. On reaching the dais the president read a loyal address expressing the appreciation of the society and profession of the interest evinced by their majesties in the health of their subjects, and the means of curing and preventing disease. It pointed out that the society was founded in 1805, but attained greater stability by the charter granted in 1834 by King William IV, who declared himself "and his successors if they should think fit" patron of the society. Pride and pleasure was expressed that these had so thought fit, and that now his gracious majesty has become patron. A supplementary charter granted in 1907 enlarged the scope of the society by authorizing the enrolment of other allied societies and changing the name of the Medical and Chirurgical to the Royal Society of Medicine. That charter ordained that females might be elected Fellows and appointed to offices equally with males. The address concluded with an expression of gratitude for the honor conferred upon the Fellows and the profession at large.

The King in reply expressed pleasure in opening the building, and confidence in the work of the profession, as none could doubt that medical science has revealed new securities for life and health during recent years and that improved public health is mainly due to discoveries made by medical men in this and other countries, and further to the guidance given by the profession to civil authorities and the precautions against the spread of disease thereupon enforced. His majesty then formally declared the building open and the royal party were conducted through its chief departments for an inspection. The floors of the lecture halls are sloped to facilitate the watching of demonstrations. In the basement is the storeroom for books, and here the honorary librarians showed how special shelves had been installed, which can be moved to accommodate volumes of various sizes. The plan interested the King, who contrasted it with the management of the British Museum, and after experimenting with the mechanism congratulated the librarians. Thence the King and Queen went to the library proper on the first floor; it is 110 feet long, 27 wide, 18 in height, and has an annex for periodicals. There are 100,000 volumes in the collection, the shelves running from floor to ceiling, and a gallery giving easy writing access. The tables are movable and a novel scheme of lighting them

has been adopted so as to dispense with the flexible wires, which are always in the way and apt to get broken. Contact is made through the legs and the tables can be moved without interrupting it. The King tested the working and accepted a model of the invention, which I learn is that of the secretary.

The royal signatures were then affixed to an emblazoned page prepared in the obligation book for this occasion. The King also signed the usual form which follows an election sign. Copies of the history of the society were presented and an adjournment to the tea room closed the proceedings.

The London School of Tropical Medicine is pressing forward for further extension. For this purpose a special committee is being formed on which Mr. Chamberlain, who did so much towards founding it when Secretary for the Colonies, has agreed to be a member, and his son, Austin, will be chairman. Sir Patrick Manson, Sir T. B. Crosby, Lord Mayor, and some others have agreed to serve when the full committee is formed, for which purpose a meeting will be held as soon as possible after the Whitsun recess. The cost of extending the school and hospital is roughly estimated at £100,000, towards which there is only in hand £4,500, raised at the recent meeting at the Mansion House. It is hoped to increase the laboratory accommodation so as to provide room for 100 students instead of 55, the present outside capacity.

It is intended to appeal for £100,000 to provide for endowment, new buildings, research and a nursing home for sufferers from tropical disease.

As to Lord Wandsworth's legacy, it has been arranged that the Seamen's Hospital Society shall act as trustee, handing the revenue to the school to be used for a scholarship. The scholar is to be nominated by the school committee and approved by the Seamen's Hospital committee; the tenure to be for two years, with a possible extension for another year. Failing a suitable candidate, the revenue will be used for some definite research in tropical medicine. The scholar will be required to present a report on his work not later than two months after the expiration of each year.

The Medical Society of London, which is older than the R. S. M., is in fact our senior society, dating from 1773, held its annual meeting and conversazione on Monday evening. Among those present was the Lord Mayor of London, Sir T. B. Crosby, M. D., the first medical Lord Mayor, and who was made an honorary Fellow of the society. The rare books, prints and manuscripts of this old established and still flourishing society were on exhibition. Some of the prints illustrated the house of Dr. Lettsom, one of the founders, and among the books was one of the few extant copies of the work of Servetus, who is said to have anticipated the discovery of the circulation of the blood. Sir Watson Cheyne, F. R. S., has succeeded Dr. Mitchell Bruce in the presidency of the society, and the vice-presidents for the ensuing year are Sir D. Ferrier, F. R. S., and Drs. William Ewart, Percy Lush and A. E. Barker.

The annual oration of the society was delivered by Mr. Bland-Sutton, who took for his subject, "Fertilization in Relation to Pathology." In a closely reasoned discourse he pointed out a number of pathological phenomena which present a certain degree of analogy with the imperfect development seen in some cases in which artificial fertilization has been experimented with.

The committee appointed by the House of Commons to investigate and report on proprietary and so-called patent medicines, has already heard witnesses testify to facts about the histories and sale of those products which are well enough known to the profession, and which it is well the public should be made aware of. The government licenses the trade and derives considerable income from the stamp duty. This stamp has been regarded by many ignorant persons as a guarantee by the government of the value of the preparation, or a certificate of the truth of the advertisements. This has been denied by some, but already it has come out that the government changed the words on the stamp to prevent deception. Notwithstanding the enormous sale of these quack remedies, the Home Office representatives have informed the committee that very few complaints have reached them, and the officials do not interfere so long as the wording of the advertisements is not indecent or suggestive of illegal practices.

At one sitting Dr. Nestor Tirard gave evidence as to the British Pharmacopœia, which is revised from time to time under the authority of the General Medical Council. The last revision was in 1898 and a new issue is in preparation. He would wish it to be more frequently revised. He would approve that any so-called secret medicine containing a scheduled poison should have the amount of that poison stated on the label. That might safeguard the public against the danger of changes of strength. It did not matter about the full formula for there was no real secrecy about them to medical men. They could all be analyzed. When some proprietary article obtained so much vogue as to be used by medical men, a corresponding formula was put in the Pharmacopœia, not because there was any discovery or skill in mixing the ingredients, but that those who prescribed it might have it of constant strength. The origin of these proprietary medicines was almost always the prescription of a medical man which was advertised by some one else.

OUR CANADIAN LETTER.

(From Our Regular Correspondent.)

MEETING OF THE ONTARIO MEDICAL ASSOCIATION IN TORONTO.

TORONTO, June 1, 1912.

THE thirty second annual meeting of the Ontario Medical Association was held in Toronto on May 21, 22, and 23 last. A new departure, in so far as arrangement of programme is concerned, has been taken by the officers of the association. Instead of all the time during which the meeting is held being devoted to the reading of papers, only the first day is given over to paper reading, the greater part of the other two days being employed in clinical demonstration. The plan seems to be decidedly good. At many meetings time is wasted, the word is used advisedly, by the reading of a multitudinous number of papers. The audience is frequently bored, or those who know what to expect absent themselves and the reader of the paper often either faces a yawning, uninterested assembly or is confronted with empty benches. Therefore it is wise to have a few good papers read by able men and to employ the remainder of the time in practical demonstrations varied so as to meet the requirements and tastes of all sorts and conditions of physicians and surgeons. If attendance be a criterion of the popularity of a meeting then assuredly the recent meeting in Toronto must have been immensely pop-

ular. The papers were read in the Medical Building of the University in one or other of the large lecture rooms, and these rooms were crowded. When the addresses of the President, Dr. Herbert O. Bruce, of Dr. Carell, and Dr. Crile were delivered the large lecture room in which the session was held was filled to overflowing.

On the first day in the morning a symposium on Graves' disease was held in which Dr. W. T. Connell of Kingston, Dr. Marquis of Brantford, Dr. Olmstead of Hamilton, and Dr. Shillington of Ottawa took part. In the afternoon the address in medicine by Sir William Aldren Turner was delivered in his absence by Dr. Fotheringham. The title of the paper was "Some Aspects of Neurology in General Practice." With regard to hysteria and to Freud's main hypothesis that the repressed complexes are invariably of a sexual character, Turner said, "It is difficult at the present time to express an opinion upon the value of Freud's view upon hysteria. He has revived the oldest doctrine of the disease, its sexual origin, but upon a physiological basis. In reintroducing the sexual element as the sole factor in hysteria and allied neuroses he has opened the flood gates for a veritable torrent of criticism. He has been attacked vigorously by his opponents and as strenuously supported by his disciples and admirers. Any criticism, however, of Freud's view ought to separate the hypothesis which he has enunciated, such as his conceptions of conflict, expression and the influence of the subconscious mind, from the method of psychoanalysis, by which he has arrived at his conclusions. There is a strong body of opinion against the universal application and acceptance of the sexual origin of hysterical symptoms. Moreover, his views upon the 'conversion' of a repressed idea into the physical symptoms of hysteria would require some further explanation than has yet been given."

Referring to psychotherapeutics Turner points out in view of the generally accepted psychical origin of all hysterical symptoms, as well as those of the closely allied psychoneuroses, such as the mental symptoms of neurasthenia, morbid fears, obsessions, and the like, it is not unnatural that the present day methods of treating those conditions should consist in the main of psychical measures.

The Röntgen rays find little application in diseases of the nervous system. It was at one time thought that they might be of value in the location of tumors within the cranial cavity. This has not been found of any real value. They are, however, of decided value in the diagnosis of morbid conditions of the bony tissues, surrounding the central nervous system, especially with reference to pituitary and other lesions at the base of the skull. A minor, but at the same time, interesting observation, has been made from their universal application in all cases of muscular atrophy affecting the small muscles of the hands. It has been found by *x*-ray photographs of the neck in many of these cases, occurring especially in young women, how frequently the presence of an additional or cervical rib is the cause of the muscular atrophy, and how satisfactory the recovery may be after the removal of the accessory piece of bone. In cases of neurasthenia, accompanied by gastritis and enteroptosis, the examination of the size, shape, position and motor action of the stomach and intestines may be easily and satisfactorily made by tracing the course of a bismuth meal through the digestive tract by *x*-ray examination. Too much importance cannot be given to this method of examining a portion of the body whose functions have so far not been open to a closer examination than could be obtained through abdominal palpation.

Regarding the effect of the bromides in the treatment of epilepsy, Turner after an experience of some 16 to 18 years, during which time he has prescribed for several thousands of epileptics in all stages and varieties of the malady, can without hesitation say that the influence of the bromides upon epileptic convulsions is both variable and uncertain. In a certain proportion of cases, amounting to about 25 per cent., so much benefit is derived that the attacks are either permanently or temporarily arrested. It is probable that the spontaneously curable cases are found in this group, cases which in the view of some writers are arrested not in consequence of, but in spite of the remedy. The curable types of epilepsy are recognizable early in the disease, and in them Turner considers the early and persistent use of small doses of the bromides most essential. In a second group of cases, amounting to a further 25 per cent., some improvement is derived from the administration of the bromides, mainly in the direction of lessening the frequency and severity of the fits. In the remaining group, amounting to about 50 per cent., the bromides either have no influence at all upon the fits or are actually deleterious. It is therefore obvious that about half the number of epileptics derive no benefit from the administration of the bromides, from which it might be argued that those salts are of little, if indeed of any, use in the treatment of epilepsy. On the other hand there is the 25-50 per cent. which derive great benefit from these drugs including the 10 or 12 per cent. which are cured. Turner holds that it is an error to say that the bromides are of no use in the treatment of epilepsy. If 50 per cent. of the cases derive some benefit from the administration of these drugs, then all cases of recent origin should be given the benefit of the remedy for a time.

OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

A THREATENED INVASION OF PLAGUE—MANILA MEDICAL SOCIETY — ACROMEGALY — SPRUE—FAILING WATER SUPPLY — TYPHOID FEVER.

MANILA, P. I., April 11, 1912.

DURING the past week the Philippines have been most seriously threatened with an invasion of pneumonic plague from Hongkong. The S.S. *Loonsang* arrived in Manila on April 2 and reported that a death had occurred in a Chinese member of the crew. The first evidence that there was anything seriously wrong was when the man fell over dead. Twelve hours before his death he had complained of some pain in the lower part of his chest at the site of an injury he had received some years before as a result of a blow. The body was brought to Manila and an autopsy was made about 36 hours after the man had died. Nothing very unusual was found. Apparently it was a simple case of pneumonia of the lower lobes and scarcely sufficient to account for the death. Cultures were, however, made and guinea-pigs inoculated and it was soon learned that the disease was actually pneumonic plague.

A second case occurred on the S.S. *Zafiro*. This vessel passed the maritime quarantine inspection on the evening of April 4. On account of the experience had on the S.S. *Loonsang*, the medical examination of the personnel was made very carefully.

but no cases of illness were detected. On the morning of April 6 it was reported that a death had occurred among the Chinese crew. Upon investigation it was found that the cook for the Chinese crew had prepared the evening meal on April 5, and that he was seen about the decks as late at 10 P. M. on the same date; the next morning when the usual 6 o'clock breakfast was not ready and search was made for the cook, he was found dead in his bunk. The body was cold and rigor mortis had already set in. This case was immediately autopsied; the only macroscopic change noted was a congestion of the lower lobes of the lungs, with some slight inflammation of the bronchi. Smear preparations made from the spleen showed bipolar staining organisms. No definite anatomical diagnosis could be made which would account for the death, but laboratory investigations finally showed this case also to have been pneumonic plague.

The diagnosis in each case was confirmed by Drs. Strong and Teague, both of whom were members of the International Plague Conference which took place in China last year. These cases are of unusual interest in that the last death must have taken place at least five days after the probable exposure.

The S.S. *Loonsang* was promptly remanded to Mariveles quarantine station, where the necessary disinfecting measures were carried out, and at this writing, seven days after the disinfection took place, no other cases have appeared. The same measures were carried out with the S.S. *Zafiro* and up to this time, three days after the disinfection was completed, no further cases have occurred. It is evident that under these conditions it is quite possible for plague to be introduced into the country in a most insidious manner without rats actually having been concerned in the transmission. Another interesting feature in connection with the case on board the S.S. *Zafiro* is the fact that this vessel was thoroughly fumigated with sulphur for the destruction of rates and vermin before leaving Hongkong, and that upon the refumigation of the vessel at Mariveles no rats or other vermin were found.

The regular monthly meeting of the Manila Medical Society took place in the amphitheater of the College of Physicians and Surgeons of the University of the Philippine Islands at 8:30 P. M. on April 1. A well marked case of acromegaly in a Filipino was presented by Drs. Musgrave and Sison. Another case of multiple aneurysm was presented by Drs. Sison and Gutierrez.

A paper entitled "Sprue as a Place Disease" by Dr. G. I. Cullen was read by Dr. R. E. L. Newberne. In this paper Dr. Cullen stated that upon a small island near Catbalogan, Samar, he had observed that many of the Americans, and these are generally school teachers and their families, who went to the islands, in the course of a few months developed sprue. In all, he stated that he had seen six cases; he did not claim that he had sufficient evidence to prove that sprue was a place disease, but merely wanted to report these facts which had come under his observation. In the discussion which followed the trend of the opinion was to the effect that from the facts available no satisfactory deductions could be drawn.

Owing to the unusual dry season which has prevailed in the Philippine Islands during the past five months, and owing to some serious leaks which have developed in the Montalban reservoir, the water supply for the City of Manila has become insufficient to meet the demands and Manila is once more confronted with the necessity of using a supply that is obtained from the Mariquina River, upon the banks and drainage area of which there live over 10,000 persons whose sewage and other refuse finds its way almost directly into the river.

In view of the fact that such excellent progress was being made in reducing the death rate in Manila, and since the records so far obtained this year bade fair to exceed anything which has been attained since American occupation, it is indeed unfortunate that a return to the use of polluted water has again become necessary. Plans are under way to dispose of the night soil in the Mariquina valley temporarily by the means of public midden sheds. Regulations have also been issued prohibiting the bathing of persons and animals in the Mariquina river. In view of the fact, however, that the persons who live along the banks consider it their inalienable right to bathe and use the river in any such manner as they please, these regulations are most difficult of enforcement and are probably more honored in the breach than in the observance.

From a public health standpoint it is most interesting to note that two weeks after the use of this water was begun, the average daily mortality has risen; formerly it was about 22 per day, whereas now it has already risen to 28 per day. This makes additional concrete proof of the great importance of a proper water supply, especially for cities.

The danger to Manila is considerably increased by the fact that typhoid fever has become more prevalent in the Philippines, and if the Mariquina river should become infected an epidemic would arise which would not only cause great havoc among the residents of the City of Manila but would no doubt be the beginning of an infection which would spread widely throughout the provinces of the Philippine Islands.

10. Fracture of the Greater Tuberosity of the Humerus by Muscular Action in a Child. W. P. Coues.

1. **Medical Impressions of America.**—C. K. Austin of Paris, France, records the impressions he gathered during a visit to his native country, the United States, after an absence of twenty-six years. What impressed him most were the high standard and excellence of the hospitals. The admirable features of the New York hospitals are ranged under four headings: (1) A marvelous organization and team work, (2) a gift for discerning the practical side of everything, (3) scrupulous cleanliness, and (4) the earnestness of everyone concerned. One of the serious defects of the hospitals is the short and intermittent service of many of the attending physicians. There is also an unusually great predominance given to laboratory work as against a possible lack of consideration for clinical examination of the patient. There is one special branch of medicine which has shot far ahead in America and which is still in its infancy abroad, namely, orthopedics, and particularly the statics

of the pelvis and foot. The author notes that as a class American physicians are awkward speakers in public.

7. **Patients Released from State Sanatoria.**—A. S. MacKnight investigated carefully the later history of twenty-seven patients discharged from State sanatoria in Massachusetts since December, 1910. The investigation disclosed the fact that 9 were known to be living, while 10 had died since leaving the institution and 8 were at large without any knowledge of the fact by a local health authority. Of the 9 persons known to be living, 3 are now inmates of a State sanatorium, while each of the remaining 6 is careless as regards the spread of infection. A striking fact which the investigation disclosed is that each patient returned from the State sanatorium as "an arrested case" was found on physical examination either in an advanced or moderately advanced stage of the disease. The investigation further disclosed the fact that persons are discharged from State sanatoria to go whither they may. They sometimes return to their original place of residence, or they may seek new domiciles in the same city. They may never return to their original location, but may go to other cities or even other states. In any event it appears that no person or organization is responsible or assumes responsibility for the care and conduct of patients discharged from a State sanatorium. It is a fact that most of the 27 patients investigated on leaving the sanatoria have been found to be careless in their personal habits, especially as regards the prevention of the spread of the disease among well persons. They have thus failed to profit by the instruction received at the State hospitals.

10. **Fracture of the Greater Tuberosity of the Humerus by Muscular Action.**—W. P. Coues reports a case of this condition in a child twelve years of age. He notes that fracture of a part of the upper humeral epiphysis is very common; when, added to this, the condition is caused by muscular action alone, it becomes extremely rare. But few cases are recorded. Ossification begins in the upper epiphysis of the humerus by three centers, one for the head, one for the greater, and one for the lesser tuberosity. Bone is deposited in the epiphysis as early as the first year. The separate bony centers begin to merge together, forming the solid epiphysis at about the sixth year; the greater tuberosity is the last center that becomes solid. The epiphysis is completely bony at puberty. Union of the upper epiphysis with the shaft does not take place until about the twentieth year of age. Separation of any one of the centers of ossification of the humeral head by fracture of the cartilage uniting them is possible, but unheard of.

1. **The Upright Position in Ether Operations upon the Nose and Throat.**—T. R. French states that with the patient in the upright position the surgeon can do his work better since he is accustomed to this position of the patient in his everyday practice. A better view of the fauces can be obtained. There is less shock and less disturbance to the patient because less ether is required to maintain narcosis when the sitting position has been attained. This is due to the diminished blood pressure in the vessels of the head when the body is in the upright position and under the influence of a general anesthetic. There is also a relatively small amount of blood lost. This is an item of considerable importance in operations upon the very young, the aged, the feeble, and the cachectic.

2. **The Value of Warmed Anesthetics.**—By J. T. Gwathmey. (See MEDICAL RECORD, May 18, 1912, page 964.)

3. **Intravenous Administration of Phenolsulphonephthalein.**—E. L. Keyes and A. R. Stevens have employed this method of administration in the study of renal function with the following results: The amount of the drug output seems to be little if at all influenced by oliguria or polyuria. The phenolsulphonephthalein percentage agrees as closely as ever with the urea in centigrams (urea percentage multiplied by c.c. of urine). The "delay," *i.e.* the interval between the injection of the drug and its appearance in the urine varies widely. Thus in fourteen "normal" kidneys the "delay" varied from two to nine minutes, averaging 4.5 minutes. Yet among thirty-eight "diseased" kidneys no less than twenty-eight showed a delay within the "normal" limits and fourteen of them below the "normal" average, while in two the drug actually appeared in the urine of the diseased kidney, respectively, one and two minutes, before it appeared from the sound one. But the most striking feature of the "delay" is that it may be approximately equal for two kidneys whose function differs widely. Hence the "delay," whether absolute or relative (as between the two kidneys), is peculiarly misleading and should be taken into consideration only for the purpose of estimating the time at which to begin collecting specimens for phenolsulphonephthalein estimation. When employing intramuscular injections of phenolsulphonephthalein, several times the authors were chagrined to find that kidneys, which excreted high percentages of phenosulphonephthalein without cystoscopy, excreted only traces of the drug during an hour when the ureters were catheterized. This inhibition has not occurred after intravenous injection. Indeed so rapid is the output of phenosulphonephthalein after intravenous injection that accurate readings can almost invariably be obtained in from ten to fifteen minutes after appearance of the color in the urine. Yet the authors feel that enough inhibition may result from cystoscopy to invalidate precise conclusions as to the normality or abnormality of the kidneys from the percentages of phenolsulphonephthalein excreted by ureter catheter even when intravenous injection is employed. Roughly speaking, however, an excretion of one per cent. in one minute for the first ten or fifteen minutes is normal.

7. **Indications for Tonsillectomy.**—E. Danziger states that the indications for enucleation of the tonsils in children are: (1) Cases of buried tonsils in which the pillars and the plica envelop the tonsils almost entirely. Such tonsils are of no use, as they will not take up bacteria with the ingested food, nor will they be able to empty their crypts in a secondary tonsillitis from nasal or buccal infection. (2) In cases of small atrophic tonsils which cannot be removed, partly on account of their size, and in which the microscope shows large defects in the epithelium of the crypts, sometimes its complete disappearance. (3) In cases of suspected tuberculosis of the tonsils. (4) In adults, recurrent attacks of circumtonsillar abscess call for enucleation as the only guarantee against future attacks. (5) Malignant affections are self-evident indications for this operation. To make the age of the patient an important factor for the choice of operation is not logical, as the microscope shows the existence of the crypts at all ages, with the same production and diapedesis of lymphocytes, even if there is an increase of connective tissue. That the total enucleation of the tonsils does not always accomplish the desired results

has been shown by Finger, who has demonstrated that in quite a number of cases new lymphatic tissue may develop from the lymphatic tissue back of the tongue. As another drawback of the total extirpation of the faucial tonsils, one has to consider the deleterious effect of this procedure on the voice especially of singers and public speakers.

3. Myoclonia Occurring Only After Rest or Sleep.—L. Pierce Clark presents the history of a case of myoclonia occurring in a college student, aged 24, in whom the legs were convulsed only after sleep or resting. There was no direct hereditary history of nervous disorders in the parents, so far as known, but of the other children of the family one was an epileptic and the other of "highly nervous temperament." The symptoms had been observed since infancy and appeared to be without any obvious cause except as mentioned, but were made somewhat worse after excessive indulgence in coffee and alcohol. The author states that this is a case of classic myoclonic contractions of unknown origin, aside from possible obscure hereditary causes and slight injury at birth, which afflicts the patient largely if not solely after rest and only during that physiological period in which normal tension of muscles is brought about, as in walking or standing. Contrary to the usual ideas, myoclonic contractions often do occur during sleep or part waking. This condition, together with many of the allied spasms, such as tics and habit spasms, are intimately dependent on physiological alterations of muscle-tone, which in the last analysis is intimately bound up with an integral part of the function of the cerebral cortex and is one more link in the proof of the cortical origin of the disease.

4. Surgical Importance of the Parathyroid Glands.—N. Ginsburg discusses the possibility of the removal of the parathyroids by confusing them with the closely contiguous lymph nodes and the dangerous consequences that might result when removing one or more lobes of the thyroid. The lymph nodes are numerous in the region of the thyroid, and the positive recognition of a parathyroid by its separate arterial twig no longer holds true since numerous lymph nodes are similarly provided with vessels springing from the inferior thyroid artery. This is especially true in the case of the small pretracheal lymph nodes lying just below the lower poles of the lobes of the thyroid gland.

8. Toxemia and Eclampsia in the Newborn.—E. V. Davis calls attention to the danger of the transmission to the newborn infant of the toxemia of the eclamptic mother. The child may be stillborn or asphyxiated, or may die in a few hours from convulsions. A certain number, however, of greater resistance survive, but these seldom fail to show some results of the mother's disorder. If, as the result of the care given to them by the obstetrician, they survive, they often go to swell the number of weaklings. A large number of them become cases of icterus neonatorum. A certain proportion of them may be relieved and their lives saved by careful attention to the elimination of the toxin through the bowels and the kidneys. The author believes that it is a mistake to put the child immediately to the mother's breast, and advises in preference the employment of a healthy wet-nurse. She has some faith in small divided doses of calomel and bicarbonate of soda, with an initial dose of castor oil and plenty of sterile water to flush the bowels. Weakened solutions of fennel or chamomile with a little sugar for a few days are also favored, and if the temperature rises, two or three drops of sweet spirits of niter to establish the urinary excretion. Overdosing should be avoided, especially of calomel, as bowel hemorrhages are not uncommon. The milk of the toxic mother contains toxic ingredients and is the cause of infantile indigestion and its results.

9. Air, Food, and Rest in the Treatment of Pulmonary Tuberculosis.—By L. Brown. (See MEDICAL RECORD, April 27, 1912, page 831.)

11. Stain for Treponema Pallidum.—R. Tunnicliff in studying cultures of *Treponema pallidum* has found that the organism stains readily, usually in two or three seconds, with a 10 per cent. mixture of a saturated alcoholic gentian-violet solution in 5 per cent. phenol. The smears may be fixed in the flame, although no fixation is necessary. The stain is also useful for staining fresh material and for phagocytic experiments. A very thin smear is essential for obtaining a satisfactory stain of fresh material. For phagocytic experiments the stain is left on about three minutes; the smear should not be fixed by heat; after washing and drying, the leucocytes are stained with Leishman's or some other suitable stain.

14. Hematuria.—H. E. Pease and E. L. Miller report a case of hematuria from tuberculosis of the patent urachus. The diagnosis was made first of an infected tuberculous cyst of the abdominal wall and it was excised. The operation was followed by a septic scarlatiniform rash, but the patient did not have the other symptoms of scarlet fever. Hematuria followed six days after the operation. Cystoscopic examination showed that the blood came from an opening in the bladder fundus, and on the eighth day following the first operation they again opened the abdomen through a mid-incision from the navel to the pubis, opening up the old cavity and extending into the space of Retzius. The wall of the incised cavity appeared infected. The open end of the patent urachus was found and this organ was excised, taking a portion of the mural peritoneum with it, down to the bladder fundus, where the heavy cord-like tubular structure widened and fused. The cord and bladder fundus for an inch on all sides of the opening were removed, and the bladder-wall was infolded and closed with catgut sutures. After closing up the wound, the patient did well and the hematuria did not reappear.

1. Fertilization in Relation to Pathology.—J. Bland-Sutton states that while the spermatozoon is the most easily identified of all the varieties of the epithelial cells, the human virgin ovum has no specific characters, being

usually recognized by its situation in the reproductive tissues. If one knew the force which impels the spermatozoon to seek the ovum many facts would be plain in pathology. In this connection there is cited the selective power of the embryo of the liver fluke for the pond snail. This embryo has been tested with all the common forms of pond and river snails, but it refuses all except occasionally very young specimens of *Lymnæa peregra* and in this development is arrested at an early stage. A good example of disturbed metabolism leading to changes in the sexual glands and in the secondary sexual characters, is that known as parasitic castration, discovered in 1887 by Geard. When the male spider crab is parasiticized by the sacculina, the former undergoes an extraordinary transformation and acquires the external characters of the female crab. The sequel is even more remarkable, for when the parasatic barnacle leaves its host the crab recovers, and in the case of the male crab which has assumed female characters, the testis not only regenerates but becomes a true hermaphrodite gland capable of producing ova and spermatozoa. At an early stage in its development the human embryo is hermaphroditic. Vestiges of the male reproductive organs are present in the female and many vestiges of the special female organs exist in the male; some are present in the gonad itself, whether it be an ovary or a testicle. It is an interesting fact that in the male spider crab the testis, under the influence of parasitism, can produce ova. Although there is an enormous distance between crustaceans and man, these observations do bear on those rare instances in which dermoids arise in the testicle, for these remarkable tumors in men and in horses, though usually described as testicular, really arise in the ovarian vestiges known as the rete testis.

2. **Clinical Diagnosis of Cancer of the Body of the Uterus.**—T. W. Eden states that cancer arising in the body of the uterus is a clinical entity, differing from cancer arising in the cervix in its relative infrequency, in attacking women of a lower degree of fertility and of a more advanced age, and in showing no special relation to poverty and insanitary conditions. The initial symptom of cancer of the body of the uterus may be merely a bloodstained discharge, thin, watery, and odorless, the blood content being at first slight and intermittent. Later the amount of blood lost becomes larger and continuous, with occasional irregular hemorrhages of a definite, but seldom of a profuse, character. Still later pain is superadded to these symptoms; the pain is seldom severe, and shows this common characteristic of the pain of malignant disease, that at night it is as bad as, or worse than, in the daytime. Profuse hemorrhage rarely occurs in either carcinoma or sarcoma of the uterine body before the terminal stages are reached, and in many cases not even then. As regards the changes discoverable in the body of the uterus it is noted that as a rule the only change which can be discovered is a moderate degree of enlargement of the body of the uterus. As a rule the cervix is found to be healthy. In earlier cases, on the other hand, where the symptoms have been of very brief duration, or where, although there is bleeding, definite enlargement is not made out, curetting for diagnosis is the proper course to pursue. When the operation is done under such circumstances the condition will often prove to be innocent. When curetting is done in this way for diagnosis the whole of the scrapings should be carefully collected, and placed immediately in about an ounce of normal saline solution to which one or two drops of 40 per cent. formalin may be added. In the differential diagnosis there are only two conditions which one needs to consider, namely, senile endometritis and uterine fibrosis or chronic metritis. Senile endometritis occurs at much the same time of life as malignant disease of the uterine body, for it is essentially a postclimacteric affection. The prominent symptom is, however, a purulent and usually offensive discharge; bleeding is often entirely absent, and when present is never considerable. Uterine fibrosis or chronic metritis differs from malignant disease both in its general incidence and in the kind of hemorrhage to which it gives rise. As a rule, the subjects of this disease are considerably below the age of uterine cancer, and as menstruation has not ceased the prominent symptom is menorrhagia; in severe cases irregular losses also sometimes occur, and altogether the hemorrhage is a good deal more than is usually the case with cancer. A leucorrheal discharge is commonly present in the menstrual intervals, but there is no admixture of blood, nor does the discharge show any tendency to become offensive. The history is prolonged and the advance of the symptoms very slow. The uterus is generally enlarged, though not so much as in cancer; its shape is normal and its consistency unusually hard.

1. **Fertilization in Relation to Pathology.**—By J. Bland-Sutton. (See page 1155.)

2. **Age and Type of Patient in Appendicitis.**—W. Billington believes that delay in the treatment of appendicitis is dangerous and unjustifiable in the case of children under 12, and adults over 40. Operation should follow immediately when a definite diagnosis of acute appendicitis has been made in these two classes of patients. The reason for this statement is not that many of these patients may not recover without operation, although the percentage of such recoveries is considerably below the average of all cases, but that the mortality associated with late operation is so great. In other words, if the disease progresses, and it is much more likely than usual to do so, many patients will die in spite of late operation. One reason why a higher proportion of children diagnosed as suffering from appendicitis develop dangerous complications is probably due to the fact that the milder forms of the disease are more often overlooked than in adults. Attacks of abdominal pain, vomiting, and bowel disturbance are very common in young children, and catarrhal appendicitis is easily, and probably frequently, overlooked. In elderly people acute appendicitis manifests peculiarities which may lead to error. The course of the disease is very insidious. The symptoms and objective evidence furnish no certain guide to what is going on inside. The temperature, pulse, and general condition often induce a false sense of security, which is rudely disturbed too late. It is not unusual to see a man lying comfortably in bed with a comparatively slow pulse, and an almost normal temperature, who expresses himself as not feeling ill, and who yet has a gangrenous appendix and a rapidly spreading peritonitis. In the elderly, as in children, the pathological condition is more often such that spontaneous recovery is impossible. It is common, even at an early stage, to find the appendix gangrenous in almost all its length and with little or no evidence of an attempt to localize the infection. This probably accounts for the fact that the early reflex symptoms are so little marked.

3. **Primary Closure of the Abdominal Wound in the Operation for Acute Appendicitis.**—J. G. Andrew favors this procedure in preference to drainage, when the

offending organ has been efficiently removed. The risks supposed to be associated with primary closure of the wound are as follows: (1) A peritonitis which has been confined to a circumscribed area around the appendix might become general. In the author's opinion, if the resisting powers of the tissues themselves be not sufficient to prevent extension of the peritonitis drainage will not help them. (2) Extension of the septic process may occur along the colon or into the pelvis, and a subdiaphragmatic abscess may form as a result of the former and a pelvic abscess as the result of the latter. Each of these conditions may happen, but each has happened when free drainage has been employed. (3) A localized abscess may form at the appendix region itself. This can, however, be treated as in the primary lesion. (4) Infection of the wound may occur. The advantages of primary union are so apparent that they need not be elaborated. The possibility of subsequent hernia is reduced to a minimum. The formation of a fecal fistula is not encouraged.

4. **Early Diagnosis and Operation in Appendicitis.**—J. H. Dauber contends that when the diagnosis of this condition has been made recourse to operation should follow as surely as night follows day. Appendicitis is what every medical man should be constantly on the lookout for; 90 per cent. of all acute abdominal emergencies are due to mischief in the appendix. It is infinitely commoner than ruptured gastric ulcer, acute pancreatitis, impacted gallstones, or strangulated bowel. The pain in the beginning is not always localized in the appendix region, but may be referred to the umbilicus or elsewhere in the abdomen. There may be nausea, there may be a rise of temperature and an accelerated pulse, but there nearly always is as a constant symptom tense rigidity of the right rectus. This is the key to the situation. It is nature's effort to protect a sick appendix. This rigidity in conjunction with two or more of the recognized classical symptoms should make diagnosis no very difficult matter. In women it is not always easy to differentiate chronic appendicitis from chronic right tubal or ovarian mischief, but these are chronic cases, and careful examination per abdomen and per vaginam may help one, but the author has seen several cases where even at the time of operation, and subsequently by pathological examination, it was quite impossible to say whether the appendix or the right tube and ovary were first affected. Both appendix and tube have been matted together, both inflamed and involved in a similar infective process. It is safe, perhaps, to conclude that if the opposite tube is normal the mischief arose in the appendix, but if both tubes are the seat of pyosalpinx or salpingitis then it is probable that the appendix became involved secondarily. It has been said that he gives twice over who gives quickly, and Dauber paraphrases in saying that the surgeon confers a double benefit upon his patient who operates quickly as soon as appendicitis is diagnosed.

6. **Postoperative Rupture of Abdominal Wall.**—A. G. Stewart states that rupture of the abdominal wall is a postoperative sequel of which little mention is made in the textbooks of surgery, although it is not a very rare occurrence. He refers to the cases in which the approximated edges of the abdominal wound completely separate, and the intestines are extruded through the opening, and not to the common presentation of a knuckle of bowel after removal of a drainage tube. It is most commonly found after suppuration, and frequently after a stitch abscess which burrows among the muscle. It would appear that the omentum, in addition to its many other uses, tends to prevent such an accident. In a series of experiments on cats, Wilkie found that when sepsis developed after abdominal operations, 5 per cent. died from rupture and prolapse of the viscera; where, however, he had removed the omentum, 85 per cent. died from prolapse. He therefore advises that when an abdominal wound has been exposed to infection the omentum should be spread out behind it before suturing up the abdominal wall. Other causes of abdominal rupture are the too early removal of stitches and the too great hurry in giving the patient up after operation. The accident frequently occurs in stout individuals, and in those debilitated, for example, by carcinoma. Straining for any reason, such as postoperative vomiting, bronchitis, or tenesmus, tends to favor the accident, while, lastly, the employment of catgut as an abdominal suture is said by the author to favor its production.

Berliner klinische Wochenschrift.

May 27, 1912.

Anemia Splenica Cured by Splenectomy.—Klemperer and Mühsam report what the former terms an illustration of the finest advances of the present day, accomplished by the resources of medicine and surgery combined. The diagnosis was made through refinements in our knowledge of medicine and the cure effected by a major surgical operation. The patient was in a miserable condition from anemia and emaciation and had a large splenic tumor. It was necessary to exclude the presence of leucemia and aleucemia which was done in part by study of splenic puncture fluids. The diagnosis therefore appeared to be Banti's disease, a term to which Klemperer objects, preferring that of splenic anemia. Concerning the intimate nature of the affecttion nothing definite is yet known, but futile attempts were made to determine whether the splenic tumor could have a syphilitic or lymphomatous component. The blood was normal save for the diminished erythrocytes. There was some tumefaction of the liver. The patient grew worse and since in true Banti's disease extirpation of the spleen has saved life this operation was performed with complete success. The outcome depends entirely on a correct diagnosis, for had the tumor been due to aleucemia or syphilis or some other forms of splenomegaly the operation would of course have been contraindicated. Only the fact that the general state was due to the splenic affection made the complete recovery of the patient the natural result.

Antibiosis of Cancer and Leprosy.—Soegaard, who showed not long ago that for Scandinavia at least lepers almost never become cancerous, has extended his researches into the autopsy records of leprosy throughout the world. The same antagonism seems to be everywhere apparent, and he seeks to explain it as follows: Leprosy is a typical chronic infectious disease characterized by progressive suppuration and eventually visceral degeneration (amyloidosis) and marasmus. There is a notable percentage of enteritis, severe and obstinate in character. Sepsis, pyemia, and erysipelas menace the patient. Despite all this bad predisposition the leper readily throws off the attack of the microorganisms, causing these complications, and he seems often to acquire immunity to them. Leprologists state that wounds of a leper readily heal. This fact has been attributed to the great rapidity with which leprous blood coagulates. The latter is believed to contain about four times as much fibrin as normal blood. Whatever the nature of these blood changes they must be of such character as to render it almost impossible for cancer to make headway against them. The patient who develops cancer is as the author has elsewhere shown one who has very often been highly resistant throughout his life to the attack of ordinary pathogenic germs. That there is any natural antagonism between the two diseases does not follow, for others who have developed immunity as a result of chronic suppuration would perhaps be equally able to resist cancer.

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

THE PHYSICAL EXAMINATION.

Walls of the Arteries.—While taking the pulse, the examiner should always note whether there is any thickening or degeneration of the radial or temporal arteries. In some unaccountable way, the precaution is often omitted notwithstanding its importance.

Full distended vessels with a moderately high blood pressure sometimes give rise to the impression that the walls are thickened. A simple way to eliminate this error is to subject the brachial artery to sufficient pressure to bring the pulsations at the radials to an end. This is effected by forcibly squeezing that artery between the finger tips under one side of the lower end of the biceps muscle and the thumb under the other. The vessels then being empty, it is an easy matter to ascertain if the walls are thickened.

Another point of importance is to examine the radials and temporals on both sides. It is not uncommon to find one radial almost normal and decided thickening in the other.

The presence of thickening or degeneration in any of the vessels should lead to rejection by the examiner. Examiners make the statement too frequently that "the arterial walls are no thicker or harder than is usual for a man of his age," when they are reporting on applicants over 50 or 55 years old. This statement will always call for criticism, as a life insurance company which does not write policies adapted to substandard risks only accepts applicants without pathological changes at any age.

Varicose Veins. Varicose veins are of no importance ordinarily and reference to them may be omitted from the report in mild cases. If they are marked or extensive, however, the condition should be fully described, and it should particularly be made clear as to whether or not there is any involvement of the veins other than those below the knee joint and whether a proper supporting apparatus is used. The examiner should also look for evidence of present or recent ulceration.

The Heart.—The examination of the heart is often a difficult matter and will be of little value unless a full exposure of the chest is secured in accordance with the scheme and diagram presented in a previous section on "General Methods in the Physical Examination." When this precaution is fully observed, not only will the ear be assisted in detecting obscure murmurs, but it will also be impossible for the examiner to be deceived into hearing the systolic murmur which may be produced by a vigorous action of the heart against a thin chest wall covered by a thick underwear or a starched shirt.

It is imperative that the place of examination be one in which there is complete freedom from noise or distraction, as the most acute ear may fail to detect a faint murmur or to differentiate a functional from an organic murmur under unfavorable conditions.

It is difficult to localize the different valvular areas and sites of cardiac murmurs if immediate auscultation with the unaided ear is employed, and on account of this objection as well as on the grounds of delicacy and cleanliness, the examiner should always use a stethoscope for the examination of the heart.

It is the purpose of the writer to confine these remarks to the practical points which are especially applicable to examination for life insurance and to direct the attention to the most common of the so-called functional murmurs which frequently have to be differentiated from those depending on an abnormal condition. The reader is referred to the text books for a complete account of diagnostic methods.

One procedure, fairly well known but not often resorted to, for timing a heart murmur may be recommended. An examiner not infrequently experiences trouble in definitely deciding whether a murmur is systolic or diastolic, and in such a case he may gain assistance by comparing the time of the murmur with the pulsation in the radial or carotid artery. If the murmur occurs simultaneously with the pulsation in the arteries, it is probably systolic; if it is heard in the intervals between the pulsations it may be regarded as diastolic.

A few examiners have the conviction that some applicants with heart murmur are good risks in view of the apparently slight involvement of the valves and of the good physical condition otherwise. The position of the companies in this respect should be plainly understood. It is unquestionably true that a few subjects with defective valves attain great longevity, but it must be kept in mind that the requirements of the companies are based upon the great law of averages and that individual cases can not be recognized except when they are being rated up, especially as there is no reliable way of selecting the few who are going to survive the others. The average death rate among applicants with defective valves is so heavy, notably so after the age of 50, that it is difficult to impose an adequate rating on their lives.

Companies which confine their business to standard risks will decline all applicants indiscriminately when the heart sounds indicate a departure from the normal. The guarantees in endowment policies are so liberal that the loading in them is not sufficient to cover the hazard in cardiac lesions. Those companies, however, which write substandard policies are interested in the character of the murmur and the situation of the valve involved, as they are inclined to consider each case on its merits and rate up the risk according to the prognosis of the particular form of heart disease in question. Every examiner will, therefore, be expected by the substandard companies to have a clear conception of the various cardiac areas and to furnish a definite description, so that the rates can be adjusted at the home office. No examiner can gauge the exact condition existing by the intensity of the murmur; a serious condition may be indicated by a faint murmur, and, on the contrary, a loud murmur may arise from a slight lesion.

Judging Nutrition by Abdominal Fat.—Oeder has made numerous measurements of the thickness of abdominal fat, lifting up a fold of the skin near the umbilicus and using a compass for telling its size. He thinks that such measurements give a good indication of the general state of nourishment of individuals, and advises that standard average figures should be obtained in this fashion for three groups: thin, normal, and fat persons. The actual measurement in centimeters should likewise be given.—*Medizinische Klinik*, No. 17, 1910.

Book Reviews.

PRACTICUM DER PHYSIOLOGISCHEN UND PATHOLOGISCHEN CHEMIE. Nebst einer Anleitung zur anorganischen Analyse für Mediciner. Von Dr. E. SALKOWSKI, Prof. o. h. an der Universität, Geh. Med.-Rat und Vorsteher der chemischen Abteilung des Pathologischen Instituts zu Berlin. Vierte vermehrte Auflage. Price 8 marks. Berlin: Verlag von August Hirschwald, 1912.

For many years Salkowski's little book has been regarded as one of the most useful of the many laboratory guides. In most concise form, it contains an unusual amount of information, and the successive editions have kept it well up to date. The present one has been enlarged by the addition of two sections, one on the quantitative determination of the ferments, and the other on the quantitative methods employed in studying autolysis. The changes in the body of the book do not appear to have been very numerous, and in some instances rather important procedures of recent date have not been included. For instance, the use of benzidin is not mentioned among the blood tests, the Schlosing method is the only one described for determining ammonia in urine, although it requires two to three days, and is inaccurate even at that, no reference is made to the centrifugal methods for determining the fat content of milk, the only urea methods given are the antiquated Liebig method, and the troublesome one of Morner and Sjoqvis, etc. None the less, the book is most valuable and deserves a place in every biochemical laboratory.

BLAIR'S POCKET THERAPEUTICS. A Practitioner's Handbook of Medical Treatment. Based Upon the Most Authoritative and Practical Methods and a Rational Treatment of Symptoms. Containing many means not commonly mentioned in the textbooks, and a plan for the solution of the vexed question of drug dosage. By THOS. S. BLAIR, M.D., Neurologist, Harrisburg (Pa.) Hospital; Author of "A Practitioner's Handbook of Materia Medica" and of "Public Hygiene"; Member American Medical Association, etc. Price $2.00. Philadelphia: The Medical Council Co., 1911.

THIS pocket volume contains a condensed account of some of the methods of treatment. The main novelty in the work is the author's plan of suggesting the size of the dose of a medicine by the size of the type in which it is printed. For example, when the author would use aconite in large doses, "ACONITE" appears in large type; when he would suggest moderate doses, "aconite" is printed in ordinary type; and when small doses seem to be indicated, *aconite* is printed in italics. To the reviewer this novelty seems to be a most treacherous pitfall; for, besides having to recall the pharmacopeial dosage of a given preparation, the user of this work will have to remember in addition whether Blair has it printed in caps, lower case, or italics. The opportunities for mistakes in dosage are thus increased. This is, however a personal opinion; and there may be physicians who are capable of using this method to advantage. The book has much in it of worth, and the personal element is quite prominent; the articles on hysteria and gynecological headaches and reflexes (for example) are refreshing and valuable. The book is printed on thin paper and contains quite a number of misprints and misspelled words.

PRACTICAL ANATOMY. The Students' Dissecting Manual. By F. G. PARSONS, F.R.C.S. (Eng.); Lecturer on Anatomy at St. Thomas' Hospital and at the London School of Medicine for Women; Examiner for the Fellowship of the Royal College of Surgeons of England; formerly Hunterian Professor at the Royal College of Surgeons of England; and Examiner at the Universities of Cambridge, Aberdeen, London, and Birmingham; and WILLIAM WRIGHT, M.B., D.Sc., F.R.C.S. (Eng.), Lecturer on Anatomy at the London Hospital; Examiner at the Royal College of Surgeons of England and at the Universities of London and Bristol; formerly Hunterian Professor at the Royal College of Surgeons of England. In two volumes. Price $2.40 each volume. New York: Longmans, Green & Co.; London: Edward Arnold, 1912.

IN size and general appearance these volumes are much like Cunningham's Practical Anatomy, but it will be found that they do not contain quite so much as the older work. The authors do not slavishly follow in the fashionable path, but dare to think for themselves. In the preface they say: "The question of nomenclature has given us much anxious thought, and we have come to the conclusion that the time is not ripe for the exclusive adoption of the revised anatomical nomenclature. We do not dare, for instance, to send a student to the wards understanding that the radial nerve is a structure in the upper arm when, to his surgeon, it is a structure in the forearm." The work commences with some general hints on dissecting and then follow the same general plans as other works on the same subject. The only fair way to test a book of this kind is to work with it for a term in the dissecting room; this we have not done. Each volume is indexed separately. This, we think, is a mistake. There should be an index to the complete work at the end of each volume. And books intended for laboratory or dissecting room use should be so bound that they will readily lie open at any given place.

PELLAGRA. An American Problem. By GEORGE M. NILES, M.D., Professor of Gastroenterology and Therapeutics, Atlanta School of Medicine; Gastro-Enterologist to the Tabernacle Infirmary, Atlanta Hospital, and Atlanta Antituberculosis Association; Attending Physician to the Tabernacle Infirmary Annex (for Pellagra). Atlanta, Ga. Illustrated. Price $3.00. Philadelphia and London: W. B. Saunders Company, 1912.

A MALADY which has been known for two centuries, which has been reported and more or less studied for 150 years, which has been found in more than half the States of the Union, and whose etiology is still unknown, may well be termed "a problem." Further, it is a problem which concerns every physician and every citizen, especially in the South. The present volume is the latest contribution to the subject, and in a general way it may be said to be quite up to the standard of the previously published volumes and papers on pellagra. We miss, however, the splendid bibliography which was a feature of Lavinder and Babcock's volume. We do not like the look of "erythema multiforma" and "lupus erythemata"; and the first sentence on page 138 is somewhat remarkable in its construction. The book represents the author's contribution to the study and possible solution of "the problem," and it is commended to the attention of other students in the same field.

DIE RÖNTGENDIAGNOSTIK DER MAGENKRANKHEITEN. Von Dr. M. FAULHABER, Privatdozent an der Universität Würzburg. Mit 28 Abbildungen im Text. Price per volume (8 parts) 10 marks; single parts, 2 marks. Halle: Carl Marhold, 1912.

FAULHABER says that three symptoms permit us to make the diagnosis of gastrectasy by means of the *x*-ray:

(1) Increase in size of the organ. (2) Retention of food. (3) Visible pathological peristalsis. Before discussing these three cardinal symptoms Faulhaber gives the classical *x*-ray picture of gastrectasy caused by a pyloric stenosis that had been in existence for years. If such a patient is given a Bismuth meal in the morning in the fasting condition it will be found that only the lowest part of the stomach is filled in the shape of a very broad and low semilunar area. Its upper level is nearly horizontal and sometimes straight. One particularly characteristic peculiarity is the fact that the semilunar area projects markedly to the right. We distinguish therefore nothing of the pylorus nor of the body of the stomach. Above this bismuth crescent there is no air but an intermediate layer consisting of masses of retained food which are always present in these cases, and for this reason the bismuth layer does not show a sharp and mobile upper boundary. There is only very little air in these stomachs; only a small flat air bubble is usually visible directly below the diaphragm.

The book is a very useful one and can be highly recommended.

RAPID CALCULATION AND MILK MODIFICATION CARD. By JAMES HERBERT YOUNG, M.D. Boston: F. H. Thomas Company, 1912.

THIS handy device consists of a celluloid envelope open at the top, into which are inserted a series of celluloid cards containing tables of figures. These figures may be seen through small windows in the envelope, which are cut out in columns marked respectively fat, proteid sugar, and whey. The cards contain tables suitable for mixtures of 20, 32, 40, and 48 ounces respectively. Thus to obtain any desired percentage of fat, proteid or sugar, or any required number of calories, or to determine the percentage of sugar contained in any given amount of whey, all that is necessary is to move the appropriate card up and down in the envelope until the given figures appear at the small windows, when the figures in the various columns may be read off at a glance. The device is a most simple and convenient one, and should prove of value to both the pediatrist and the general practitioner.

Society Reports.

AMERICAL MEDICAL ASSOCIATION

Sixty-third Annual Meeting, Held at Atlantic City, N. J., June 3, 4, 5, 6, and 7, 1912.

(Special Report to the MEDICAL RECORD.)

SECTION ON DISEASES OF CHILDREN.

(*Continued from page 1122.*)

Wednesday, June 5—Second Day.

DR. ISAAC A. ABT OF CHICAGO IN THE CHAIR.

The Menace to the Young Child of the Common Infectious Cold.—Dr. THOMAS SOUTHWORTH of New York brought out the fact that besides the injury of the cold itself upon the development of the child, it frequently caused otitis, pneumonia, sinus infections and interference with nutrition. He thought that the lack of appreciation of the injurious effects of colds was partly due to the terminology and that if bacteriological investigation could determine a proper classification they would be understood and guarded against. He believed that the most prolific source of infection in young children was from visitors and other members of the family, while in older children the kindergarten, the school, trains, and hotels were largely responsible.

Dr. ENGLISH of Summit, N. J., said that a certain number of colds were caused by the influenza bacteria which produced a prostration, an effective remedy for which was iron and sodium and caffeine benzoate in moderate doses every hour.

Dr. ZAHORSKY of St. Louis thought that most acute diseases of the upper respiratory tract were due to germs communicated by others. He said that he thought that the term "grippe" was better for this class of infection than the term "cold."

Dr. MCCLANAHAN of Omaha said that in nursing mothers he had cautioned against coughing and sneezing near the child, and even the protection against her breath by the use of a mask or handkerchief. In a series of eleven cases that had developed nephritis he found five giving no other etiological factor than a common cold.

Dr. SCOTT of New York said that he did not believe that the cold required so much emphasis as the fact that it prepared the way for the invasion of other bacteria which are more or less universally present.

Dr. MCCLEVE of California said that in his practice he treated the well as well as the ailing members of the families, using as his remedies of choice hexamethylenamine and benzoate of soda. He said that in one tuberculosis sanatorium he had heard it reported that when one inmate had a cold a vaccine from his excreta was prepared and inoculated into the others.

Dr. KERR of Brooklyn said that most healthy children carried numbers of germs which, after a cold, found a field of invasion, therefore precautions were necessary. He deplored the practice of housing in, without fresh air, the child with a cold. He believed that if one exposed to infection had plenty of fresh air he would be more apt to throw off the symptoms. He did not believe that the temperature of the air was of importance because all air reached the lungs at uniform temperature through the act of breathing.

Dr. SEDGWICK of Minneapolis reemphasized the necessity of eliminating the idea of simple colds from these infections in order to educate the laity to a realization of their danger.

The Properties, Uses and Indications of the Various Carbohydrates in Infant Feeding.—Dr. HENRY DWIGHT CHAPIN of New York presented this paper, stating that this general term referred to a chemical combination of carbon and water. He said that its function was to supply carbon which would liberate energy and heat when oxidized. In infant feeding there were five forms of carbohydrates used, namely, starches, dextrines, maltose, saccharose, and lactose. He thought that some required cooking and predigestion for proper assimilation: others could be taken directly into the blood and the form should be determined by the findings of each individual case.

Dr. DOUGLAS of Detroit said that his experience had been that children would digest a definite amount of casein, irrespective of the addition of corbohydrate. He believed in the addition of starch in its solid form as soon as the child would take it.

Dr. GRIFFITH of Philadelphia called attention to the fact that the feeding of normal infants was simple, while adjustment of foods to sick children required skill and care.

Allergy to Common Foods: 1. Idiosyncrasy to Hen's Eggs.—In reading this paper Dr. OSCAR M. SCHLOSS of New York brought out the fact that idiosyncrasy to hen's eggs was far more common than is usually supposed. He said that while single symptoms might present in many cases, it was not uncommon to have them all in a single case. He had found the general symptoms to be first gastrointestinal, then cutaneous, and, lastly, general. He said that the recent experimental work on anaphylaxis seemed to indicate that the underlying cause of the idiocynerasy was protein sensitization or hypersusceptibility of the patient. Experiments showed that the blood of these patients produced a reaction capable of sensitizing guinea pigs to egg white. The condition might be inherited or acquired. In his cases he had succeeded in establishing complete immunity by the careful administration of small quantities, gradually increased until any amount could be tolerated.

Dr. MILLER of Atlantic City said that his daughter had shown an idiosyncrasy, but in her case it was only for the yolk of the egg—the white causing no disturbance. He had therefore come to the conclusion that there was some poisonous alkaloid present. He thought that the symptoms were much like those of ptomaine poisoning.

Dr. DENNY of Brookline, Mass., reported a case in which there was not only gastric disturbance, but local disturbance from application to the lips. A child of two, in his practice, had been made violently ill after eating but a mouthful of egg. At another time an egg shampoo was used on the same child's head, with an immediate swelling of all parts of the skin that the fluid touched. She had since been gradually immunized so that she could tolerate egg.

Dr. ZAHORSKY of St. Louis thought that possibly a test of idiosyncrasy could be made by rubbing egg upon the lips, but in view of Dr. Schloss' finding that all did not show the cutaneous infection, doubted its reliability.

Dr. DOUGLAS of Detroit thought that care should be exercised when one had determined to alternate a milk diet with egg, to first determine that there was no such idiosyncrasy.

Dr. RICH of Detroit had noticed a similar anaphylaxis in the milk of nursing mothers. He cited a case of an infant five days old which presented the clinical picture outlined, and which when put on barley water recovered, to renew her symptoms when put back to the breast.

Dr. ABT of Chicago called particular attention to the violence of the symptoms, saying that it was usually by accident that the cause of the clinical picture was attributed to this idiosyncrasy.

Dr. SCHLOSS in closing said that he had not before heard of a case in which the yolk of the egg produced the condition and the white did not. He could not explain the variation. He could offer no explanation of the symptoms presenting in the case of the disturbance from mother's milk, no work having been done upon that subject.

Tuberculosis of the Mesenteric Glands in Infants.—Dr. FRITZ B. TALBOT of Boston concluded from his studies and observations that tuberculosis in the young was almost uniformly of the glands. The mesenteric glands being so intimately connected with digestion, when they became diseased they disturbed the normal digestive process. He thought that if a sufficient number became diseased they formed a wall through which the fat could not pass, and it was thrown off in the stool. He therefore advanced the idea that where large amounts of fat were taken in the food a secondary intestinal indigestion might result, whereas if fat was removed from the food the child would improve. He thought the food should be regulated according to stool findings and in all conditions where the disease had progressed to the point of checking the lymphatic system, fats should be withdrawn and their place supplied by carbohydrates.

Dr. DENNETT of New York wished to know if postmortem any of his cases showed lung lesions.

Dr. JOHNSON of Grand Rapids thought it unwise to say that because fats appeared in the stools an obstruction had occurred. He thought that without question in conditions where the liver was involved there would be poor fat absorption so that it would be unwise to argue backward from that to a diagnosis of tuberculosis of the glands.

Dr. PISEK of New York thought that children suffering from malnutrition would also show poor absorption of fats, and their reduction would improve the condition of the child.

Dr. TALBOT in closing said that only two cases came to autopsy and they showed rather remarkable findings, nor-

mal lungs, and unmistakably tuberculous glands. It was said that this study was not of metabolism, but of clinical observations coming in routine hospital service. In making the usual examinations of the stools they happened to see the fat coming through in the stools of many cases, notably in all jaundice cases, but they did also find it in these cases of tuberculous peritonitis. He called attention to the fact that many tuberculous children were fed cod liver oil and olive oil and said that in the light of these examinations he thought it had practice.

The Caloric Requirements of Bottle-Fed Infants.—By Dr. ROGER H. DENNETT of New York. He said that the percentage designation of food proportions was misleading, it being better to get into the habit of thinking in calories. He said that while caloric needs differed in normal, atrophic, and very fat babies, still careful record keeping would enable one to determine the minimum number of calories on which a baby would gain in weight. He showed a number of charts from his practice showing that approximately 120 calories were the average food requirement.

Dr. PISEK of New York disagreed with the method of caloric feeding, saying that the object of feeding was to obtain growth.

Dr. TALBOT of Boston thought that the variation in the food properties of cow's milk discounted to a certain extent the findings shown by such charts. He thought that both percentage and caloric measures should be used in determining the proper amount of food, but that in every case the needs of the particular infant should be the guide. He said that in his practice he had fed as high as 160 calories per kilogram, while on the other hand he had had an infant thrive on 80 or less.

Dr. DOUGLAS of Detroit said that these findings were not applicable to babies that had been damaged by feeding, and urged the necessity of explaining diet requirements to mothers to get their cooperation in feeding properly and in not too hastily changing foods.

Dr. MORSE of Boston called attention to the fact that every food should be adapted to the individual child.

Dr. CHAPIN of New York said that mere calories had nothing to do with the feeding of the child, that 120 calories of something that would produce no growth at all could be given. Therefore growth was the criterion.

Dr. DENNETT in closing said that the idea he intended to convey was the addition of caloric measurements to percentages. He thought that the fat content in different samples of cow's milk would be so small that when divided as it was in infant feeding there would be nothing that could really be taken into consideration. One of the charts showed a baby weighing but six pounds at two and one-half months of age, which had come up nicely under this method. He thought that there would be few whose nutrition would be below this point.

The Relation of the Infant Welfare Movement to Pediatrics.—Dr. THOMAS B. COOLEY of Detroit showed the scope and importance of this movement in relation to preventive medicine. He considered its most important development the education of mothers, prospective mothers, and young girls in the care of themselves and children. He called attention to the grave danger of the work being taken over too soon by the health departments before standards had been set or dignity given it. His plea was for the cooperation of pediatrists and the absolute necessity for their affiliation with the welfare associations.

Dr. DOUGLAS of Detroit said that the pediatrist is the only one who is capable of directing the public on this subject upon lines that will not need to be reversed in a short time.

Dr. PISEK of New York said that he had been actively engaged in this work in New York. He thought that for some time it should be in the hands of private philanthropists, and that with the cooperation of social workers and pediatrists the work could be mapped out in a way to be carried on successfully by the health boards when the public had been educated up to it.

Dr. HILL of Philadelphia called attention to the "Baby Saving Shows" now going on in Philadelphia under the direction of the leading pediatrists. He said that the interest shown was remarkable and indicative of possibilities for great good.

Dr. JOHNSON of Grand Rapids said that since their exhibits and instruction of prospective mothers the mortality of infants had decreased 55 per cent. last year from the mortality of the five preceding years.

Dr. KERR of Brooklyn lamented the fact that the pediatric societies had not the standing they should have, and feared from this report that the health departments would too soon undertake entire supervision of the work.

Dr. HOWE of Albany said that the health departments had no desire to undertake the work, save under the guidance of pediatrists, and said that there was far more danger of the pediatrists not taking the interest in it that they should.

Dr. MCCLEVE of California said that the statement in the paper that the milk philanthropy had not been productive of good should not go unchallenged. He said that the feeding was the very first consideration, therefore pure supplies of milk were the first step in child welfare.

Dr. HARRINGTON of Milwaukee said that in their city the work had been started by a social worker in August, 1911, and had proven very successful, showing a decrease in infant mortality in the one district in which it was carried on of over 60 per cent. He said that it had been since put into the hands of a physician with a visiting nurse to look after home conditions. He called attention to the practice of newspapers of giving birth records, thus furnishing patent-food manufacturers with mailing lists for their samples, and thought that if the custom was common the postoffice authorities should look into it. He called particular attention to the necessity of the physician undertaking such work being a sociologist.

Dr. ZAHORSKY of St. Louis said that he thought the difficulty would be in getting pediatrists to agree on any rules for feeding, care, etc.

Dr. COOLEY in closing said that he did not intend to convey the impression that there were few competent pediatrists, but there were too few of any sort who would undertake this work, as had been shown by the inability of the promoters of the work to get them. He said that in his statement that milk philanthropy was a failure he meant that the giving of pure milk, without instructions as to how to keep it clean, how to prepare, and how to administer it, which came under education, had been a failure. He thought that there would be no difficulty in getting pediatrists to agree on a diet for normal children, that when controversy crept in it was in the case of sick infants, and that was a matter for determination in each individual case.

The Value of the Social Service Department to the Children's Dispensary.—Dr. MAURICE OSTHEIMER of Philadelphia read this paper, showing that as a result of their work many conditions deemed incurable by parents had been either cured or greatly improved. He said that within twenty-four hours after a child had been to the dispensary the social service department nurse visited the home to investigate conditions—sanitation, housing, hygiene, food, illness, work, etc. She saw that all the physician's advice and orders were understood and carried out; left diet lists, corrected abuses or bad habits; and sent the child back to the dispensary. If there were other illnesses in the family she referred them to the hospital. If necessary she helped some to sanatoria, or open-air schools, and secured open-air positions for those who needed them. He said that she worked closely with the Children's Home and Aid Society, often securing wet-nursing-mothers for babies with inanition. By this plan the mortality, especially during the summer, had been greatly reduced.

Dr. FUSSELL of Philadelphia called attention to the marvelous results produced by this work in Philadelphia. The particular feature, he said, was the visiting nurse, who looked into all the conditions, and followed up cases, instructing in care and hygiene. He said that no nurse was expected to recommend any measures of treatment, or in any way to interfere with the work of the physician, but where she found patients with conditions that needed attention, she saw that they got to the physican, who, in turn, recommended them to the proper department for treatment. He said that the nurse visiting the homes acted just as much in conjunction with the physician as any well trained nurse in private practice would do.

Dr. COOLEY of Detroit called attention to the fact that a physician practising among the poor was just as much obliged to be a sociologist as he was to be a physician.

Dr. MILLER of Atlantic City said that in his town (and in some others) proprietary food manufacturers kept two nurses in the town to go and instruct mothers in the preparation and use of their foods, and he thought physicians should discourage such practices, as he knew of quite harmful results accruing.

Dr. DOUGLAS of Detroit thought that physicians were not at fault in that matter, nor that medical teachers were at fault, but that the students themselves did no appreciate the importance of infant feeding and that other professors did not impress it upon them.

Dr. OTHEIMER in closing merely re-emphasized the point that the chief function of the nurse, after the educational

feature was the reference of cases to the physician, she herself not attempting to give medical advice.

Some Reasons for Surgical Failures in Children.—Dr. LeGrand Kerr of Brooklyn read this paper emphasizing the difference between the understanding of surgical success on the part of the laity and the surgeon. He thought that if more careful examinations were made, more consultation with the pediatrist to determine previous illnesses and physicial conditions the diagnoses would be more exact, therefore results better. He thought that the assistants often hindered more than they helped because they were either too interested, paying more attention to the surgeon than to their own work or not interested enough, or not well trained. He said that the anesthetist, too, was frequently not looked upon as a coworker, merely as a tool, and that he did not have an opportunity to do the best for the patient possible because he could not adapt the anesthetic to the patient merely giving what was designated in the quantity desired. He said that until these various procedures, all necessary to surgery, were reconciled and harmonized results could not be what they should and that parents would not be satisfied with a surgery that did not fully equip a child for normal childhood.

Dr. Neff of Kansas City said that the matter of the child's previous history was important. He said that among his cases operations had been done without his knowledge with indifferent results that could have got along much better if he had been consulted as to the child's general condition and previous illnesses.

Dr. Spinney of New York said that under anesthesia the patient was being given a most potent drug, and that unless this was realized by the physician and the anesthetist and every precaution to have it given just right, and evenly balanced, good results could not be produced. He thought that possibly there was as much danger from toxemia as from cyanosis.

Juvenile Psychasthenia.—Dr. Tom A. Williams of Washington, D. C., read this paper. He showed by the cases cited that psychasthenia was a condition characterized by the presence of obsessions. Contrary to the theory of Janet that it did not occur in children, he he had found it in many cases evidenced by morbid fears, mental disorders and day dreaming. Analysis of these cases showed that the psychological mechanism in childhood was the disturbing factor. He traced many analyses of cases in adults to neuroses in childhood. He believed, contrary to Freud, that bodily harm played a more important rôle than sexual excitement. He cited a case of an adult the cure of which occupied a period of eighteen months, due to wrong education of childhood. He thought that dreams did not play as important a part as had been attributed to them, believing that he could get at all of the conditions which they would show much more quickly and easily by direct methods. Pediatrists did not appreciate the importance of the study of these cases, and from the text books imagined them to be very complicated and difficult, while as a matter of fact they were not. He said that merely a common sense view needed to be taken of them, and a little study of the workings of the child mind, which he said he had found far more easily understood than the adult because they were more frank and open. In the two cases of children cited first he saw them each but once for half an hour and was able to make the diagnosis. The other, the boy of thirteen, was much more difficult, but even in this case he saw him but four times for half-hour intervals. He emphasized the necessity of studying these cases just as one would a disordered stomach, applying the treatment to the individual case.

Thursday, June 6—Third Day.

Dr. Thomas S. Southworth of New York read the report of the executive committee recommending the election of Dr. Henry Dwight Chapin of New York as chairman, Dr. J. M. Miller of Atlantic City, vice-chairman, Dr. Frank C. Neff of Kansas City, Mo., secretary, and Dr. Charles Douglas of Detroit for delegate. Upon motion duly made, seconded, and carried the report was accepted.

Methods of Estimating Kidney Function.—Dr. Richard M. Smith of Boston read this paper showing that the functionating powers of the kidney could be determined by the excretion of salt, protein, and iodine, but that the amount of water eliminated was no criterion to go by. Even in normal individuals, he said, there is a large variance in the quantities of water eliminated. He thought that the elimination of urea was valuable, but on account of the difficulty of determining it it was hardly practical. He had employed the test which, by the introduction of phenolsulphonephthalein into the body, enabled him to determine kidney function and from this knowledge make a differential diagnosis in many obscure cases and often an accurate prognosis.

Influence of Climate on Summer Diarrhea of Infants.—Dr. L. T. Royster of Norfolk, Va., read this paper giving statistics showing the relation of mortality and morbidity curves to heat and humidity curves in some twenty-eight cities of the United States from which he determined that when humidity was great a day or two later will show marked increase in the death rate. He had found, however, that ill effects of heat and humidity in white children were cumulative, so that often deaths during the fall months were attributable to excessive humidity in the early summer months. In negro children he thought that almost invariably the death followed in a day or two after the increase in humidity. He advanced his findings to show that humidity did play a part in the production of these conditions and urged the gathering of more careful statistics than were at present possible.

Dr. Hoobler of New York called attention to the fact that while in individual homes conditions of heat and humidity were not readily changed, in hospitals they might be. In gathering data on ventilation problems he had found that as humidity went up the blood pressure went down which he thought might account for some of the deaths from summer diarrhea.

Dr. Pisek of New York thought that unless heat retention in the infant was understood the troubles of the days preceding the hot spell would multiply. He had found the greatest humidity at three o'clock in the morning and after hot waves had placed infants upon substitute diets with marked lessening of gastric disturbances. He thought that the prime factor in reducing mortality was the education of mothers.

Dr. Schwartz of New York said that their death rate frequently went to seventy-one in a single day after a hot wave. He thought that the deaths were due to loss of body moisture because in zones where there are not extremes of heat and cold there is practically no summer diarrhea.

Dr. Rawlings of El Paso, Tex., said that although their humidity was very low, and rainfall but about ten inches during the year, they had a great deal of gastrointestinal disturbance. He thought that they secured best results by removing the children to a higher altitude.

Dr. Hillway of Cincinnati said that the study of summer diarrheas in hospitals, and gathering of such statistics would hardly give a fair estimate of conditions. He thought that visits to tenament homes were necessary to an understanding of the contributing factors. He said that heat produced increased peristalsis and diminution of the functionating power of the stomach, because of the stimulating effect of heat upon the emotions.

Dr. Butterworth of New Orleans said that their greatest humidity was in May and that April, May, and June showed the greatest mortality, although the hottest months were August and September. He said that going farther south he had found freedom from gastric disturbance during the rainy seasons, and that in his practice sending such children to the seashore, where the humidity was even greater, proved beneficial, so that he thought other factors played as important a part as humidity.

Dr. Zahorsky of St. Louis emphasized the necessity of studying morbidity rather than mortality. He thought that the increased death rate during humid periods was due to the fact that many bottle-fed infants are below par and that the heat aggravated the symptoms.

Dr. Johnson of Grand Rapids said that in experimentation in hospitals severe cholera infantum had been produced by steadily increasing the heat and humidity of the ward.

Dr. Douglas of Detroit said that he had been educating mothers to reduce the food about 25 per cent. during the hot periods, giving more cool water to children, with very good results.

Dr. McCleve of California said that except for the narrow strip between the mountains and the ocean the humidity in that State was very low and the heat extreme, but that summer diarrhea was practically unknown. This he attributed to the almost complete outdoor life of the inhabitants.

Dr. Cooley of Detroit called attention to the necessity for more careful gathering of statistics which would include all contributing factors to this troublesome disorder so that a correct determination of its etiology might be arrived at.

Dr. Parke of Birmingham thought that the wide variation in symptoms also led to confusion. He said that in London they did not know any such severity of symptoms as was seen in the southern states, therefore their findings could be of little value here.

Dr. ROYSTER in closing the discussion said that he had not contributed this investigation as showing the direct cause of the disorder, but merely to start an investigation as to what part heat and humidity did play. He said that in PHOENIX, Arizona, where the average temperature was 108 and the humidity was about four degrees, the mortality was very low—among a population of 20,000 about one a month. He agreed that the work of the German investigators could not be applied in this country because of the different climatic conditions. He thought that radiation had something to do with producing the conditions because children from inland sent out on boats in an almost moribund condition came back at night freshened and better in every way. He said that he had noticed difference in the discharges from year to year: one year watery, the next typically diarrheal, etc.

Effect on Later Development of Severe and Prolonged Illness in Infancy.—Dr. THOMAS D. PAGE of Birmingham gave a set of skiagraphs of the wrists of a series of children showing almost uniform under development of the bony structure even in children who were taller and heavier than average children of their age. He concluded, however, from his investigation that this condition could not be called uniform because some children showed even advanced bony development.

Dr. PISEK of New York called attention to the necessity for measurements in children from two to five years of age, the lack of such tabulation often handicapping the physician.

Exophthalmos in Scorbotus.—Dr. L. R. DEBUYS of New Orleans presented photographs and skiagraphs of an infant with marked displacement of the left eye outward, forward and downward, swelling of both legs below the tibia, and all the typical indications of scurvy in which a diagnosis of rheumatism had been previously made. He administered antiscorbutic treatment and orange juice with marked improvement. He called attention to the necessity for therapeutic diagnosis in these cases.

Dr. MCCLANAHAN of Omaha said that in his practice he saw an average of four cases a year, all coming in from the country, and all of which were variously diagnosed by other physicians. He said that most of his cases presented gingivitis. He had noticed hematuria as a common symptom, which often confused the diagnosis.

Dr. BUTTERWORTH of New Orleans called attention to the lack of education in differential diagnosis among physicians which would admit of a diagnosis of rheumatism being made in such cases.

Dr. DEBUYS said in closing that the English clinicians paid more attention to urine examinations which accounted for the frequency with which they mentioned hematuria as a symptom.

Anesthesia by Pharyngeal Insufflation.—Dr. FRANK W. PINNEO of Newark, N. J., said that the elements of ideal anesthesia were quick, tranquil induction, even maintenance, prompt, complete recovery and no sequelæ. He thought that these conditions had not maintained generally on account of the intermittent giving of the anesthetic which was partly due to the fact that in nose and throat surgery the operator and the anesthetist used the same field. By the use of an instrument which he demonstrated the anesthetic could be given through a mouth tube, a nasal tube, or nasal catheter, according to the requirements of the case. He advised a sequence of anesthetics to produce best results and an even temperature of from 84° to 87°, which with the heating device of the apparatus could easily be maintained.

Dr. GWATHMEY of New York said that since the practice of heating ether for administration much better results had been obtained. He thought that shock in children was almost invariably due to loss of body heat. He thought that for children the chloroform and ether sequence was best and said that very nice results might be obtained by starting to anesthetize during the child's nap, so that it would not struggle against the anesthetic.

Dr. WOOLSEY of New York said that the extreme susceptibility of children to toxins was an important consideration. He thought that many bad results from either anesthesia could be attributed to the fact that its action produced an obstruction in the thorax so that the child was not thoroughly anesthetized or the anesthesia evenly maintained.

Dr. PINNEO in closing said that he did not advocate nitrous oxide in children on account of the small air spaces. He thought that chloroform in sequence did not show the mortality statistics that plain chloroform did, so that he considered it the anesthesia of choice in children.

The Relationship Between Tuberculous Infection in the Child and Clinical Tuberculosis in the Adult—Dr. F. M. POTTENGER of Monrovia, Cal., considered this a lymphatic disease present in nearly all children before the fifteenth year. Even where it was discovered, he believed that the clinical symptoms presenting in adults could be directly attributed to old lesions of childhood. He thought that early infection afforded quite an immunity against further inoculation. He believed that the early recognition of its presence, and proper handling of tuberculous manifestations in children, offered the best preventive yet known against tuberculosis of adults, and for the ultimate eradication of the disease. He thought that tuberculin testing of children should be far more common and that all giving a reaction should be most carefully watched, if not put upon protective treatment.

Dr. AM ENDE of New York said that in his work he used the Moro test because it was simple. He said that where he found a reaction he put the child upon a formula of one part quinine and one-fifth iodoform, adding creosote and other remedies as indicated in individual cases and had had good results.

Dr. KNOPF of New York thought that the Moro test did not amount to much, and said he did not think that any of the tuberculin tests were very accurate. He said that in children over five there was almost universal reaction to von Pirquet, which would indicate that approximately all children did at some time have tuberculosis. He thought that the intensity of the reaction was a valuable diagnostic aid. Where it was violent, the disease was active, and where it was less active it was latent. He emphasized the desirability for constant examination of school children and thought open air schols should be the rule rather than the exception.

Dr. VON RUCK of Asheville, N. C., said that few children of tuberculous parents seen in their institution did not show evidence of infection. He said that they treated chiefly with tuberculin but were soon to introduce a vaccine which, if it proved as successful as the tests had, would present an immunization against tuberculosis as positive as the vaccine virus against smallpox.

Dr. HANSE of Lakewood, N. J., thought the leucocyte count an aid in diagnosis. He thought that tuberculous children usually showed a high percentage of mononuclear cells. He said that even where tuberculin therapeusis was used the other treatment and hygiene should not be overlooked.

Dr. RITTER of Chicago thought that in infants of from six months to two years the Moro test was by far the best. From three to ten years he used the von Pirquet and in older people the subcutaneous. He said that a successful tuberculin should represent all of the antibodies of the disease, because it was not known which were present in individual cases.

Dr. STOLL of Hartford, Conn., said that he used tuberculin both diagnostically and therapeutically. He thought that the delicate child which did not react should have just as much attention as the robust child which did, because he presented a better field for infection upon exposure.

Dr. MCKEE of Philadelphia said that he started his cases upon 1-10000 milligram of tuberculin biweekly, using the old tuberculin, and gradually increased the dose.

Dr. POTTENGER in closing said that the most important point in the treatment was the early diagnosis and that any method which substantiated it should be used. He thought that no one should use but one test, because patients who responded to one test would not to another, so that he used several tests in suspected cases if the first one gave a negative reaction. He emphasized the desirability of familiarizing one's self with one tuberculin and using it, rather than attempting to use several and doing it indifferently.

An Automatic Device for Reading Systolic and Diastolic Blood Pressures in Children.—Dr. B. RAYMOND HOOBLER of New York presented this device which by mechanical means gave the correct blood pressure, without the danger of the physician being misled, as he often was, with the use of his fingers or ears. He said that great difficulty had been experienced in reading blood pressure in children by means of tactile pressure over the radial artery or by means of auscultation over the brachial artery. The device which he presented consisted of a double cuff, one to fit below and the other above the elbow. The lower cuff was attached to a modification of a Fedde's pith-ball indicator, so that when pulsation was permitted to pass under the upper cuff it was recorded by means of the lower cuff and was shown by the oscillation of the pith ball. He said that in very small children the leg could be used as well as the arm, by merely calculating the 10 per cent. difference normally present in limb pressure. Through the use of his instrument he said that the findings were standardized and that the readings would be found to approximate very closely those of the Erlanger sphygmomanometer.

Effect of Cold Air on the Blood Pressure of Tuberculous Children.—Dr. B. Raymond Hoobler of New York read this paper, also showing that from his tabulated cases tuberculous children carried a very low pressure, but by removal to cool out-door air it was raised ten, twenty, or thirty degrees. He thought that this furnished additional argument in favor of open-air treatment. He said that the more advanced the case the lower the blood pressure fell and the more increased it became upon removal into open air.

Dr. Potenger of Monrovia, Cal., asked if the doctor had taken pressure in tuberculous children other than pulmonary. He wished to know if other than the pulmonary cases showed the same reduction in blood pressure. He said that if the lowered pressure was due to toxins then the non-pulmonary should show the same condition. He believed that the lowered pressure might be attributed to the fact that the diaphragm was interfered with so that it did not act normally, and he thought that this would also account for the pallor of tuberculous children, many of whom are not anemic. He thought that the effect of cold air was physical and that no conclusions could be drawn from it. He said that well children might show the same rise in blood pressure.

Dr. Ritter of Chicago said that he had recently reported 400 cases of analysis of blood pressure in tuberculous children and adults and asked the doctor if he had compared the pressure taken sitting, standing, and reclining. He said that in his cases he found that where the blood pressure was high in the reclining position the pulse was rapid, there being a difference of ten points between the three positions in blood pressure and six points between the pulse rate in the three positions.

Dr. Hoobler in closing the discussion said that he had presented only pulmonary cases and that the blood pressure had all been taken in bed. He said that this tests on well children showed that the rise in blood pressure when they were taken into the open air was not nearly so great as in the tuberculous.

The Diagnosis of Enlarged Bronchial Glands.—Dr. Henry F. Stoll of Hartford, Conn., read this paper and said that in his experience there were often no symptoms by which the condition could be diagnosed. Any of the symptoms might be present in a case, or all might be absent, but he considered the interscapular whispered bronchophony the most universal and the most valuable sign. He thought, however, that even here there was possibility of error because this might be caused by a dilated left auricle or an aneurysm of the aortic arch. He had found that paravertebral dullness was often present when neither vertebral, sternal, or parasternal dullness could be detected. He emphasized the necessity for extremely light percussion or the vibration would mislead its interpretation. He said that the *x*-ray usually presented a shadow in the first and second right interspaces to the right of vertebræ.

Dr. Ritter of Chicago wished to know if the doctor placed any dependence upon the Smith sign.

Dr. Potenger of Monrovia, Cal., thought that enlarged glands were more common than supposed. He said that while he had always held to the opinion that infection took place in the air passages, recent writings showed that if the gland was traced back to the part of the lung it drained a definite focus would be shown. He said that unless one percussed very lightly he soon lost his perception for slight sounds and so was less likely to interpret indistinct findings.

Dr. Muller of Atlantic City said he had found the Smith's sign misleading, and that in its early stages, of only slight enlargement of the gland one not experienced in these cases could not make a diagnosis.

Dr. Pisek of New York said that this condition could only be diagnosed by most careful attention to physical signs and that all suspected cases should be submitted to *x*-ray.

Dr. Hoobler of New York wished to know where the line was drawn between anatomical and clinical tuberculosis. He thought that no tuberculosis should go unattended to.

Dr. Stoll in closing said that the Smith sign seemed to occur so often in healthy children of stocky build with short necks that he did not use it as a diagnostic feature. He said that in adults intrathoracic goiter would give the dullness, weakness, and vasomotor instability that was present in tuberculosis so that the differential diagnosis was hard to make. He said he could not say what sized gland would produce the first sign of dullness but he had noticed that often the dullness seemed to be in excess of the enlargement shown by the *x*-ray.

The Hypodermic Injection of Hematinics in the Treatment of Anemia in Children, with Report of Cases.—Dr. H. Lowenburg of Philadelphia gave his results in a number of cases in which he had used a combination of hematinics upon which he based his opinion that results depended upon the character of the preparation. He said that citrate of iron did not always produce uniform results, that arsenic sometimes produced nausea so that the preparation should be varied according to the needs of the individual. He laid stress upon the need for absolute asepsis and for injecting the fluid into the deep tissue to avoid pain and swelling. He concluded from his experiments that small doses gave as beneficial results as large and that the toxic effect was noticed almost immediately.

Dr. Zahorsky of St. Louis had noticed frequent vomiting when a dose of $\frac{1}{24}$ of a gram was given so that he had given not more than $\frac{1}{4}$ to $\frac{1}{2}$ grain to young infants. He had also had rise in temperature to 99° or 102° in his cases but had noticed no especial harm from either of these symptoms.

A Demonstration of a Graphic Milk Chart.—Dr. Charles Henry Smith of New York demonstrated a chart by means of which the caloric and percentage values of foods could be determined for any milk modification. He said that the chart was based on 4 per cent. top milk, the straight lines of the chart indicating sugar and protein values of the food, dotted lines the calories. He had worked out the chart from his own practice and presented it as a means for obviating lengthy figuring to find out what milk modifications to make for the needs of each case.

SECTION ON PRACTICE OF MEDICINE.

Thursday, June 6—Third Day.

Cardiospasm with Sacculation of the Esophagus with Special Reference to the Persistence of the Sac.—Dr. Jesse S. Meyer and Dr. R. D. Carmen presented this communication which was a study of four cases of cardiospasm which had come under their observation since they had reported their series of ten cases two years ago. Since that time they had been able to observe three of their cases for periods of four years or more, and five cases ranging from one to three years, and this had enabled them to verify the beliefs previously expressed that even after complete stretching and paralysis of the cardia, it was questionable whether any of these patients in whom sacculation existed would be found entirely free from symptoms; they would always have to exert more or less care in the amount and character of food taken, and the manner of ingesting it. Without exception these patients who had been followed stated that their condition was much better than prior to treatment, yet they had to exert care in eating. The reason for the persistence of symptoms had been clearly shown by them to be due to the persistence of the sacculation, which seemed to undergo but little shrinkage after the spasm had been overcome, and to the consequent loss of the normal peristalsis of the lower third or two-thirds of the esophagus. They had made observations to determine to what extent the normal esophagus could be stretched and in no case were they able to inject into the intragastric bag within the esophagus more than 40 to 60 c.c. They believed that spasm was the primary condition and sacculation the secondary and that the earlier the condition was recognized the more complete would be the cure. They also described their method of determining the presence and size of the sacculation by means of the stomach tube and intragastric bag.

Adhesions and Constrictions of the Bowel: Their Demonstration and Clinical Significance.—Dr. G. E. Pfahler of Philadelphia presented this paper, choosing this subject because its importance was being recognized by a large number of writers. After reviewing the literature of the subject, describing his own *x*-ray work, and exhibiting charts illustrative of the various conditions for which adhesions were responsible, the writer concluded as follows: 1. Localized peritonitis resulting in adhesions was a common condition, and while it must often be present without producing symptoms it was a pathological condition that should be considered in all obscure abdominal cases. 2. Constriction of the bowels might be permanent or temporary. The permanent constrictions were liable to be due to adhesions or carcinoma and had been demonstrated by a number of roentgenologists in many cases. 3. Temporary constrictions might or might not be present during an examination, but the condition which would give rise to such obstructions would be present and could be demonstrated. 4. Colonic loops, particularly affecting the sigmoid, was a condition that might produce repeated temporary symptoms and had been found associated with the group of periodical "sick-headache" cases. 5. The cases of "colonic loop" that the writer had been able to

study so far had been too few to enable him to draw definite conclusions, but pointed the way to the conduct of many chronic cases.

The Value of Serial Radiography in the Diagnosis of Gastroduodenal Lesions.—Dr. Lewis Gregory Cole of New York presented this communication. After considering the types of stomach, types of gastric peristalsis, systole and diastole of the stomach, and the various types of caps (or first portions of the duodenum) he stated that the differential diagnosis of carcinoma from adhesions or hour glass stomach was very important. In extensive cases this might be made with great accuracy, and many inoperable cases might be saved the shock of unnecessary exploratory operation. Even in early cases the radiologist could differentiate between the malignant and non-malignant lesions with about the same degree of certainty as could the surgeon at an exploratory operation, without microscopical examination of the specimen. It was more conservative, however, for the radiologist to state the character, location, and extent of the adhesions and leave the practitioner or pathologist to determine the cause. If there was any radiographical evidence of malignancy, surgical interference was indicated, regardless of whether or not the symptoms were severe enough to justify such a procedure. If there was no evidence of malignancy the cases grouped themselves into three classes: 1. Adhesions with or without dilatation of the stomach, accompanied by symptoms sufficiently severe to indicate surgical procedure. 2. A definite lesion without sufficient symptoms to justify surgical procedure. 3. Definite radiographic findings, with obscure but prolonged symptoms, referable to the right hypochondrium. Dilatation of the stomach resulting from pyloric obstruction or from atony might be recognized by other methods of examination.

A New Method of Treatment of Ulcer of the Stomach.—Dr. J. W. Weinstein of New York read this paper. He stated that his method for the treatment of ulcer of the stomach was a combination of various remedies proposed at one time or another for the treatment of this condition. The diet was original; the other measures were not. This method did not require a stay in bed; the patient was allowed to go about his business as usual, but hard work was forbidden. His experience with the method had been confined solely to the chronic type of ulcer. The most of the cases treated belonged to that type of ulcers known years ago as hyperacidity but which had been shown conclusively to be ulcers. This class presented the syndrome of pain, heart burn, belching, and sour eructations coming on one hour or more after meals, and with these this method had been a most pronounced success. As to the diet, the patient might take white bread, zwieback, toast, soda biscuit, corn flakes, farina, cream of wheat, potatoes (mashed only), eggs (soft boiled, hard boiled if they agreed), cream, cream cheese, butter (in plenty), sugar, fish (boiled only), raw or stewed oysters, baked apples (without skin and core). The patient might drink water, milk, buttermilk, zoolac, fermillac, vichy, weak tea (in moderation only), cocoa. The articles forbidden were: any other food, all fried foods, all seasonings, except the least bit of salt. Meats and broths were excluded because they stimulated gastric secretion. This diet must be strictly adhered to for four weeks, when easily digested soups and meats might be added. Fried meats were forbidden and all the coarser portions of the meat, sinews, tendons, burnt or charred portions should be avoided. Soups and broths should not contain vegetables of any sort. To cure the ulcer he gave bismuth; the subcarbonate given once a day, in the morning on an empty stomach, had proved most satisfactory. The patient must not have anything for an hour afterward. He had found it expedient to cleanse the digestive tract once a week by the administration of a dose of castor oil to remove the bismuth which had a tendency to accumulate. To check the flow of hydrochloric acid, he gave atropine in doses of one grain three times a day or extract of belladonna in doses of one-fifth of a grain. In addition he gave an alkali in the form of magnesium oxide in varying doses, according to the condition of the bowels. For patients who did not do well on this plan he gave, instead of the belladonna and the alkali, olive oil in doses of one or two tablespoonfuls ten or fifteen minutes before meals. The stasis of food, if it existed, was met by lavage of the stomach seven hours after the meal. If there was but little food present once a week was sufficient, but if there was considerable food present, it should be done twice a week. The motility of the stomach should be determined in every case before starting the treatment. The last step in the treatment was the application of wet compresses to the stomach every night. This course of treatment was carried out for eight weeks and the patient was questioned every week as to whether he carried out the instructions. The results had been very satisfactory and all of his cases had been of long standing, dating back as long as fifteen years and had taken treatment at the hands of a number of practitioners. The great value of the method was in its simplicity and the lack of sacrifice on the part of the patient.

Comparative Studies in Cancer and Normal Tissue Ferments.—Dr. Walter W. Hamburger of Chicago read this paper. He said that several investigators had devised new biological tests for the diagnosis of malignant disease, which while they differed in minor detail were all based on the supposed activity of proteolytic or peptolytic ferments contained within the cancer cells. A widespread divergence of opinion as to their clinical value had been expressed. Hence they had directed their research toward the ferments themselves and had devoted their preliminary work to the development of an adequate biochemical technique. After reviewing the problems presented by the literature on the subject and showing sources of error, the writer described his methods and concluded as follows: 1. The ferments of cancer tissue, upon which the glycyltryptophan and less well known biological tests were based, belonged to the group of ereptases. 2. The ereptases of cancer tissue could not be distinguished in their ability to split peptone and form tryptophan from the ereptases found in normal tissue, blood serum, saliva, mother's milk, pleuritic and ascitic fluids, and leucocytes. 3. It appeared likely that these several ereptases were identical and that the ereptases of blood serum, leucocytes, saliva, and other body fluids were derived from the fixed tissue cells. 4. Compared quantitatively, most cancer tissue contained less ereptase than normal kidney (dog) and normal liver (dog) although slightly more than normal spleen (dog) and distinctly more than blood serum (various animals). 5. While blood serum contained relatively less ereptase than most tissues, the last trace of serum must be removed if one wished to work solely with the tissue ferments, and to accomplish this they had found that it was necessary to subject it to repeated washings.

Diverticulitis of the Large Bowel: Clinical Review of Twenty-seven Cases.—Dr. H. Z. Giffin of Rochester, Minn., read this paper. He said that a detailed analysis of the symptoms and physical findings had not yet been made in a group of personally observed cases, and it was with the idea of determining whether or not a more or less definite clinical picture presented itself that this review was made. From January 1, 1902, to January 1, 1912, twenty-seven cases of diverticulitis of the large bowel were operated upon at St. Mary's Hospital and studied clinically and pathologically. This number included only those cases in which the operation was done primarily for this condition. In the light of their findings it seemed that a probable clinical diagnosis of diverticulitis of the sigmoid could be made in certain cases. The points in evidence which would favor a diagnosis of the chronic proliferative type of diverticulitis were as follows: (1) The absence of those shadows of malignancy in the general picture; (2) a tendency to obesity and the maintenance of good nutrition; (3) a long history of attacks of low abdominal pain localized in the left lower quadrant; (4) a history of the former formation of a mass and its subsequent disappearance; (5) a failure to obtain a more or less continuous history of the frequent passage of macroscopic blood in the stools; (6) the demonstration of vesical fistulæ which, upon cystoscopic examination, appeared to be inflammatory, and (7) the failure to demonstrate malignancy positively by sigmoid examination. In carcinoma of the lower bowel there was usually an early loss of flesh. Pain was not a prominent complaint until obstruction advanced and the mass was often found before pain was complained of at all. Tenderness to pressure was a late finding. In their experience carcinoma of the sigmoid had been only seven times as frequent as diverticulitis. The other inflammatory forms of perisigmoiditis could not be positively differentiated. A diagnosis of appendicitis in cases of transposition of the viscera should not be difficult. If nonrotation of the colon existed, a radiographic or fluoroscopic examination after a bismuth meal would be necessary. It should not be forgotten that a pelvic tumor might be a sigmoidal tumor and the possibility of diverticulitis was to be considered. Pelvic inflammatory disease might be very closely simulated. Diverticulitis should be carefully considered in the diagnosis of all tumors of the left lower abdominal quadrant and of the pelvis.

The Prognosis in Cases of Albuminuria with or without Casts.—Dr. Theodore B. Barringer, Jr., of New York read this paper which was based on a study of 396 men, residents of New York, who were insured during 1900 and 1901. As far as the ordinary physical examination could

determine, they were normal at that time except for the presence of serum albumin in the urine, with or without casts. At the time of the examination these 300 men were divided into groups; the first, numbering 115, showed albuminuria without tube casts; the second group, numbering 203, showed albuminuria and a few hyaline casts; the third group included 53 men showing albuminuria and a few granular casts. The men with albuminuria and granular casts showed an increasing incidence in each decade, until, between forty and fifty years they were four times as frequent as between twenty and thirty years. The men showing albumin alone were five times more frequent before the twentieth year than afterwards. During the summer of 1911, seventy of these men were examined again. The deaths in the original group of men numbered twenty-five. This mortality was decidedly high. A study of the causes of death and of conditions found at the second examination in those living led to the following conclusions: 1. Renal albuminuria, without casts, was most frequently found in young adults. It was exceptional for it to be a symptom of incipient nephritis. It was rather to be regarded as an evidence of generally lowered resistance which predisposed to tuberculous infection. The mortality among these people was higher than among normal subjects. 2. Cases of albuminuria with a few hyaline casts had no particular age incidence. The mortality in this group was also above normal. 3. People with albuminuria and granular casts showed much higher mortality than normal people and a much greater tendency to renal and arterial disease than either of the preceding groups. 4. Whatever the urinary findings, age was a factor in prognosis, young people having the most favorable outlook as regarded the possibility of an ultimate nephritis.

Hunger Pain.—Dr. ALLEN A. JONES of Buffalo read this paper. After defining hunger pain as a sensation of gnawing distress coming on several hours after meals, varying in intensity and accompanied by impatience and irritability of temper, he stated that it was not the accompaniment of any constant or invariable chemical state of the stomach. As a rule hydrochloric acidity was high, but even low degrees were often found. Hunger pain might be associated with gastric ulcer near the pylorus, and the location of the ulcer had much to do with the incidence of the pain in its relation to the ingestion of food. If it was in or near the fundus, or proximal to the antrum pylori, some degree of discomfort or actual pain followed soon after eating. In cases with gastric ulcer, near or at the pylorus, or with pyloric irritability and spasm due to hyperchlorhydria, the pain was usually well localized to the pyloric region of the stomach, but in cases having organic stricture the pain was more generally distributed over the gastric area and it often extended to the region of the cardia. When the latter was the case the pain supervened sooner after eating than in the case of ordinary hyperchlorhydria and was more apt to be accompanied by vomiting which gave relief. The reason food ingestion gave rise to temporary relief in case of ulcer at the pylorus was probably that its alkaline constituents neutralized and its proteid elements combined with hydrochloric acid. The nature of the ingesta had a large influence upon the incidence of pain, bland articles of diet giving a longer respite from pain. While hunger pain was a rather constant result of gastric ulcer, it should be remembered that gastric ulcer not infrequently existed without pain and hemorrhage might be the first symptom of its presence. Instances had come under his observation where achylia gastrica was accompanied with hunger pain. It might be a symptom of acid gastritis and was also occasionally found in catarrhal gastritis. It was also present in gastrectasia and was quite often found in gastroptosis, enteroptosis, or nephroptosis. In hyperorexia, or parorexia, the sensation of hunger might become so intense as to amount to actual pain. Not only did late postprandial gastric suffering result from a variety of chemical and nervous disorders of the stomach, but it was found in cases with disease of other abdominal organs. Most common among these were pathological conditions of the gall-bladder and appendix. The treatment of the symptom should be guided by a consideration of its cause and might consist of the regulation of the diet, the giving of alkalies and gastric sedatives, the observance of proper rest, the wearing of a suitable abdominal support, the administration of tonics, the employment of lavage or operative measures as the case might demand. In conclusion the writer emphasized the need of careful consideration and study of the patients afflicted with this symptom.

The Treatment of Pulmonary Tuberculosis by Compression.—Dr. MARY E. LAPHAM of Highlands, N. C., read this paper in which she described the methods of applying nitrogen compression in cases of tuberculosis. The safest method was that of Brauer, which consisted in making a tree incision, retracting the tissues, and examining the surface of the pleura. If this was smooth and glistening and the motions of the lung beneath were seen, the pleura was pierced with a Solomon catheter and the nitrogen turned on. After calling attention to the dangers resulting from mistakes in the introduction of the needle, the writer said that this method was applicable to cases in which all other methods had failed, when symptomatic and tuberculin treatment could not arrest the tuberculous process. The contraindications were any complication sufficient in itself to inhibit recovery and too great an involvement of the other lung. In typically successful cases the results were spectacular. The temperature fell, the cough lessened, the tubercle bacilli disappeared, and the patient gained in weight and strength. Cases with high fever, drenching night sweats, profuse purulent expectoration, profound cachexia, and exhaustion were saved as by a surgical operation. The method was being used by the best men in Europe. About six hundred cases had already been reported, all advanced and hopeless cases, and 40 per cent. of recoveries had been secured. The causes of failure were not in the method but in the inability to use it. The pleural surfaces might be so adherent that a pleural cavity could not be formed. If recovery did not follow the patient was usually much improved.

The Intensive Treatment of Syphilis.—Dr. HOMER F. SWIFT and Dr. ARTHUR W. ELLIS of New York presented this communication. They stated that the Wassermann reaction had been in use long enough to definitely establish its place as an indicator of efficient treatment. While a single negative reaction did not mean that a patient was cured, a positive reaction certainly indicated the presence of spirocheta in some part of the body. In latent syphilis within three years of the time of infection, 75 per cent. showed a positive reaction. A study of figures made it probably safe to conclude that 50 per cent. of all patients with syphilis were insufficiently treated. The use of the reaction and autopsy findings showed that less than 50 per cent. of syphilities treated with mercury were cured. The advantages of an early diagnosis of syphilis could hardly be overestimated from the standpoint of protection of the community; early diagnosis, and, hence, early treatment of the disease decreased the danger of the spread of the disease. This paper emphasized the importance of making an examination for the spirocheta and warned against the use of local antiseptics in suspicious ulcers until after a diagnosis had been made. The dark field microscope was the best instrument for this purpose and it was regrettable that so many colleges and hospitals were without this instrument. In discussing the relative values of the Wassermann reaction and the determination of spirocheta in initial lesions, these writers stated that when the initial lesion was young the spirocheta were most easily demonstrated, but as it became older the conditions were less favorable, and the serum reaction was more valuable. This did not mean that the examination for spirocheta was not of value late in the primary stage. The serum reaction was also useful as an indicator of the extent of the invasion. The probability of a rapid abortive cure had become almost certain, provided the treatment was properly carried out. It had been their experience that cases treated before the appearance of the Wassermann reaction remained negative. If the disease was allowed to reach its second stage, the difficulty and time of cure was increased threefold. Since the combination of salvarsan and mercury had come into use, the relative number of "cures" had materially increased. The use of salvarsan alone had resulted in a large percentage of relapses. In order to carry on a successful campaign against syphilis the attitude of the public must be changed. Syphilis was one of the most poorly treated of all diseases, one of the reasons for this being the exclusion of the patient with syphilis from the majority of our hospitals. Statistics from a number of hospitals illustrated the attitude toward this disease. The syphilis of to-day was not usually the pox of the older writers, but its nervous manifestations were increasing and the burden of caring for the paretic fell on the public. This was the result of the short-sighted policy of failing to provide adequately for the treatment of the disease in its early stages. All that remained to conquer the disease was a universal recognition of the efficiency and importance of the recognized methods of treatment and an opportunity in the wards of our hospitals to apply them.

Election of Officers.—*Chairman*, Dr. Jarvis Barlow of Los Angeles, Cal.; *Vice-Chairman*, Dr. Thomas McCrea of Philadelphia; *Secretary*, Dr. Roger S. Morris of St.

Louis, Mo., *Member of the House of Delegates*, Dr. Joseph A. Capps of Chicago; *Alternate Delegate*, Dr. Alexander Lambert of New York.

THE SCIENTIFIC EXHIBIT.

Exhibits.—A feature of unusual interest was the scientific exhibit, held in the balcony of the hall of registration, under the general direction of Dr. Frank P. Wynn of Indianapolis. Among the most interesting of the exhibits were the following: The U. S. Bureau of Animal Industry had a number of excellently mounted specimens showing especially the lesions of cysticercus and tuberculosis in animals. From the Army Medical Museum were specimens illustrating tropical diseases—notably leprosy, pellagra, and amebic dysentery—and various bone injuries, and an historical collection of stethoscopes. In another section was a collection of photographs, made during the joint investigation of the U. S. Bureau of Fisheries and of the New York State Institute for the Study of Malignant Disease, illustrating various specimens of so-called fish cancer. The Harvard Medical School sent a collection of photographs by Dr. F. B. Mallory of cases of leprosy, yaws, keloid, and phagedenic ulcers, and also a number of beautiful photomicrographs illustrating various pathological processes and forms of trypanosomiasis. A noteworthy exhibit was one from the Mt. Sinai Hospital, New York, containing a number of hearts showing the lesions of bacterial endocarditis. Dr. J. Shelton Horsley of Richmond, Va., showed a collection of mounted specimens illustrating blood-vessel suturing. A number of fine photomicrographs and *x*-ray pictures were sent from the Mayo Clinic in Rochester, Minn. The Medical Missionary Society's Hospital of Canton, China, had on exhibition a collection of 1,100 urinary calculi which had been removed from the natives in that institution. There were also many interesting exhibits well repaying study sent by the New York Lying-in Hospital, the U. S. Public Health and Marine-Hospital Service, the Indiana University School of Medicine, the Jefferson Medical College of Philadelphia, the American Association for the Conservation of Vision, and a number of other societies and institutions.

Demonstrations.—In connection with the exhibit demonstrations were made on several days as follows: 1. Demonstrations Relating to Syphilis: (*a*) Laboratory Phases, by Dr. Hideyo Noguchi, New York. (*b*) The Visceral Lesions of Syphilis, by Drs. William H. Welch, Baltimore, and Joseph McFarland, Philadelphia. (*c*) The Bone Lesions of Syphilis, by Dr. D. S. Lamb, Washington, D. C. 2. A Series of Hearts Showing Bacterial Endocarditis, by Dr. E. Libman, New York. 3. Experimental Endocarditis, by Dr. E. C. Rosenow, Chicago. 4. Experimental Nephritis, by Dr. M. H. Fischer, Cincinnati. 5. Experimental Intestinal Anastomosis, by Dr. W. D. Gatch, Indianapolis. 6. Malaria and Amebic Dysentery, by Dr. W. M. James, Canal Zone.

ASSOCIATION OF AMERICAN PHYSICIANS

Twenty-Seventh Annual Meeting, Held in Atlantic City, May 14 and 15, 1912.

(Special report to the MEDICAL RECORD.)

Tuesday, May 14—First Day.

DR. J. G. ADAMI OF MONTREAL IN THE CHAIR.

President's Address.—Dr. J. G. Adami believed that Canada should be congratulated because of his election to the presidency of the Association of American Physicians. Many years had passed since its beginning, and there were many men who stood high in the profession who should be enrolled among its members but who were not. The Royal Society of London, the New York Academy of Medicine and other representative bodies required conditions for entrance that were severe, but made entrance a worthy object of ambition representing the best of the medical profession. This was a matter that, in his opinion, should be looked clearly in the face, and they all should look back and see what they had accomplished during the past few years. Should not meetings be held more than once a year? Should they not do what they could to have a special building set apart for international and other congresses in Washington, similar to that which Great Britain had for various medical societies? This was a question that had been raised time and time again, and the authorities in Washington should see to it that there was provided a place for these various medical meetings. Dr. Adami suggested that this matter be taken up by the council. Only one member had fallen from the ranks during the past year, Dr. John H. Musser of Philadelphia.

Amendment to the Constitution.—This was offered at the meeting of May 10, 1911. *Resolved:* That Article II of the constitution be amended so as to read: The number of active members shall be limited to one hundred and sixty. *Resolved:* That a by-law be adopted to read as follows: This increased limit of membership of one hundred and sixty shall be attained by adding not more than five new members in any year, in addition to such as are elected to fill vacancies occurring in the usual ways, until the total membership reaches one hundred and sixty. This resolution was seconded and carried.

A Clinical Study on the Effects of Sleep and Rest on the Blood Pressure.—Dr. HARLOW BROOKS and Dr. JOHN CARROLL of New York presented this communication. After an explanatory introduction, a brief statement was made of the fall in blood pressure occurring during sleep under physiological conditions; they discussed the drop which occurred during sleep in patients with medium blood pressure, as well as the drop that occurred in patients with low or sub-normal blood pressure. They discussed the variations that occurred after sleep in patients with high blood pressure, and they made interpretations of these variations from the physiological drop. What factors apparently altered the drop and the time of occurrence? Was there a normal blood pressure curve? Did artificial deepening of sleep accentuate the drop of blood pressure? Did rest produce the same changes in blood pressure as sleep? Might the drop in pressure occurring after sleep be utilized therapeutically? They had found that the night pressure was lower than the day pressure. In the work a stiff leather cuff was used. Very neurotic patients were not included in this report. They divided their patients into three classes, those in which the systolic pressure was between 110 and 170, those in which it was less than 110, and those in which it was above 170. In 68 patients the pressure was about 142.5; in 30 there was a low pressure, about 100. More careful studies should be carried out before any real conclusions could be reached regarding these blood pressures.

Dr. THEODORE C. JANEWAY of New York said that the fall in the systolic blood pressure was not synonymous with the fall in the mean blood pressure; an excessive fall corresponded with a fall in the mean pressure and was largely due to the diminished size in the pulse wave during sleep. An early drop occurred during the first hours of sleep. Surprising effects were often observed from simple physiological rest when combined with hospital care; he had seen a drop of 100 mm without any other therapeutic measures. Rest in bed, regulation of the diet, and other measures would cause a great reduction in the blood pressure; but when the patient was up and about there would be an increase. Mental rest was very important in these cases.

Dr. JOSEPH L. MILLER of Chicago believed that mental rest in these cases was as important as the rest that followed when these patients slept.

Observations on the Effect of Various Forms of Respiration.—Dr. DAVID L. EDSALL of St. Louis made a report upon the studies of the extent of apparent and real ventilation with different types of breathing. He told of the marked differences in effort required in accomplishing the same extent of ventilation and the same intake of oxygen and output of carbon dioxide and, bearing upon this, he gave some points in the treatment and upon the use of respiratory stimulants. He also gave some observations upon the relation between acapnia and shock. Especial emphasis was laid upon the use of morphine in cases of respiratory distress, this agent producing such great improvement when there was a failing respiration.

The Study of Respired Air in a Case of Cyanosis without Dyspnea.—Dr. C. H. HOOVER of Cleveland reported the case of a man, fifty years old, who had been under his observation for two years and who always had been during that time cyanotic. He had chronic bronchitis and emphysema with a moderate myocardial disease. There was a pronounced cyanosis without dyspnea. The cyanosis was not dependent upon any impairment of the mass movement of the blood. The volume of respired air was eight liters per minute, and it was poor in carbon dioxide and relatively poor in oxygen. The alveolar air was rich in carbon dioxide and relatively poor in oxygen. Further experiments had shown that, in spite of an abundant tidal air, the ventilation of the pulmonary infundibula was impaired. This patient had never had asthma and never had had evidences of any trouble with the pulmonary artery or pulmonary vessels. He did have bronchitis and emphysema.

Dr. Theodore C. Janeway of New York asked if the patient had a polycythemia.

Dr. Hoover replied that he had, but it was slight.

Dr. S. J. Meltzer of New York asked if the cyanosis was very extensive.

Dr. Hoover replied that it was, even the tongue being cyanotic.

Organic Matter in the Expired Breath, and Its Significance.—Dr. M. J. Rosenau of Washington, D. C., said that the presence of organic matter in the expired breath had been denied, but experiments had proven that there was organic matter in the expired breath, protein matter as well as albuminous and probably in a colloidal suspension.

A Comparison of Physical Signs and X-Ray Pictures of the Chest in Early Stages of Pulmonary Tuberculosis.—Drs. Henry Sewall and S. B. Childs of Denver, Colorado, presented this communication. Variations in the characters and distribution of the voice and whisper as heard through the stethoscope were considered as the most delicate of all evidences of physical changes within the thorax. There were two sources of the vibrations producing voice, the viscera and the chest wall (mural vibrations). The vibrations of the latter were damped by pressure with the stethoscope. Whisper sounds were due wholly to visceral vibration. The normal character and distribution of these auscultatory signs and their change in disease were referred to. The earliest Roentgenographic sign of tuberculosis was probably indicated by evidence of increased vascularity in the picture. The skiagram usually showed physical changes where physical examination detected abnormalities.

Dr. William P. Northrup of New York presented an x-ray picture of a case in which there were only an irregular temperature and running ear with no other symptoms. No autopsy was allowed.

The Effect of Digitalis and Digitalis-Like Substances Localized Chiefly in the Right Heart.—Dr. John Auer of New York said that lethal doses of digitalis preparations and strophanthin caused in rabbits a total, or almost total, loss of irritability of the heart ventricles. On immediate autopsy the heart was usually found quiescent and strongly dilated; mechanical and faradic stimuli caused no contractions. (Orfila, Stannius.) If the heart was excised and split open, the endocardial surface of the right ventricle would be found to show considerably more resistance to the finger nail than the left ventricle, and this resistance might be so pronounced in the right ventricle that the muscle felt like connective tissue. This toughening of the muscle fibers was most pronounced in the columnæ carneæ, especially the trabeculæ near the tricuspid valve. The corresponding endothelial surface of the left ventricle offered but little resistance to the finger nail which easily dug into the muscle tissue; the papillary muscles at times showed some resistance. The same effect was also observed in the hearts of rabbits which had succumbed acutely in serum anaphylaxis. In normal rabbit hearts this difference between the two ventricles was never encountered. Microscopical examination of digitalis hearts revealed no striking difference between the right and the left ventricles. Substances with a digitalis-like action, therefore, seemed to exert, at least in lethal doses, a more profound action on parts of the right ventricle than upon the left. Digitalis compounds should be exhibited with great caution.

The Symptoms of Sudden Obstruction of the Coronary Arteries.—Dr. James B. Herrick of Chicago reported some experimental work done in which it was shown that obstruction of a coronary artery or one of its larger branches was not necessarily immediately fatal. The continuance of the heart beat depended upon the existence of functionating anastomosis between coronary vessels, and proof of this anastomosis was shown by dissections, pathological findings, animal experimentation, and clinical phenomena. The symptoms of obstruction that was not quickly fatal were given and verified by a report of cases. Numerous clinical observations had shown that obstruction of the coronary arteries, in a very large percentage of the cases, was not necessarily followed by sudden death, and numerous cases were on record in which there was a clinical history followed by autopsy. Two years ago Dr. Herrick saw a man, fifty-five years old, who had always been in good health. He was suddenly seized with a very severe pain in the epigastric region, high up. His stomach was washed out but the pain continued and morphine was administered. After about three hours the pain subsided, but he only lived fifty or sixty hours after. The post mortem showed an obstruction of the left coronary vessel. The most striking symptoms in this case were the initial pain, the collapse, the feeble pulse, the very little dyspnea, the slight cyanosis, and a clear mind until the end. The heart tones were remarkably feeble; there was a rather confusing hyperresonance over the chest. There was a certain amount of edema of the lungs which accounted for the presence of numerous rales.

Dr. E. Libman said he had been in the habit of classifying the lesions one generally met in the coronary arteries as follows: Besides the recent thromboses and embolisms there were cases with partial or complete obstruction by plaques. These were specially to be found in men who had been heavy cigar smokers. If the occlusion by the plaque was incomplete, it might be made complete by a thrombus. In some cases the symptoms were due to a narrowing of the orifices of the arteries by plaques due to atherosclerosis, or by puckering. Some cases with closure of the coronary artery lived not only for weeks but for months. They presented a remarkable facial appearance from which the diagnosis could in some cases be adduced. They had a peculiar dirty ashen color: Sansom referred to it as "a leaden overcast" (but he believed it to be due to disease of the aorta itself). It was valuable to recognize the condition, when possible, because such patients were apt to succumb at any time, and particularly after operative procedures. The observations of Dr. Herrick on pericarditis following attacks of angina were of great interest. Kernig has described such cases under the name of epistenocardial pericarditis, and ascribed to this condition the febrile reaction which sometimes came on after attacks of angina pectoris.

Experimental Studies on Pneumococcus Infection in Animals.— Dr. A. B. Wadsworth of New York read this paper. He said that virulent pneumococci when studied in the test tube, and as compared with many other bacterial species, were exceptionally insusceptible to both bacteriolysis and phagocytosis—the two processes by which the body rids itself of the infectious agents of disease. Virulent pneumococci in the body tissues were also insusceptible to the action of most of the immune sera with which attempts had been made to cure the infection in both man and animals. Yet recovery took place spontaneously in both animals and man. In order to determine why it was that the significance of pneumococcus immunity was so strikingly manifested in the recovery of man from lobar pneumonia, and the action of the blood sera of immunized animals on the pneumococcus so singularly inadequate in the test tube and in the treatment of infection, the following series of experimental studies were undertaken. These comprised: Studies on the action of dead pneumococcus cultures on animal tissues; on the action of immune sera on the pneumococcus; on the action of elevated temperatures on the pneumococcus; on the action of hyperthermy on pneumococcus infection, and finally studies on the action of immune sera on pneumococcus infection and of the mechanism of recovery from pneumococcus infection.

In general it was found that the dead pneumococcus cultures failed to incite disease processes comparable with those seen in active infection, but that an adaptive tissue reaction was incited which rendered the animal immune and gave rise to the well-known agglutinative, precipitative, lytic, and opsonic activities in the blood serum. From the study of the action of immune sera on the pneumococcus under ordinary conditions it was found that the insusceptibility of the pneumococcus to bacteriolysis and phagocytosis was due to the exceptional virulence, adaptation, and growth of this organism. But in the tissues both lysis and phagocytosis took place and the activity of the pneumococcus was therefore inhibited or neutralized in some subtle manner. The thermal limits of pneumococcus growth were found to approximate very closely temperatures often attained by the pneumonia patient and the bactericidal action of the immune sera at these temperatures was greatly exalted. These significant results were further supported by those obtained in the study of the effect of hyperthermy on pneumococcus infection by which it was shown that although the animal organism might be injured, the activity of the infectious agents might be markedly inhibited during the hyperthermy under certain conditions, the most important of which was the presence of an active protective mechanism in the tissues. Finally it was found from the results of the study of the action of immune sera on pneumococcus infection that the curative action of antibacterial and antitoxic sera obtained by the immunization of animals with dead virulent pneumococcus cells and with culture filtrates free from bacterial cells was slight, whereas sera obtained from animals immunized with virulent living cultures possessed marked curative action inducing crisis. In the mechanism of such recovery the neutralization of the products of the pneumococcus, whether toxins or endotoxins, was found to be

the dominant determining factor to which the destruction of the bacteria, whether extracellular by bacteriolysis or intracellular by phagocytosis, was incident.

Clinical Experience in the Drug Treatment of Edema.—Dr. Joseph L. Miller of Chicago reported the failure of diuretics to affect the nephritic kidney as shown by their action in experimental nephritis. The same is true in man; the use of drugs in edema, digitalis, strophanthine intravenously, calomel, theocin, and Fisher's solution sometimes failed to produce the expected effect.

Dr. E. Libman of New York said that when the agents discussed by Dr. Miller did not cause diuresis, he was accustomed to try some of the older diuretics and often a striking result was obtained. He recalled a case treated by Dr. J. Rudisch ten years ago with oil of juniper, a drug that must be used with great caution. The patient was waterlogged for months and all the ordinary diuretics had been used. The juniper caused so marked a diuresis that the edema entirely disappeared, and the patient was doing well when seen several months later. In several cases he had seen splendid results from the use of the infusion of apocynum. He usually gave it by rectum, diluted with water. He asked Dr. Miller whether he had tried the various remedies in conjunction with the Karell diet.

Complete Permanent Heart Block in Auricular Fibrillation Following the Use of Digitalis.—Dr. Albert E. Taussig of St. Louis said that in auricular fibrillation digitalis slowed the pulse by producing partial heart block, thus interfering with the passage to the ventricles of some of the very numerous and irregular auricular impulses. In some cases, if the digitalis was pushed, complete heart block might result, with the establishment of the very slow, regular rhythm characteristic of this affection. Ordinarily this condition of complete heart block was temporary and ceased a few days after the administration of digitalis was discontinued. It might happen, however, if there was an organic lesion interfering with the conductivity of the bundle of His, that the administration of digitalis was followed by the establishment of a complete and permanent heart block, possibly because the drug gave the *coup de grâce* to the already diseased bundle.

Clinical and Pathological Observations on Subacute Bacterial Endocarditis.—Dr. E. Libman of New York read this paper. He said that during the course of a study of eighty-nine cases of subacute bacterial endocarditis (so-called chronic malignant endocarditis) evidence was obtained that persons with this disease could spontaneously overcome their infection and that the lesions on the valves might heal in part or entirely. This was shown by the following observations. In seventy-five cases blood cultures were made, and in sixty-nine the endocarditis coccus (*Streptococcus viridans*) was found, and in four the influenza bacillus. In the cases which were examined post-mortem the endocardial lesions were quite characteristic in the cases in which the mitral valve was infected. There was marked involvement of the left auricular wall; there was a great tendency for the development of vegetations on the chordæ tendineæ, and the latter often became brittle and were ruptured. While these observations were being made two cases came to post-mortem examination which had clinically been supposed to be instances of cardiac disease with uremia. In these hearts there were present lesions like those found in subacute bacterial endocarditis, but in a healed state. In the kidneys of these cases Dr. Behr found the glomerular lesions which are believed to be characteristic of cases of subacute bacterial endocarditis, and which had thus far been found by the speaker only in the cases in the group which were due to the endocarditis coccus. Later, at the autopsies in some cases of the condition they were wont to call "chronic endocarditis with fever," lesions of the aortic valve were found in which there were no bacteria. These lesions consisted of organized vegetations with calcareous infiltrations. The characteristic lesions were found in the kidneys. Altogether they had observed eleven times bacteria-free healing or healed lesions of subacute bacterial endocarditis. The cases in which they had found bacteria in the blood and which they could follow up all succumbed. In one case of influenzal endocarditis the bacillus was found five times in the blood. Four later cultures were negative, and the patient died within a few months. There was unfortunately no autopsy. It was remarkable then that there should be so many cases in which the bacterial infection was overcome without its being discovered. The explanation that seemed the most likely was that in such cases the bacterial infection was of short duration, and the patient did not feel sick enough to see a physician, and that if he did he was not put to bed. The patients who overcame their infections before they were seen presented at least four clinical pictures: 1. They developed a chronic nephritis and died of uremia. 2. They presented the clinical picture of "chronic endocarditis with fever." 3. This group presented a clinical picture that seemed to have been entirely overlooked. They developed a remarkable brown color of the face (to which he wished to draw particular attention), sternal tenderness, palpable spleen, slight rises of temperature, and the evidences of a valvular lesion. The subsequent history of such cases was unknown. 4. They had a valvular lesion with marked anemia and died from exhaustion alone, or combined with decompensation. Whether cases could recover entirely and have only the valvular lesion which they had before they were affected by subacute bacterial endocarditis could only be determined by further studies and possibly by complement fixation tests. All of the cases in which the blood cultures were positive and which they were able to follow up succumbed. Those that spontaneously recovered from the infection must have had an infection of short duration. This was, however, more fully discussed in the full paper. It was remarkable how little the cardiac murmurs changed in the course of this disease, and how little the walls might increase in thickness. Dr. Libman had generally ascribed this, at least in part, to the fact that the recent lesion involved the walls of the auricles and the chordæ tendineæ rather than the valve itself. He did not intend to have it appear that he believed that sternal tenderness was pathognomonic of this disease. Sternal tenderness occurred in pernicious anemia, in all systemic diseases of the bone marrow, and in some other conditions. What he wanted to bring out was that when one saw a patient with a valvular lesion and the sternum was tender, and particularly if there was some pigmentation of the face, he should examine the case further and observe it, and see whether it was not a case of subacute bacterial endocarditis in the bacteria-free stage. Not every case presented this symptom of sternal tenderness. This in itself would not be surprising, because its presence depended a great deal upon whether the patient was sensitive to pain or not. There were patients who were hyposensitive to pain and some almost insensible to pain; in these patients clinical pictures, of which pain was usually a component part, were incomplete.

Medicolegal Notes.

Presumption as to Sanity.—Sanity being the normal and usual condition of mankind, the law presumes that every person is sane; hence the State in a criminal prosecution may rely upon such presumption without proof relative thereto. But when the defendant in a homicide case produces sufficient evidence to raise a reasonable doubt of his sanity the law then imposes on the State the burden of establishing the sanity of the defendant, the same as any other material fact necessary to warrant a conviction; and if, upon consideration of all the evidence in the case, the jury have a reasonable doubt that the defendant at the time of the commission of the act charged was mentally competent to distinguish right and wrong, or to understand the nature of the act he was committing, he must be acquitted.—Adair *v.* State (Okla.), 118 Pac. 446.

Granting Authority to Refill Prescription.—A complaint alleged that the defendant was a physician and was employed to cure the plaintiff, and in the course of his duties prescribed heroin. After the plaintiff, a woman, had taken this for about two months, the druggist refused to refill the prescription without special authority from the defendant, and the allegation was that the defendant "carelessly and negligently" instructed the druggist to refill the prescription whenever the plaintiff wanted it and did not revoke this for more than a year after, and that the plaintiff, being ignorant of the deleterious effect of the drug, continued to get the prescription refilled and to use it for 14 months thereafter, whereby she was seriously injured in body and mind. It was held that the question of the defendant's carelessness or lack of skill would depend wholly on whether he ordered the drug to be taken too often or in too large quantities, or directed or knowingly or negligently permitted her to continue its use as prescribed for too long a period. But as to these points the complaint was silent. It is one thing to give medicine in an improper manner, another thing to give it too often, another thing to give it in too large quantities, and still another to direct or permit its use to be too long continued. The proof which would meet one of these charges might be essentially different from that necessary to meet another. The defendant had a right to know which of these acts constituted the negligence charged. If it was claimed that the taking of the drug for 14 months in the smallest quantity and at long intervals is necessarily injurious, the complaint should have alleged the fact. It did not aver that the defendant did not instruct the plaintiff not to continue its use so long or inform her that the long-continued use of the drug was likely to be injurious. It was held that the complaint was defective on special demurrer and judgment for the defendant was affirmed.—Billesbach v. Larkey, California Supreme Court, 120 Pac. 31.

Testamentary Capacity—Deathbed Will.—In a will contest where the will was made while the testator was on his deathbed in a hospital after he had been told by the physician in attendance on him that he was about to die, the subscribing witness to the will testified that the testator was at times stupid and at other times his mind seemed to wander, and that when not aroused he paid but little attention to his surroundings, but when aroused he was rational and fully understood what was going on around him, and that on the evening of the execution of the will he talked intelligently with his attorney as to the disposal of his property. It was held that this evidence was sufficient to show that the testator possessed testamentary capacity at the time he made his will, as he had apparently sufficient mental capacity to comprehend the nature and character of his property and the objects of his bounty, and the fact that he was suffering from disease and about to die at the time he executed the will would not avoid it.—McCoy v. Sheehy, Illinois Supreme Court, 96 N. E. 1069.

Employer's Obligation for Employee's Medical Expenses.—Where a contract of employment fixes the wages of an employee at a specified rate, and authorizes the deduction of a specified monthly sum for a hospital fund, and it is provided by the employer's hospital fund association by-laws that all employees shall be members of the association and entitled to receive the benefits including medical attendance, there is an obligation on the part of the employer to pay medical expenses incurred by an employee injured during his employment. It is not necessary that the employee should give the employer formal notice of the injury or ask for a physician if the employer, who does not maintain a hospital, knows of the injury.—Jackson v. Pacific Coast Condensed Milk Co., Oregon Supreme Court, 120 Pac. 1.

Medical Items.

Combined Tuberculosis and Syphilis of the Larynx.—St. C. Thomson reports the case of a woman, aged 43, who had no physical signs in the chest, but the Wassermann was positive, and tubercle bacilli had been found in the sputum. The larynx showed the deposits of tubercle and syphilis each in a typical form. The interarytenoid space was infiltrated, and both cords infiltrated and abraded, and there were "mouse-nibbled" ulcers on both ventricular bands. The epiglottis was swollen with deposit, and there was a punched-out ulcer in front of each arytenoid.—*Proceedings of the Royal Society of Medicine.*

Treatment of the Three Main Symptoms of Gastric Ulcer.—M. Leper states that these symptoms are hemorrhage, vomiting, and pain. The treatment of the first is the most important part of the treatment of gastric ulcer. The essentials of this treatment are: Complete rest in bed, ice per os or in local applications, hot recta' injections, and drugs. In subacute hemorrhages perchloride of iron or bismuth salts may be useful; but adrenalin, chloride of calcium and gelatin are certainly better and may be given per os with excellent results in all cases of hemorrhage. Ergotin, ergotinin, or adrenalin hydrochloride may be given in hypodermic injections; their action is rapid but temporary and often there is a recurrence of hemorrhage soon after their use. Horse serum or normal saline solution are also useful, the former in hemorrhages of long duration where there are distinct modifications of the blood, the latter in profuse or prolonged hemorrhages to make up for the loss of fluid of the system. Gelatin solution may also be tried hypodermically, but it seems to be less used nowadays than some years ago. The food must be as bland as possible, and Leper is distinctly in favor of the old-fashioned milk diet for at least four weeks; however, when the hemorrhage cannot be checked rectal feeding must be tried. Vomiting must be checked by external means and cold applications (ice, ether, etc.), since the analgesic mixtures taken per os are likely to cause vomiting. Alkaline powders are very often of great value and generally well borne. For hypodermic injections, a mixture of atropine and morphine gives excellent results in most cases. Nitrate of silver may also be of use, but it is likely to give an extra stimulus to the mucous membrane of the stomach which is already so irritable.—*Progrès Médical*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended June 7, 1912.

AN EPIDEMIC OF EPITHELIOMA (MOLLUSCUM) CONTAGIOSUM, WITH SOME NEW OBSERVATIONS CONCERNING THE "MOLLUSCUM BODIES."

By M. B. HARTZELL, M.D., LL.D.,

PHILADELPHIA.

PROFESSOR OF DERMATOLOGY IN THE UNIVERSITY OF PENNSYLVANIA.

ACCORDING to the statistics of the American Dermatological Association, molluscum, or better epithelioma contagiosum, comprises a little more than one-sixth of one per cent. of all diseases of the skin observed in America, and only a slightly larger proportion—one-fifth of one per cent.—is seen, according to Crocker, in the hospitals of London. From 1896 to 1900 inclusive only eleven cases of this disease were treated in the Skin Dispensary of the University Hospital, and in four of these ten years not a single case was seen. In 1907 there were seven cases, in 1908 there were twelve, in 1909 there were six, while in 1910 no less than twenty-one cases were recorded in the dispensary in the course of a few months. Practically all the cases seen in these four years were from a common source, viz., a large institution for young men. Owing to the sudden increase in the number of cases from this source it was decided to examine the entire student body in order to learn just what proportion was affected, but after examining 345 it was found to be impracticable, for various reasons, to continue with the examination. Of the 345 examined seventeen, or about 5 per cent., were found to have the disease; but owing to the hurried way in which it was necessary to make the examinations, chiefly on account of the very limited time at our disposal, a certain number of cases in which the lesions were small and few doubtless escaped detection, so that the proportion of cases was probably somewhat larger than these figures would indicate. If the same proportion held good in those not examined, and it probably did, there must have been at this time no less than 250 to 300 cases in the institution. In addition to those treated at the dispensary a small number from the same source were seen in my office, and a considerably larger number were treated by other physicians in various parts of the city. From the foregoing it will be seen that the epidemic was very extensive, amounting to some hundreds of cases spread over a period of four years.

Apart from its extent and duration, this epidemic presented some interesting and unusual features. The eruption was practically confined to the covered parts of the body—in not a single instance, as I recall, were there any of the tumors upon the hands or face; they were upon the trunk, especially the posterior surface, and upon the arms, the lower extremities escaping entirely. The number of lesions present was in most cases large, amounting to scores, while in a considerable number there were hundreds of them. In a few instances the little tumors were arranged in a line, the inoculation evidently having taken place in a scratch. They were for the most part unusually small, the largest being no larger than a split-pea, while the greater number were the size of a pinhead, and instead of being flat, as is usually the case, they were quite acuminate. A large number of the patients complained much of itching, indeed, the eruption was commonly spoken of as an itch, and the skin often bore unmistakable evidences of this itching in the shape of many small excoriations and blood crusts where the tops of the lesions had been torn off by scratching. In a few cases the tumors were quite red and inflamed from the beginning, surrounded by a rather circumscribed inflammatory halo such as is often seen about the bites of insects, and the small central opening was so minute as to require the closest examination to be seen at all. These lesions resembled acne papules so closely that in one case at least, in which they were of this inflammatory type upon the back, the true nature of the disease was not at first recognized, having been mistaken upon a cursory examination for acne.

There is apparently but little doubt that the contagion was conveyed from one to another in this epidemic by the bath towels used in the gymnasium. Proceeding upon this theory every student found with the disease was excused from further attendance upon the gymnasium exercises until cured, and especial care was taken that the gymnasium towels, instead of being laundered en masse as it were, should be laundered in such a way as to ensure that each towel should receive a thorough boiling. The result of these simple precautions seemed to amply confirm this theory of the manner of the transmission of the disease, for with their adoption there was an immediate falling off in the number of new cases; and during the past year I have seen but a single case in a student and that was not a new one, but had existed for a year or more, its long duration being accounted for by the fact that, the number of lesions being small and unattended by any annoying symptoms, nothing had been done for it.

The agency of the bath in communicating the affection has been recognized by a number of observers, among them the late Dr. Radcliffe-Crocker and Sir Jonathan Hutchinson. The former has reported a number of such cases under his own observation, and the latter noted that all his male patients were in the habit of going frequently to Turkish baths where, in his opinion, the gloves and towels were the medium of contagion. In one of

*Read before the College of Physicians of Philadelphia, April 4, 1912.

Crocker's cases, a woman who was in the habit of taking a Turkish bath every day in her own home, the source of the infection was traced to her son, who had contracted the disease from his schoolmates and had infected the bath. In Damascus the

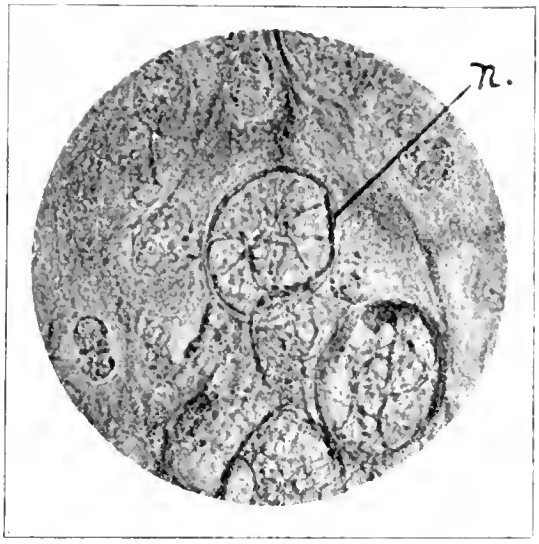

Fig. 1. Cell (c) of the first variety, with nucleus (n) flattened out into a thin curve and pressed against the inner cell wall.

malady is called by an Arabic name which means "the itch of the bath" (Norman Walker).

In the treatment of the cases observed in this epidemic a number of local remedies were tried, among them a lotion of formalin, one or two drams to the pint of water. This lotion seemed to be effective in several cases, as the lesions disappeared to a considerable extent, but it commonly set up such a dermatitis that its use had to be suspended from time to time until this subsided. Upon the whole the most effective application was pure carbolic acid applied with a pointed match-stick or wooden toothpick by boring into the central opening of each tumor. A single application of this kind was usually sufficient, the tumor becoming inflamed and soon disappearing.

In connection with the treatment of this malady it is of interest to refer to an observation made by Kistyakovski. This author found that a number of molluscum tumors present on a young man with syphilis became inflamed after intramuscular injections of mercury given for the syphilis and then disappeared. In view of the well-known fact, however, that inflammation with disappearance of the tumors sometimes takes place spontaneously further observations are necessary to prove the curative influence of mercury thus employed. Sakurane has quite recently reported five cases cured by the internal administration of a decoction made with the grain of *Coix Lacryma*, a remedy long employed in Japan in the treatment of molluscum. In four of these five cases the lesions disappeared in from one to two weeks. In four other cases in which the same treatment was employed, but which were not included in the report because they could not be followed up by the author, the disease was said to have likewise disappeared.

The appearance of the tumors is usually so characteristic that their nature is readily recognized, but occasionally they present such variations from the usual type, both as to size and appearance, as to lead to error in diagnosis. Pringle observed a case in which the lesions, situated upon the scalp, resembled rodent ulcer; and some years ago I had a case under my own care in which a single lesion on the forehead at the margin of the hair was mistaken for epithelioma of the ordinary type and excised; subsequent examination of sections made from it revealed the error in diagnosis. Although usually insignificant in size they may in rare cases reach very large dimensions. Walter Smith has reported a case in which there were many tumors, one of which was three inches in diameter; and Laache has described one in which the tumor, situated upon the occiput of a woman fifty-six years old, was the size of two fists. When the disease attacks the mucous membrane, as it may do, although rarely, the chances of error in diagnosis are greatly increased. Abrahams, at a meeting of the Dermatological Society of London, described a case in which, in addition to many lesions upon the skin resembling lichen planus, the tongue was the seat of large white patches resembling leukoplakia which were shown to contain molluscum bodies.

The mode of transmission, although probably usually indirect, through the intermediation of baths, towels, etc., is in some instances due to direct contact, as when the mother's breast is inoculated by contact with lesions on the cheek of her nursing infant. In view of the difficulty which always attends the attempt to inoculate the disease experimentally this mode of transmission must be rather infrequent; but a most remarkable example of what was probably direct inoculation has recently been reported in the Westminster Hospital Reports for 1909. In seven cases under the care of a particular member of the staff of the hospital infection of operation wounds with molluscum occurred, the operator being found subsequently to have molluscum tumors on the hand. In all of these cases the tumors were situated in the scar or its vicinity, and had appeared in from six to nine months after operation.

In the vast majority of cases the disease is, without doubt, acquired through contact, immediate or mediate, with another individual, *i.e.* it is of human

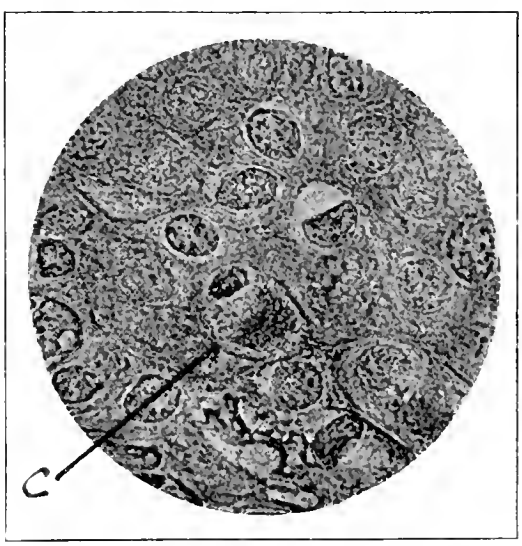

Fig. 2. Cell (c) of the second variety with polar nucleus and filled with a felt-like mass of fine fibrils.

origin, but there is reliable evidence to prove that it is occasionally of animal, and more particularly, of avian origin. Its occurrence in the domestic fowls, such as the chicken, turkey, goose, and in pigeons and other birds, is well established; and a

few apparently well authenticated ex... of transmission from these to human beings ... be found in literature. Salzer has reported the case of a young woman with molluscum of the lid ... which he believed was acquired through feeding pe... ns

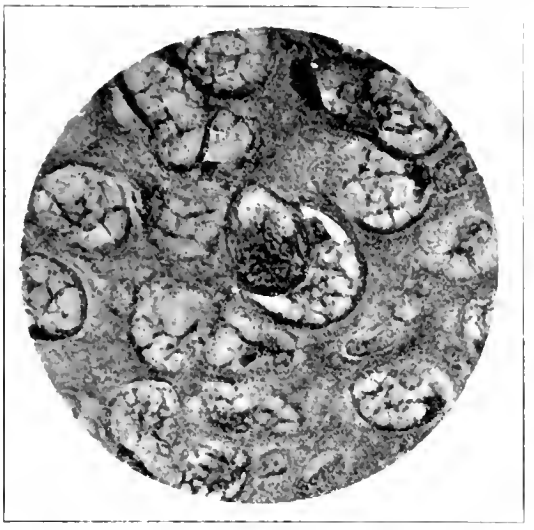

Fig. 3.—Cell of the second variety, partly within a cell of the first kind.

affected by the malady which existed as an epidemic among them and proved fatal to many of the birds. Sir Jonathan Hutchinson has reported a case, also occurring in a young woman, in which the affection was traced to a pet dog. Heller, commenting upon this case, thinks it should be accepted with some reserve, since, according to him, molluscum contagiosum does not occur in mammals; but the nature of the tumors on the dog seems to have been well established by microscopical examination. Constantinides has described an affection similar to molluscum contagiosum as occurring in horses in Greece, the tumors having an anatomical structure similar to that of human molluscum. Jürgens, in performing some inoculation experiments with avian molluscum, infected himself, getting a tumor on the thumb. Czoker succeeded in inoculating the comb of a fowl with human molluscum, but Török and Tommasoli failed in their attempts to transmit it to rabbits and hens.

Although the affection is usually a trivial one in the human being, it has a very extensive literature, attracting attention largely because it is one of the few examples, if not the only one, of an epithelial neoplasm definitely known to be the result of an infection, although the actual demonstration of the infecting agent has thus far not been accomplished. The nature of the peculiar cells found in the interior of the tumors, the so-called molluscum bodies, has long been the subject of lively discussion. At first they were regarded as parasitic organisms, and some observers, the chief of whom is Neisser, still so consider them, but most investigators regard them as epithelial cells derived from the rete mucosum which have undergone some form of degeneration. According to Unna they are only hyaline or colloid prickle-cells, while C. J. White, who has quite recently studied the histopathology of the malady in a most painstaking and thorough manner, thinks that the change in the cells "is not a colloid or hyaline degeneration, but rather an extraordinary metamorphosis of rete cells into keratin;" and this author also expresses the belief that no one has yet succeeded in demon... ny parasite in the tumor.

During the course of this ... four tumors were removed from as many dif... subjects for microscopic study, three of them ... fixed and stained in the usual way, while the ... th, an unusually small lesion just barely visible, was fixed and stained according to the method of Levaditi. The study of the first three gave results which differed in no essential particular from those obtained and described many times by other observers, but the fourth, which was found to be situated in a lanugo follicle, gave histological pictures which, besides exceeding in clearness and sharpness anything which I have hitherto seen, revealed some new and interesting features which I shall describe with some detail.

In the area occupied by the molluscum bodies it was easy to distinguish three quite distinct varieties of cell. First, and most numerous, occupying the central portion of the tumor, were many large, round, and irregularly rounded bodies with double contoured walls and segmented contents, the walls and the lines separating the segments being stained a deep brown and presenting on careful focusing under a high power a finely beaded appearance. (Fig. 1.) In most of these cells the nucleus was still preserved, although usually much distorted, and was always situated eccentrically; in many of the cells it was flattened out into a thin concave disc closely applied to the inner cell-wall as if it had been forcibly driven against the wall by some force within the cell. The finely beaded appearance of the cell-wall and of the lines dividing the cell-body probably represented the remains of the so-called prickles seen in profile which are normally present in the cells of the rete. Even the oldest of these cells, those occupying the upper part of the tumor nearest the central opening, which in sections stained with the usual stains present a homogeneous appearance, still showed distinct segmentation. The second form of cell (Fig. 2), far less numerous than the first, more deeply situated, and often lying in the midst of apparently normal epithelium, was

Fig. 4.—Cell of the third variety.

oval in shape, had a thick laminated wall, and contained an oval nucleus always situated at one pole of the cell where there was always more or less of a cavity, the remainder of the cell being filled with a felt-like mass composed of very short and fine

fibrils. In a few sections some of these oval cells were found lying partly within another cell of the first form (Fig. 3), an observation which, so far as I know, is new. The third and smallest variety of cell (Fig. 4), of which only a few examples were seen, was a perfectly oval body with a distinct double wall, entirely filled with a mass of fine fibrils in which no nucleus could be discovered; but all the cells of this variety were so deeply stained that it was extremely difficult to make out details satisfactorily. This apparently represents a form of cell which has not been described before in this disease (Fig. 4).

In conclusion, it may be regarded as quite certain that the large cells first described are epithelial cells which have undergone some form of degeneration peculiar to this disease, but I do not regard the nature of this degeneration as at all definitely determined. The other forms of cell which I have described are probably also degenerated rete cells, but the evidence for this seems to me much less convincing than in the case of the first variety of cell, and therefore other possibilities are by no means excluded.

A CONTRIBUTION TO THE STUDY AND SURGICAL TREATMENT OF OBLIQUE INGUINAL HERNIA.*

By FRANZ TOREK, A.M., M.D.

NEW YORK.

SURGEON TO THE GERMAN HOSPITAL AND THE NEW YORK SKIN AND CANCER HOSPITAL; ADJUNCT PROFESSOR OF SURGERY IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

THE operations for inguinal hernia, as practised at the present time, seem to indicate that a certain anatomical factor has been either overlooked or disregarded. I refer to the following: In every case of oblique inguinal hernia one will find that the hernia has forged its way out between the vas deferens and the vessels of the cord, so that at the internal ring the vessels are situated above the sac and the vas deferens below. This relation of the structures is a constant one in oblique inguinal

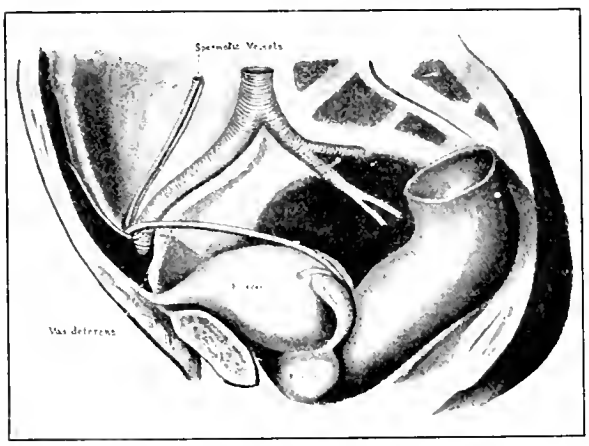

Fig. 1.—(After Spaltehlz.) Internal inguinal ring seen from within. Lateral view. Notice how the spermatic vessels and the vas deferens meet at an angle forming a wedge between them. The illustration shows the relation in the normal state; if there is an oblique inguinal hernia, the vas deferens and the blood vessels are separated at the internal ring by the interposition of the sac, and the ring is larger.

hernia. A little farther forward the vas and the vessels are found united, forming the cord; but at the internal ring they lie apart, and the sac, or at least a portion of it, is situated between them. In their intraabdominal course the vessels come down from above, while the vas comes up from below, and in the normal condition they unite at the internal ring to form the cord (Figs. 1 and 2). This

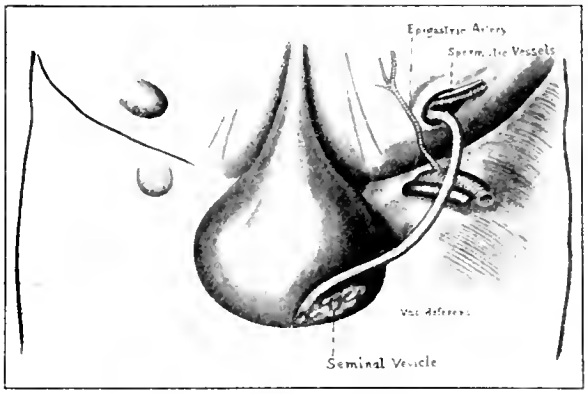

Fig. 2.—View from behind to show the same relations as Fig. 1.

union is found undisturbed where there is no hernia and also where there is a direct hernia, whereas in oblique hernia the above-mentioned interposition of the sac between vas deferens and blood vessels is found. Let me say, parenthetically, that quite a number of surgeons do not seem to be aware of this relation of the structures, although they may have operated in a great many cases of hernia. The reason is that they are not in the habit of dissecting the structures out to a sufficiently high point to demonstrate it. Anatomically we might differentiate indirect from direct hernia by stating that the former emerges between vas deferens and vessels, while the latter does not.

Considering the anatomical points mentioned, is it not natural to investigate whether the relative position of these structures can in any way be a contributing cause in the production of oblique inguinal hernia? Let us see. The vas deferens and the vessels of the cord, before they are joined, lie in planes which meet at an angle at the internal inguinal ring (Figs. 1 and 2), thus rendering them readily capable of being wedged apart. This enables a loop of intestine or a piece of omentum by repeated pressure against the internal inguinal ring to wedge itself in between vas and vessels which, owing to the angle at which they meet, render more effective the downward progress of any smooth, pliable tissue that is forced against that spot.

Admitting this reasoning to be correct, we would also have to allow that the persistence of this relative position of vas deferens and blood vessels after an operation for inguinal hernia may be a cause for recurrence. This consideration has, as long as seven years ago, impelled me to modify our otherwise excellent method of treating inguinal hernias in such manner as to do away with this wedge formed by the vas and the vessels.

The latter object is attained very simply by refraining from bringing these structures out together, but leaving them separate, or even separating them a little further, before the deep row of sutures, that which unites the internal oblique and transversalis muscles with Poupart's ligament, is placed. The vessels, thus, are made to come out at the highest possible point, while the vas will be found to emerge most naturally at a point two centimeters or more below the vessels, so that at least three stitches, a centimeter apart from one an-

*Read before the Surgical Section of the New York Academy of Medicine, May 3, 1912.

other, will separate these structures (Fig. 3). The remaining sutures are inserted below the vas deferens, down to the pubes.

The procedure just described constitutes the essential part of my method of operating in inguinal

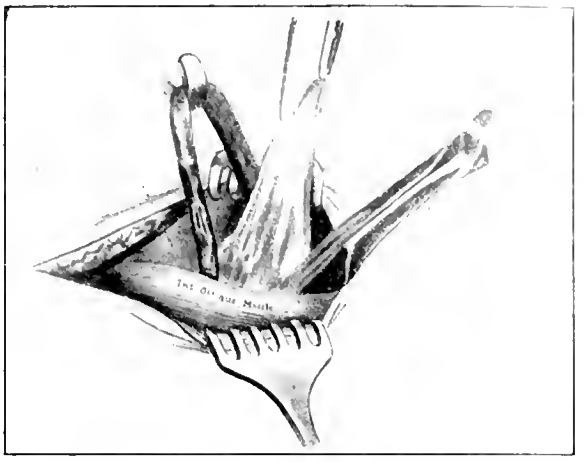

Fig. 3.—Left oblique inguinal hernia. The sac emerges between the spermatic vessels and the vas deferens. For the sake of clearness in the illustration the separation of the vas from the vessels has been carried farther down in the direction of the testicle than usual.

hernia. The other points in which it may or may not vary from the methods pursued by others are not essential, and it must be left to the individual operator what kind of stitch he will employ, what method of tying the sac he will select, and whether he gives preference to chromicized catgut, kangaroo tendon, silk, linen thread, or silver wire, etc. Nevertheless, I believe it proper to describe the complete operation, as I perform it, not only in its essential principle, but in detail.

The same incision as in Bassini's operation is made through skin, superficial fascia, and aponeurosis of the external oblique in a direction corresponding to the course of the fibers of the latter. The incision through the aponeurosis of the external oblique, or rather the separation of its fibers, is made to terminate below in the external inguinal ring. The lateral, lower edge of the divided external oblique is now seized and reflected outward and downward, and Poupart's ligament is thoroughly and completely exposed down to its insertion at the pubic bone. Then the other edge, the upper, medial edge of the divided aponeurosis, is retracted upward and inward and dissected off the underlying tissues far enough to expose the edge of the internal oblique and transversalis muscles and the conjoined tendon. As these structures must be sutured later on to Poupart's ligament, their edge is at once dissected free at this stage of the operation. Next the sac is separated from the cord in the usual manner, with this difference only, that in the upper part of the cord the vas is separated from the vessels, the dissection being continued up to a point where the above named relation of vessels, sac, and vas is evident (Fig. 3). If a surgeon, unaccustomed to this method of dissection, will at first separate the sac from the cord in the usual way and will then proceed to separate the vessels and vas from each other until the mentioned relative position is evident, he will find, as a rule, that after doing so, the sac will be liberated to a higher point, sometimes a much higher point, than it was before, a circumstance which will at once impress him favorably, even apart from any other worth that my operation may have. According to Halsted's principle the size of the cord is diminished. I do this, however, not by resecting some of the veins, but by removing all unnecessary connective tissue and fat from its upper part, and often by resecting the cremaster. If then we have nothing left but the vas and the vessels, the cord will take up very little room. The sac is now opened and its contents dealt with as usual. If the neck of the sac is small, it may be ligated in the customary manner; but if it is large I prefer the employment of a purse string suture of silk. The suture begins and terminates on the peritoneal surface, so that, when the purse string is tied, the knot will lie on that surface. If the purse string is properly inserted and placed high enough, the peritoneal surface will be smooth and free from any dimple, a result which cannot be claimed after the ordinary manner of tying. The sac is now cut off, but the ends of the purse string are not cut off until we have convinced ourselves that there is no bleeding from the stump of the sac, and that we may safely drop it.

Now we proceed to the closure of the inguinal canal in three layers. The first, which is the important one, unites the internal oblique and transversalis with Poupart's ligament. It will be remembered that by our high dissection the cord was at the top divided into two parts, the vessels above and the vas deferens below. The vessels are now made to emerge at the uppermost portion of the wound, and a suture is placed beneath the vessels, as close to them as possible (Fig. 4). The sutures are placed about a centimeter apart, rarely closer. The vas is allowed to come out at the place that seems to be most direct for it, which will usually be found to be beneath the third, sometimes beneath the fourth or even fifth suture, depending on the size of the hernia. Sutures are placed all the way down, the lowest one so close to the pubes that the needle, as it picks up Poupart's ligament, almost or actually grazes the bone. Not infrequently one cannot get any conjoined tendon to unite to Poupart's ligament at the lowest part. In that case the sheath of the rectus is taken instead. It can usually be drawn over without opening it. In

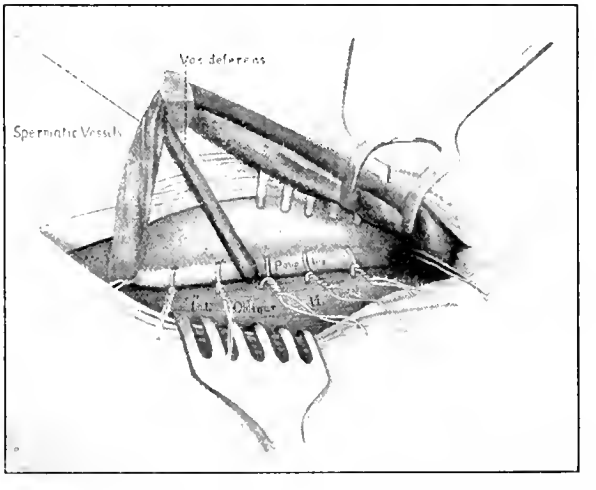

Fig. 4.—Closure of the deep layer. The internal oblique and transversalis muscles have been united with Poupart's ligament by silver wire sutures. Three of these separate the vas deferens from the spermatic vessels.

a few cases I have taken a small flap of the sheath and turned it outward and downward to be attached to Poupart's ligament.

When one sees how, after a thorough dissection, the vessels emerge from the internal ring at the

top and the vas deferens below, it seems natural to ask oneself, why in the world the vas should be displaced in such manner as to be carried high up on the posterior aspect of the abdominal wall, simply to be carried down again under a more superficial

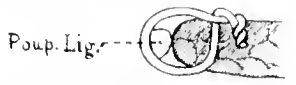

Fig. 5.—Diagram to show how the cut end of the silver wire is imbedded into the muscle.

layer. Possibly it is the awkwardness of thus displacing the vas that has induced some surgeons, perhaps intuitively, to discard all displacement of the cord whatever and has influenced others who do displace the cord against carrying it to the highest possible point and in favor of inserting a stitch above the cord,—a sort of compromise between displacing and not displacing it. I never place a stitch above the cord, and to any one who performs the operation according to my method of separating the vas from the vessels, the ease, one might almost say spontaneity, with which the vessels can be brought out at the uppermost end of the deep layer, will at once be apparent, so that the desirability of introducing a suture above the cord will not suggest itself.

As I have already indicated, I do not wish to be dogmatic on the kind of suture material, but personally I prefer silver wire. Individual silver wire sutures are recommended, not a continuous suture, much less a filigree network. The muscles and Poupart's ligament are brought together by the silver suture only to the point of close apposition; the structures are never squeezed tightly together, as by doing so one might cause localized necrosis. Silver wire lends itself particularly well to the task of bringing the tissues into good approximation without strangulation, for, as soon as the silver wire has been twisted, we know that the adapted tissues will stay where they were laced. This cannot be said with equal force of other suture material, where the knot may give a little. In tying the knot with catgut or similar material we are apt to draw it a little tighter than necessary for approximation, as we fear it may loosen somewhat; and this little extra pull may be just enough to produce a slight degree of strangulation. It may appear out of place to deal at such length of so small a point as the introduction of a suture, but we must remember that we are bringing into apposition tissues which do not tend to unite very kindly. On the one side we have the smooth muscle fasciculi; on the other, the still smoother Poupart's ligament, and even if we were to roughen them artificially they would not offer ideal conditions for the prompt formation of a firm union. Anything therefore that will help to make union more certain is worth while.

I use a No. 26 silver wire or one slightly stronger. The silver wire is twisted about four half turns and is cut off to leave an end about one-eighth to three-sixteenths of an inch long. This end of wire is bent by the aid of forceps to the medial side, so as to lie on the muscle; then the distal half of it is bent a second time, so as to embed the point of the wire in the muscle (Figs. 5 and 6). This puts it with certainty out of harm's way, and it cannot hurt the structures of the cord.

Much has been said for and against the use of silver wire. I may say that I am not a friend of the silver filigree network, several specimens of which I have had to remove from patients, because they were broken, and the sharp ends stuck out through the skin; in one case they even stuck inward against the hernia which the wire net was intended to cure, but which had recurred. If a silver filigree is introduced into so flexible and movable a part of the body as the abdominal wall, its meshes are subjected to frequent changes of position; the net will be alternately bent and straightened again, a condition which predisposes the wire eventually to break. Not so in the case of an interrupted wire suture. The single silver suture with its small twist takes up very little room and becomes thoroughly encapsulated. It readily follows all changes of shape of the abdominal wall. I have been able to convince myself of the thorough encapsulation of the silver sutures in one of these operated patients who returned to the hospital eleven weeks later on account of acute appendicitis to which he succumbed, and upon whom an autopsy was performed. Dr. R. McCready kindly dissected out for me the parts concerned in the operation for hernia, and we saw that the silver wire sutures were imbedded in a very firm tissue, making the task of exposing them quite difficult. This observation influenced me even more strongly in favor of the use of silver wire. While it is doubtlessly true that the only object of the suture is to hold the tissues in apposition until they have united, we must admit that there are different degrees of union, from a very firm union down to an exceedingly loose one. The presence of the foreign body, the silver wire, is the very thing that incites the tissues to produce so firm a fibrous material; an absorbable suture never does it to the same extent. Of course, when this firm union has been established, we have no further use for the silver wire; but who would think of removing it, when we know that it is not in the way and does no harm.

Only once did I have to remove a silver suture which presented directly under the skin at the upper end of the incision; it showed unmistaken evidence of carelessness in operating. Although I was not present at the operation, which was performed by a member of the house staff, I am nevertheless sure that the technique was faulty, for, when I removed the stitch, I found the cut end of the wire pointing straight forward toward the skin. It had not been bent down in the manner which I have described.

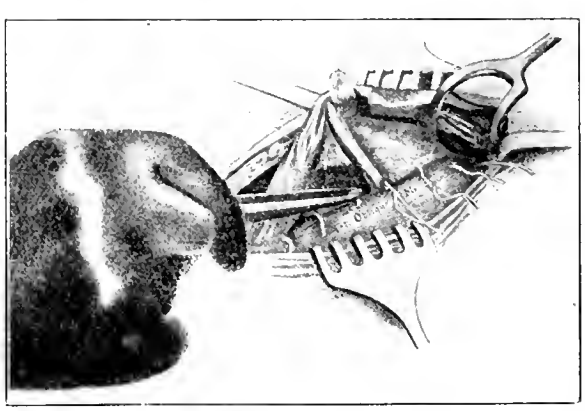

Fig. 6.—The upper two stitches are finished; the ends of the silver wire have been embedded in the muscle. The third suture has been cut, and its end is being turned over across the muscle.

When the suture of the first layer has been completed, the cord, including both vas and vessels, is placed on the structures forming the deep layer, and the aponeurosis of the external oblique is closed over it with a continuous catgut suture, allowing

the cord to emerge at its lower end. This is [illegible] second layer of sutures. Lastly, the skin is s[illegible] forming the third layer.

The after-treatment does not differ from that [illegible] other operations for hernia. The patients are [illegible] tioned to refrain for about half a year from such gymnastic exercises as alternate squatting and [illegible] ing, or horseback riding, or similar postures that put an extra strain on the inguinal canal.

Now, as to the results of the operation. Between six and seven years ago, while the method was still in its formative stage, I paid little attention to the closure of that part of the wound below the exit of the vas deferens, at the pubic end of the wound; in fact, I occasionally omitted closing the lower part altogether. Although none of these cases had any recurrence of their oblique hernia, one of them developed a direct hernia at the place where no stitches had been put in. It manifested itself as a slight bulging, so small that the patient declined to have anything done to it. Since that experience I have been practising the method as described in this article, including the closure of the deep layer down to the pubes, and have had no recurrence except in the following case in which, I am sure, you will grant that the failure was not due to the method I have presented to you. The case was one of very large sliding hernia of the left side, which had recurred several times after previous operations. Around the sac there had formed an enormous amount of adventitious tissue which I detached extensively in order to remove it. When I became aware that I had to deal with a sliding hernia, and that the sac could not be resected, the unfortunate idea struck me to use this tissue as a pad to help holding in the hernia. Such a method, permit me to say, is in direct violation of my principles of clean dissection and removal of all unnecessary tissue in this operation, and what could have induced me in this instance to depart from those principles I don't know; but, at any rate, I pushed this large amount of badly nourished tissue up against the replaced sac. An infection of that tissue with the formation of a large abscess and extensive necrosis resulted, and it took four and one-half months until the wound was definitely closed. This patient has a small recurrence which must be ascribed, not to the method, but to the infection and tissue necrosis, the consequence, probably, of an error of judgment on the part of the operating surgeon. The patient, by the way, in this instance, is better pleased than the surgeon. He claims to feel vastly better than he did before the operation, and is one of my very grateful patients.

In the remaining 303 cases, operated at least one year ago, that I have been able to trace, there has not been a single recurrence, although the cases include a considerable proportion of very large and complicated hernias and also many that had been operated once or oftener by other surgeons and had recurred. In ten cases the operation was combined with removal of the appendix according to my method,* and in four I brought down the retained testicle at the same time, employing the method of orcheopexy described by me.†

Although I have been practising this operation for seven years, I have up to this date refrained from publishing it, as I wanted [illegible] to convince myself of its value. Now I am [illegible] freely certain that it is an improvement on the [illegible] method.

The more experience one gets, the [illegible] he is willing to ascribe his success in any [illegible] particular factor. Therefore, although I believe that the abolition of the wedge formed by the vas deferens and the vessels and the separation of these structures before putting in the deep sutures is of essential importance, I am not prepared to say whether the success is due mainly to this procedure or whether the high ligation of the sac, the purse-string suture in the case of large sacs, the careful preparation of the muscles and of Poupart's ligament, together with their exact approximation without undue tension, and the use of silver wire have something to do with the result, or whether, perhaps, it is the combination of all these points, that is responsible for the good results. I must say that I lean to the last-named assumption. At any rate, the results of this operation, which at first I employed only in the most unpromising cases, have been so uniformly good that I feel justified in bringing it to the notice of the profession and in asking them to give it a trial, if not in the simple cases, at least in those in which the outcome by the present customary methods seems doubtful.

TRANSPLANTATION OF RIB FOR DEPRESSED DEFORMITY OF THE NOSE.*

By HAROLD HAYS, A.M., M.D.,

NEW YORK.

ASSISTANT SURGEON IN OTOLOGY, NEW YORK EYE AND EAR INFIRMARY, ETC.

About two years ago Dr. William W. Carter read a paper before the laryngological section of the New York Academy of Medicine, in which he described a method for the correction of depressed nasal deformities of the nose by the transplantation of one of the patient's ribs. He presented three cases, all of which were markedly improved in appearance by the operation. The operation has met with general favor, and in suitable cases is a radical advance over any other known method.

The depressed deformities of the nose, commonly termed "saddle-back," are usually congenital in origin, or due to disease of the bony and cartilaginous tissues (syphilis being the chief cause), or else due to some local trauma. Two cases I have seen recently were caused by the patient being struck on the nose by a baseball. Many of these cases can be corrected by simple plastic operation or by the injection of paraffin. However, where the bony framework of the nose has almost entirely or entirely disappeared it is well-nigh impossible to build up a "bridge" on which the tissues should rest, and the injection of paraffin in such cases is disastrous. All sorts of artificial bridges have been tried, made out of celluloid, metal, or even out of bone of some other animal; but in most instances, in the course of time, the bridge has given way. Therefore, this operation of Dr. Carter's has supplied a long-felt want, for one uses a homogeneous tissue, taken from the same person, and nourished by the same blood.

The young woman whose photographs are shown below consulted me some two months ago. She

*Case presented before the Laryngological Section, New York Academy of Medicine, March 27, 1912.

had a typical "saddle-back" nose. Examination showed a total destruction of the nasal bones and the septal cartilage. The tip of the nose was held down by cicatrices. She said that she had had no trouble with her nose until she was about fourteen

Fig. 1—Before operation.

years of age, when it gradually began to sink in. The process continued for about two years, and for the past six years there had been no change. The Wassermann reaction, much to my surprise, was negative.

I operated upon her at the New York Eye and Ear Infirmary on March 3, 1912. Figures 1 and 2* show her appearance before operation. An incision, three-quarters of an inch in length, was made between the eyebrows, with a slight concavity downward. This incision was deepened down through the subcutaneous tissues and a dull dissection made to the tip of the nose with a periosteal elevator, such as is used in work on the septum. The tissues separated very easily. The dissection was continued outward for some distance, so that

Fig. 3—Before operation; profile view. As no profile picture had been taken before operation, this photograph has been "doctored," but the deformity was even greater than here shown.

plenty of room was made for the insertion of the rib. The wound was then covered with a piece of gauze, dipped in a weak bichloride of mercury solu-

*The photographs were kindly made for me by Dr. Geo. S. Dixon of the New York Eye and Ear Infirmary.

tion. I then dissected out the ninth rib on the right side, taking about two and one-half inches from the sternal end. The dissection of the rib was a very simple matter. The periosteum was stripped back from the rib on both sides, as it is found that

Fig. 2—From a photograph taken nine days after the operation.

it is unnecessary to transplant the periosteum with the rib. A slight nick was made in the pleura, which healed over very nicely.

After the rib was removed it was split down its entire length and only the outer shell used. The medullary tissue was scraped out and the ends slightly rounded off. Unfortunately, at this stage of the operation I dropped the rib on the floor. I immediately had it washed in a weak bichloride solution, and then immersed for a few seconds in salt solution, all three of which procedures are distinctly detrimental to the success of the operation.

Attention was then paid to the original wound. An incision was made through the periosteum of the frontal bone and a dissection made between it and the bone for a distance of a half inch. The rib was then inserted down to the tip of the nose

Fig. 4—Same as Figure 2, profile view.

and the upper end slipped in between the periosteum of the frontal bone and the bone itself. When this procedure was completed it was found that the lower end did not quite reach to the tip, so that it would have been an advantage if I had allowed

myself another half inch of rib. The subcutaneous tissues were then united to the periosteum covering the rib and the skin united with a silk suture. The cosmetic result even at the time of operation was excellent. A dry dressing was applied over the wound on the face and a similar dressing applied to the chest.

The postoperative recovery was uneventful. For the first few days the face was swollen and extravasations of blood showed underneath the eyes. The patient had no temperature and was able to be out of bed on the eighth day. Figures 3 and 4 were taken on the ninth day after operation. The bone seems to be encapsulated in a sheath of connective tissue. The deformity has been entirely eliminated.

11 West Eighty-first Street.

A CASE OF BONE SYPHILIS MASQUERADING AS TUBERCULOSIS.

By LEONARD W. ELY, M.D.,

DENVER, COLO.

The following case is interesting from a number of different aspects. Doubtless it will seem instructive in various ways. To me it shows the importance of taking pains, of a knowledge of bone pathology, of an open mind, of scientific scepticism, and of other things.

The patient, a physician, 33 years of age, was referred to me in April, 1911. He had one child,

Fig. 1—Skiagram taken September 6, 1910. Observe the intact articular cartilage. In a tuberculous osteomyelitis of this extent the cartilage would be badly damaged.

had previously been in health, and denied syphilitic infection absolutely, then and later. Two years ago (from date of history taking) a painful swelling appeared in his left index finger. The swelling subsided, returned in about three months, and grew worse. Two months later the [illegible] was incised and was treated with wet dressings.

At this time the patient was under observation of some of the most eminent [illegible] he country, in one of our largest cities, a surgeon

Fig. 2—Skiagram taken February 7, 1911. Observe the new bone along the margin of the radius.

thought the disease clinically was syphilis, but the Wassermann test was negative, the von Pirquet test was positive, and a skilled pathologist reported, after examining some of the tissue, that the disease was tuberculosis. The finger was therefore removed, about six months after the onset of the disease.

A few weeks after the removal of the finger the patient began to experience soreness over the sternum, which grew worse, and a fluctuating swelling appeared. This never broke down. The examination of the lungs at this time was negative.

About three months after the amputation the left wrist and the left knee became involved, and became painful, swollen, and tender. These symptoms have persisted to date.

The patient affirms that the disease in the finger was located in the shaft, and under the microscope appeared as a periostitis. He gave up his practice, moved West, and traveled about in this section of the country seeking health.

Examination: The patient is in excellent general condition and walks with a decided limp, using canes. His forefinger is gone clean. The lower end of the left radius is swollen and decidedly sensitive to the touch, but the disease apparently does not involve the joint. Thickening is present over the sternum. The left thigh is two cm. smaller in circumference than the right, and the left calf 1½ smaller than the right. Sensitiveness can be elicited over the left internal semilunar, but no swelling of

the joint, sensitiveness of the synovia, nor fluid in the joint. Flexion is limited to about 80°.

Skiagrams showed an appearance typical of syphilis, the multilocular lesions, not involving the joint, pointed in the same direction, and the history was decidedly not that of tuberculosis.

A study of the radiograms will show that the bone condition had improved between the time of taking No. 1 and No. 2. This almost absolutely bars out tuberculosis. In joint tuberculosis in adults the morbid process is almost invariably steadily progressive until it destroys the joint.

Dr. Arneill, who referred the patient to me, rejected the diagnosis of tuberculosis, and, disregarding the Wassermann test, had another test done, which resulted positively. The patient was therefore put on intramuscular injections of salicylate of mercury, and began immediately to improve. All the symptoms in his knee disappeared, and the symptoms in his sternum also. The radius also grew much better, and the sensitiveness and swelling decreased. After a while the improvement ceased, and the case came to a standstill. Then the radius grew worse. Iodide of potassium was tried without avail.

On February 7, 1912, Dr. Markley administered a dose of salvarsan, and the patient immediately improved markedly. The radius decreased greatly in size and lost its sensitiveness.

March 10. The physical signs in the radius have almost disappeared. Dr. Markley administered a second dose of salvarsan, and the patient departed for his home, eastward, cured of his severe "bone tuberculosis."

Two things deserve mention in addition. The first is that the patient, while traveling about in the West preparatory to coming to Denver, had an afternoon rise in temperature. The second is that a thorough and careful examination of the many slides made from his amputated finger, on which the whole treatment of his case had been based, failed to reveal any sign whatever of tuberculosis.

NON-OPERATIVE TREATMENT OF STERILITY.*

By Sarah Jane McNutt, M.D.,

New York

In the treatment of sterility it is necessary to treat the special conditions that cause it, and in no department of gynecology is more persistent, patient work demanded. Insufficient treatment nearly always results in failure. When the patient first presents herself it is well to ascertain if there is difficulty about intercourse. Especially in those recently married, but even where the sterility has existed for years it may be discovered that there has never been any proper consummation of the act.

Notwithstanding the exceeding delicacy of these inquiries, there is rarely difficulty in getting definite answers which will enable an opinion to be formed.

It is necessary by questioning, to find out whether there is any sexual pleasure or desire, or the reverse, whether intercourse takes place too frequently or at reasonable intervals, or very seldom. If there be exhaustion of the genital centers from excessive sexual activity or masturbation, the latter should be discontinued and the cause of irritation that has induced the habit searched for and removed, which as a rule can be done. Frequent coitus should be discouraged.

The patient should be told that the most likely time for conception is immediately after menstruation. Exceptionally the time varies, and some may conceive later, or only just before menstruation. It would be well to suggest that the time of most desire, if recognized, should be selected.

Certain vicious practices play an important part in inducing sterility, and are unquestionably a fruitful cause in a large percentage of cases in inducing a chronic engorgement of pelvic tissues of a very stubborn type, not always yielding to the most wisely directed and thoroughly persistent treatment.

Some of these practices are the use of medicated douches immediately following intercourse, sponges inserted in the vagina, withdrawal, or use of condom. The treatment is the cessation of the practice, and the use of remedies to relieve the condition. In such cases where the sterility has been of long standing, a guarded prognosis for cure should be made.

The man may be wanting in power, or suffering from some other condition that prevents conception taking place. Several years ago a young woman came to the author to be cured of her sterility. She had been married 18 months, but had never conceived. Conditions were found which very readily suggested a cause, but when they were relieved pregnancy did not take place. Directions were given that the husband see a specialist. The microscopical examination showed that the semen did not contain spermatozoa. He had spent several months in Colorado for incipient tuberculosis, but had been pronounced cured.

Other cases are found where the spermatozoa are present but immobile, and are rendered active by tonic and invigorating general treatment to the man.

Examination.—After eliciting anything which can throw light on the possible cause of sterility, a regular pelvic examination should be made, in the ordinary way, noting first the condition of the external genitals, the skin and mucous membrane of the vulva, the hymen if ruptured, or if tough and unruptured, the meatus, the vulvovaginal glands, if vaginismus is present, if the vagina is normal, if the position of the uterus is correct, whether the uterus is movable or if there be any signs of previous pelvic inflammation, and what is its present condition; if the cervix is normal, conical, unusually small, if the os is closed or patulous, if it seems natural to touch or unhealthy; any tumors of the uterus or swelling of the ovaries or tubes, or tumors connected with them.

Treatment.—Urethral caruncles or vulvar vegetations should be removed or destroyed with other sensitive excrescences. In mild cases they should be tied off or cauterized under cocaine in the office; if severe they should be removed under ether.

If the hymen is intact or a condition of mild vaginismus exists, accentuated by fear, small pledgets of absorbent cotton saturated with a solution of cocaine (5, 10, or 20 per cent.) applied against the hymen, or where sensitiveness is present, cocaine vaseline applied direct will soon render the parts quite insensitive for complete examination, and enable us to discover if the pelvic conditions are normal, and will enable us at the same time to convince the patient that these remedies can be used as directed 15 or 20 minutes before coitus with entire relief of discomfort. In prescribing cocaine vaseline it is necessary to write for

*Read before the Women's State Medical Society at Buffalo, May 10, 1912.

the cocaine alkaloid, since cocaine hydrochlorate will not assimilate with oily preparations. The ointment can be ordered in a 1, 5 or 10 per cent strength. In mild cases these directions are sufficient for cure. Should the local condition be aggravated by more or less traumatism from frequent unsuccessful effort to have intercourse, a condition not infrequently seen, entire rest of the parts should be insisted upon, until with the use of soothing lotions or mild ointments the injury is removed, when the cocaine vaseline, or solution of cocaine, can be used with satisfactory results.

Should a tough unruptured hymen be found, it is not necessarily a cause for sterility, since patients have become pregnant where a tough hymen still existed and where the male organ has not gained an entrance to the vagina. Where menstrual fluid passes spermatozia can travel.

A tough hymen may be dealt with in the office by cutting or rupture after cocainizing the part. This treatment will frequently be sufficient in many cases where no vaginismus exists.

If the hyperesthesia of the vulva persists when the effects of the cocaine passes off or the hyperesthesia extends up into the vagina, or the vagina is abnormally small, thin glass dilators may be given to the patient with directions to pass them herself. One ought to be passed every day for a time, vaseline or some other lubricant being freely used—the solution of cocaine or cocaine vaseline if needed.

Some cases will not yield without more active treatment, and will be cured by stretching of the vulva and vagina under ether. Exceptionally cases are found that thorough dilatation under ether has not relieved, and severe neurasthenia has developed. Gibbons reports such cases relieved by the Paquelin cautery, lightly applied to the inner sides of the labia minora and all around the orifice of the vagina, and especially to the posterior fourchette, ascertaining the most sensitive points before giving the ether, so as to bear them in mind in applying the cautery.

Discharge.—It is especially important in looking for the cause of sterility to make sure if there be a vaginal discharge, and if present what its character. It may be non-irritating and simply due to engorged pelvic vessels, from the pressure of a constipated bowel, or some displacement of pelvic organs.

The treatment for these conditions will generally relieve the symptoms. Whatever the starting point of the catarrhal condition of the mucous membrane of the vulva, vagina, cervix, uterus or tubes, the more or less continuous secretion will often act in a toxic manner on the spermatozoa, probably due to the living organism it contains which is antagonistic to the spermatozoa, or it may render the implantation of the ovum impossible.

If a specially acid leucorrhea exists a simple vaginal douche of bicarbonate of sodium, a dram to the pint of lukewarm water once or twice daily, may be sufficient for its cure. The alkaline douche favors the vitality of the spermatozoa, and it has been found that where the sterility existed with an acid discharge, a single douche ordered immediately before coitus allowed conception to follow.

When the uterus seems to be the starting point of the discharge alkaline intrauterine irrigation should be tried. In stubborn cases it has been suggested that following the intrauterine irrigation (or without it—a probe loosely wound with cotton, which has a strong thread tied to the end of the cotton, farthest from the top of the probe, can be saturated with a solution of bicarbonate of sodium grams x or xx to the ounce [illegible], and if the canal is sufficiently open pa[illegible] the uterus; then one should slide off the [illegible]etting the thread extend half an inch out[illegible]he vulva. Direct the patient to remove the [illegible] drawing on the thread just before coitus, which should take place soon after its introduction [illegible]ct). A much safer method, however, is to [illegible] place of the cotton, several strands of lamp [illegible] o the uterus with very slender curved uterine forceps, or a narrow piece of sterile gauze. Where the secretions are acid, it would be well to see if alkalies internally are indicated.

Should the discharge be the result of a glandular endocervicitis or endometritis, vaginal douches followed by antiseptic intrauterine irrigation if there is no tubal disease and the os is patulous, should be given and followed by scarification of the cervix if the glands are involved. This treatment with knee chest tamponade to insure good drainage may entirely effect a cure.

Should the condition not readily yield to treatment, and there be profuse menstrual flow, thorough curettage under ether, with amputation of the cervix if indicated, should not be delayed.

Gonorrheal Sterility.—If with an irritable vaginal discharge, pus can be made to ooze from the urethra and vulva vaginal glands, it should be regarded with suspicion and should be examined for the gonococcus. Since men are responsible for 50 to 75 per cent. of sterile marriages, in all suspicious cases the wife should not be subjected to a course of treatment until the husband has been examined by a specialist. The absence of the gonococcus is not always diagnostic, however, as the germ disappears from the discharge after a time anyway.

A man who has had gonorrhea may by careful treatment be apparently cured, but the germ can live for years or indefinitely in a perfectly dormant state, and only after the abuse of stimulants or at the height of an orgasm can it be expelled into the vagina and produce an actively acute inflammation, and display its utmost malignancy.

Should the microscopical examination of the discharge discover the gonococcus in husband or wife, the treatment should be the local and general treatment of gonorrhea.

It is only in comparatively recent years that we have come to know how much men are to blame for sterile marriages, and this knowledge is largely owing to the work of Noeggerath, the leading authority 30 years ago, and when he sounded a warning declaring that the individuals with gonorrhea could remain infectors during a lifetime, he was regarded as an alarmist and his statistics of the frequency of this disease in married men as exaggerations. Recent attention has been called to the fact of the undeserved blame which women have been carrying for so many centuries, as being the chief factor when no offspring was forthcoming.

In all cases of sterility where the wife is presented for examination, it has been insisted that the husband should also submit to an examination. As a result it has been found that the man had venereal disease in about 80 per cent. of cases—in 25 per cent. of cases he was himself sterile through the infection of this disease.

Only too often, even at the present day, is the woman treated, operated upon, and otherwise maltreated and humiliated to correct her sterility, when the fault is exclusively with the man—a fact that cannot be too often repeated.

Cervical Conditions the Cause of Sterility.—If the examination reveals an infantile or a hyperinvoluted uterus the condition may be improved by galvanism, the sterilized negative electrode being passed into the uterus, and the positive attached to a broad pad placed upon the abdomen over the fundus; a current up to 50 milliamperes has been suggested by Hare for five minutes, two or three times weekly, and the uterus lightly massaged afterwards. Such treatment has been successful in enlarging the uterine body, and since it does, may increase the probability of conception. In cases of neurasthenic impotence a pad with the positive electrode over the fundus, and one with the negative attached, over the lumbosacral region to stimulate the genital centers by a mild current for 10 to 15 minutes two to three times a week, has seemed to be of nutritive value.

In a conical elongated cervix, more or less stenosed sterility has been overcome by the use of galvanism, the negative electrode being passed into the uterus, the positive placed over the fundus. The current should be only of sufficient strength to allow relaxation of the tissues. Treatment can then be readily made if the mucous membrane is not normal.

Hard rubber stem pessaries or tents should not be used. If the galvanism is not immediately effective, there should be no delay, but forcible dilation should be made with steel dilators, not in the office, however. The patient should be prepared as for a serious operation with antiseptic precautions, and it should be done under ether and the patient remain in bed until all sensitiveness has disappeared.

Displacements.—A displaced uterus, a frequent cause of sterility, should be replaced and held with pessary or tampon in a position to allow spermatozoa to enter the cervical canal. If the cervix is acutely anteflexed and low in the pelvis, so it presses on the floor of the vagina, helping to accentuate the flexion—a not infrequent condition—a tampon placed in the posterior cul-de-sac in the knee-chest position raises the uterus, and putting the uterosacral ligament on the stretch often helps to modify the antiflexion sufficiently to allow the canal to be patulous and permit pregnancy to take place.

Early last year a patient came to be cured of her sterility. She had one child six years old, and no other pregnancy had occurred. She was very constipated.

Examination showed a rather large uterus in forced retroversion, the fundus rather lower than the cervix, which was crowded up behind the sympathis, completely closing the os and preventing the entrance of the semen. The posterior cul-de-sac was entirely effaced and fundus pressed directly into rectum. It was comparatively easy to replace the uterus in its normal position; a small tampon pressed well up behind the cervix to stretch the fornix was sufficient to retain the uterus in the normal position.

The patient became pregnant almost at once, and was delivered in November, 1911, of a healthy child. The uterus had to be held forward for some time by tampons, to overcome its tendency to revert to its former position.

If the vaginal vault is shallow or illy developed, or the natural S shape of the vagina has been destroyed by the dragging down of the vaginal wall by a displaced uterus, or a lacerated perineum, making the vaginal floor an inclined plane down toward the vulva, it is highly important that this S shape should be re-lined or restored by stretching the vault by means of a ring pessary, or of a tampon introduced well behind the cervix in the knee-chest position.

Lacerations of the perineum should be repaired. "In these cases the patient should remain flat on her back after coitus, with the hips raised on a pillow to allow retention of the semen in the vagina, and to favor the formation of the so-called 'seminal pool,' also to permit the cervix to remain for a time immersed in the semen; if the spermatozoa are active they may readily find their way into the cervical canal and up into the uterus. One should remember in these cases to order a preliminary alkalin douche to favor the vitality of the spermatozoa." (McDonald.)

Salpingitis and ovaritis usually cause sterility by the adhesive inflammation displacing these organs, closing the abdominal end of the tube, thus preventing the entrance of the ova, or blocking the passage for want of ciliary movement. Much, however, can be done by proper treatment, as pregnancy has frequently occurred after systematic effort that has relieved the inflammatory condition, even in a gonorrheal inflammation, which most frequently leads to permanent sterility. The patient should be advised of the uncertainty of a cure for her sterility, but of the immediate need of getting rid of the inflammation. If she is willing to make the effort, the local treatment should be continued, so long as progress is shown, and there is a prospect of curing her, and while improvement continues an operation should not be advised, which will entirely destroy her hopes.

Where involvement of the tubes and ovaries occur, they should be packed up in the knee-chest position, higher than the uterus, to insure drainage and help establish better circulation. Painting the vaginal roof with Churchill's tincture of iodine, followed by glycerine tampons, of nonabsorbent cotton or wool, which should be small enough to be kept entirely up in the posterior cul-de-sac, well behind the cervix, and held there firmly by the operator's index finger while the patient rises up from the knee chest position straight on her knees, which will allow the cervix to grasp the tampon and hold it in place.

To prevent the tubes dropping back and refilling, the patient should never be without such tampon while the condition remains—two to three times a week will usually be sufficiently often to replace it—if not it should be introduced oftener.

If adhesions are formed, they are not infrequently separated or stretched by the tampon. A typical case came to the office in November, 1910. The inflammation followed a curettement some weeks after an early miscarriage. Her physician advised the removing of the tubes as the only hope of restoration of health. The patient was informed by me that if the present condition could be relieved, it would be only after patient, persistent work for a long time, and should such a result be obtained there could be no promise that pregnancy would occur, although it had happened in some other cases. She was anxious to make the effort and was rejoiced when, eighteen months later, pregnancy did take place, and early in January, 1912, a fine boy weighing ten pounds was delivered. The mother made an uninterrupted recovery, and since mother and child have done well. During the early months of pregnancy, however, the small tampon in the posterior cul-de-sac had to be continued, since evidently the inflammatory condition

within the tubes was quicker to disappear than the exudation in the surrounding tissues. The adhesions were sensitive if the increasing weight of the uterus was not taken off them by the tampon.

When the ovaries are small and impalpable, when severe dysmenorrhea or delayed irregular or scanty menstruation exists, often approaching menopause, the administration of lutein extract, one grain twice daily, has occasionally seemed of great value. Lutein has been used for several years at the Johns Hopkins' Hospital. There is a preparation which contains all the active principles of the ovary—the lutein, as well as the secretions of the Graafian follicles—besides the extract of the secretion of all the ductless glands. The parotid, spleen, pituitary body, spinal cord, and mammary gland are taken from the cow, the suprarenal and thyroid from the sheep, ovary and pancreas from the sow, thymus from the calf, and the orchic from the ram. Iron and arsenic are added. The cases of sterility in which I have used this method have been too few to establish definite conclusions as to the value of organotherapy, but in all cases tested the result seemed most gratifying, in appearing to establish an improved pelvic circulation, and to induce a feeling of general well being in the patient.

General Health.—In treating all cases of sterility one must never ignore the general condition of the patient. Systematic vices must be eradicated so far as possible, since many cases of sterility can be cured by general treatment alone. Repeated abortions indicating the possibility of syphilis must receive continued, persistent antisyphilitic treatment for at least two years. Anemia, malaria, struma, must all receive thorough treatment.

Tonics and hygienic measures, well regulated open air exercises, baths, suitable food, a spare diet to the plethoric, a more generous one to the poorly nourished—all must be systematically carried out, since it is found that an improvement in the general health has some important influences upon ovulation.

In cases where there is nothing wrong with the pelvis, it has been found to be a distinct advantage to have the wife go away alone for a time.

When other treatment has failed, artificial impregnation has been successfully accomplished by the introduction of the semen directly into the uterus by means of a syringe and tube, or by an intrauterine syringe alone.

265 Lexington Avenue.

THE CHEST INDEX IN PULMONARY TUBERCULOSIS.

By WM. NARINS, M.D.,

NEW YORK.

ASSISTANT ATTENDING PHYSICIAN GOUVERNEUR TUBERCULOSIS CLINIC

In going over the literature of the subject of chest measurements of tuberculous patients, one finds the view prevailing from the ancients until very recent times that the phthisical chest is flat, *i. e.* its anteroposterior diameter is relatively smaller than the similar diameter of a healthy individual.

Osler, commenting on the observations of Hippocrates and others, states that "undoubtedly the long, narrow flat chest, with depressed sternum is commonly enough seen in tuberculous patients." Strümpel and others speak of "the paralytic, pterygoid, or phthisical chest in which there is an abnormal flattening of the sternum and ribs" with consequent diminution of the anteroposterior diameter as common in tuberculous subjects, etc.

More recent observers, as Hutchinson and Niles, have, however, proved by actual measurements taken on chests of tuberculous patients that the tuberculous chest not only is not flat, but on the contrary is round, approaching more nearly the chest of the infant, whose anteroposterior and transverse diameters are nearly alike. In explanation of this rather startling observation, the theory is advanced that the tuberculous subject suffers from an arrest of development of the chest, causing it to remain in a more or less infantile state, which, as stated, is more nearly round than flat. These observers further claim that the apparent flatness of the tuberculous chest is merely an "optical illusion caused by the throwing forward of the shoulder girdle, giving the chest a sunken or hollow appearance."

Our own observations on 900 cases treated at the tuberculosis clinics of Gouverneur Hospital do not coincide with these latter views of the rotundity of the chest in tuberculosis, but rather tend to confirm the former view that the phthisical chest is more often flat than round. Measurements of our cases have been made on an imaginary plane passing through the level of the junction of the fourth costal cartilage and sternum.

The anteroposterior diameter divided by the transverse gives the ratio which one bears to the other, and is called the "clinical index" of the chest. From a number of observations made by several investigators of the subject the normal average adult chest index is placed at 70, so that A. P.: T.:: 70: 100. Some place the normal index as high as 80, others as low as 60, but if we were to group all cases between these extremes as normal, there would be very few others, and no occasion for this report; hence we decided to accept 70 as the normal chest index, allowing a variation of 2 either way as still within the normal limit, so that all chests with an index of between 68-72 were grouped as normal, those below 68 as below normal, and those above 72 as higher than normal. Several cases have been recorded with a chest index of 100, while the lowest index observed was 52.

In classifying our cases we have divided the positive, negative, and doubtful cases into separate groups, with a subdivision of each group into male and female, and of each subgroup into decades. Children up to 15 have been grouped separately because of the essential difference between the child and adult chest. The figures are as follows:

	Male	Female	Total
Positive	385	281	586
Negative	114	75	189
Doubtful	39	16	55
	Positive	Negative	
Under 15	34	36	70
Total number of cases			900

We find here a total of 385 positive male cases, of which 240 occur between the ages of 20 and 40, an age when tuberculosis is most common; of these 240 cases, 109 or 45 per cent. have anatomical indices below normal; 76 cases or 32 per cent. have anatomical indices above normal, while the remainder have normal anatomical indices (quite a predominance in the number of flat chests).

In the same table we have 100 cases occurring between the ages of 40 and 60. Of these only 33 per cent. are below normal, while 47 per cent. are above normal, the remainder being normal.

TABLE I.

Male Cases.	Average Expiration.	Average Inspiration.	Expansion.	Average Index.	Above Normal.	Normal.	Less Than Normal.	Total Cases.
15–20	77.1 c.m.	83.2 c.m.	6.1 c.m.	68.7	10	10	20	40
20–30	80.6 c.m.	86.1 c.m.	5.5 c.m.	67.2	32	28	65	125
30–40	83.2 c.m.	88.7 c.m.	5.5 c.m.	69.8	46	25	44	115
40–50	84.6 c.m.	89.0 c.m.	4.4 c.m.	66.2	31	15	29	75
50–60	84.2 c.m.	88.4 c.m.	4.2 c.m.	75.7	16	5	4	25
60–70	83.7 c.m.	87.7 c.m.	4.0 c.m.	82.5	5	2	.	5
General Average.	82.1 c.m.	87.1 c.m.	5.0 c.m.	71.7	138 35.8 per cent.	85 22 per cent.	162 42.1 per cent.	385

The greater number of high indices in this group, *i. e.* between 40 and 60, is easily accounted for by the frequency of emphysema occurring in these older patients.

TABLE II.

Positive Female Cases	Average Expiration.	Average Inspiration.	Expansion.	Average Index.	Above Normal.	Normal.	Less Than Normal.	Total Cases.
15–20	72.0 c.m.	77.7 c.m.	5.7 c.m.	67.6	6	9	9	24
20–30	76.0 c.m.	80.5 c.m.	5.5 c.m.	68.5	19	11	29	59
30–40	75.9 c.m.	80.0 c.m.	4.1 c.m.	70.5	25	20	21	66
40–50	76.5 c.m.	80.1 c.m.	3.6 c.m.	71.3	16	9	10	35
50–60	80.0 c.m.	83.5 c.m.	3.5 c.m.	76.0	9	3	3	15
60–70	89.2 c.m.	92.9 c.m.	3.7 c.m.	92.0	2	..	..	2
General Average.	78.2 c.m.	82.4 c.m.	4.2 c.m.	74.3	77 38.3 per cent.	52 25.8 per cent.	72 35.9 per cent.	201

Table II proves the same thing, though to a lesser degree. Of 201 positive female cases there were 125 between the ages of 20 and 40, and of these 50 cases or 40 per cent. were below normal anatomical index; 44 cases or 35 per cent. above, the remainder being normal. Between the ages of 40 and 60 we have a total of 50 cases, of which number 13 cases or 26 per cent. are below normal, 25 cases or 50 per cent. above normal, the remainder being normal. Adding the male and female positive cases together, we have a total of 580 cases, of which 305 occur between the ages of 20 and 40; of these 305 cases, 150 or 43 per cent. are below normal chest index, 120 cases or 32 per cent. are above normal, the remainder being normal. Between the ages of 40 and 60 we have a total of 150 cases, of which 40 or 30 per cent. are below normal, 72 cases or 48 per cent. are above normal, the remainder being normal.

In comparing these two sets of figures one is struck by the great number of flat chests occurring between the ages of 20 and 40, and the still greater number of round chests occurring between the ages of 40 and 60, and the inevitable conclusion one must reach is that factors other than the tuberculous infection *per se* are responsible for this variation. Emphysema, essential or compensatory, we believe to be the chief single factor responsible for the great number of high chest indices occurring between the ages of 40 and 60.

In a chest index study as here undertaken, it seems to us not unfair to divide the cases into two main groups, one between the ages of 20 and 40, when tuberculosis is most common and is apt to be uncomplicated by other factors, and another group between the ages of 40 and 60, when tuberculosis is not so common and is very frequently complicated by other factors tending to alter the chest contour, such as emphysema; for after all it is the tuberculous chest mainly, uncomplicated by anything else, which interests us most. And this is best exemplified by the young and adult up to 40 years of age; as we have seen, the flat chest predominates in these cases.

We now come to a class of cases that still further tends to disprove the high index theory of tuberculosis. This subdivision consists of children up to 15 years. No sex differentiation is made. If, as it is claimed, the tuberculous chest is round because of arrested development, certainly this group of cases, being in the period of development, ought to show it, whereas the contrary obtains in our series.

TABLE V.

Cases Under 15.	Average Expiration.	Average Inspiration.	Expansion.	Average Index.	Above Normal.	Normal.	Less Than Normal.	Total Cases.
Positive	64.0 c.m.	69.5 c.m.	5.5 c.m.	71.8	16 47 per cent.	4 12 per cent.	14 41 per cent.	34
Negative	61.3 c.m.	66.7 c.m.	5.4 c.m.	73.4	18 50 per cent.	6 16 per cent.	12 34 per cent.	36

Of a total of 70 cases, there were 34 positive with 16 cases or 47 per cent. above normal, and 14 or 41 per cent. below normal; the rest were normal. While of the 36 negative cases there were 18 or 50 per cent. above normal, and 12 or 34 per cent. below normal, the rest being normal. If tuberculosis arrests the development of the chest we ought to have a greater number of high chest indices among the positive cases than among the negative, whereas the contrary is true. In fact, we notice that the number of flat chests is greater among the positive than among the negative cases.

It may not be inappropriate to speak here of the positive cases between the ages of 15 and 20 years. These, too, may be regarded as in a more or less developmental period, and ought to throw considerable light on the subject. Of these we had a total of 64 cases, of which 16 or 25 per cent. were above normal; 19 cases or 30 per cent. normal, while 29 cases or 45 per cent. had a chest index less than normal. This last group of figures is very significant and argues strongly for the flat as against the round chest in tuberculosis.

The negative cases at our clinic have also been measured, with the following result. There were a total of 189 negative male and female cases, which for the sake of brevity will be grouped together:

Of these 100 cases, 104 were between 20 and 40, of which 40 cases or 38 per cent. were below normal; 38 cases or 37 per cent. were above normal, the remainder being normal. We notice among this

group of negative cases not quite so many flat chests as among the positive cases of the same ages, while the proportion of high index chests is somewhat greater than in the positive group.

chest expansion. We find that while a small number have a fairly good chest expansion of from 8 to 10 or even 12 cm., the majority are very poor and shallow breathers, having a chest expansion in

TABLE III.

Negative Male Cases.	Average Expiration.	Average Inspiration.	Expansion.	Average Index.	Above Normal.	Normal.	Less Than Normal.	Total Cases.
15–20	75.0 c.m.	81.2 c.m.	6.2	70.8	10	6	4	20
20–30	83.1 c.m.	89.8 c.m.	6.7	70.2	13	8	14	35
30–40	84.1 c.m.	89.8 c.m.	5.7	70.7	11	7	4	22
40–50	84.2 c.m.	89.4 c.m.	5.2	69.0	8	5	5	18
50–60	85.0 c.m.	87.0 c.m.	2.0	75.0	2	1	2	5
60–70	81.8 c.m.	85.0 c.m.	3.2	70.4	4	1	1	6
General Average.	83.3 c.m.	86.9 c.m.	3.6	72.6	48	28	41	117
					42.1 per cent.	21.9 per cent.	36 per cent.	

TABLE IV.

Negative Female Cases.	Average Expiration.	Average Inspiration.	Expansion.	Average Index.	Above Normal.	Normal.	Less Than Normal.	Total Cases.
15–20	74.5 c.m.	78.9 c.m.	4.4	68.8	3	2	4	9
20–30	79.5 c.m.	84.0 c.m.	4.5	68.0	6	4	2	12
30–40	81.3 c.m.	86.2 c.m.	4.9	70.3	6	7	2	15
40–50	81.0 c.m.	85.4 c.m.	4.4	73.5	9	3	6	18
50–60	78.2 c.m.	82.6 c.m.	4.4	70.4	4	1		5
General Average.	78.3 c.m.	82.8 c.m.	4.5	71.9	30	17	25	72
					40 per cent.	22.6 per cent.	33.3 per cent.	

Between the ages of 40 and 60 of the negative cases we had a total of 48, of which 10 cases or 33 per cent. were below normal, 23 cases or 48 per cent. above normal, while the rest were normal, which is about the same as in the positive group of the same age. Of the doubtful cases we had a total of 55, of which 30 cases were between the ages of 20 and 40. Of these 30 cases 10 or 40 per cent. were below normal, 7 or 23 per cent. were above normal, the remainder being normal, here also showing the relative increase in the number of flat chests as the possibility of tuberculosis increases. Between 40 and 60 there were 11 cases, of which 3 or 27 per cent. were below normal; 6 cases or 54 per cent. were above normal, the remainder being normal.

some cases as low as ½ cm., but mostly 3, 4, 5 or 6 cm., their breathing being mainly diaphragmatic and abdominal.

In summing up the value of the chest index as an aid in the diagnosis of pulmonary tuberculosis and attempting to explain the findings in our cases, which, by the way, do not agree with the findings of other observers, we must bear several things in mind.

We must remember first of all that (1) the chest in health is not always perfectly symmetrical and with a normal chest index; many departures from the normal occur that are not pathological, depending rather on the general physique of the individual, his occupation, racial characteristics, etc. (2) The class of patients treated at our clinic are mostly

The positive, negative, and doubtful cases between the ages of 40 and 60 all show the same thing, namely, a low percentage of flat chests and a high percentage of round chests, and we repeat here that we believe emphysema (essential or compensatory, or both) is responsible for this. There is one other thing we wish to speak of in connection with the chest measurement study, and that is chest expansion. All of our cases have had the circumferences of their chest measured during expiration and inspiration, the difference being the

Hebrews, many of whom are or have been tailors, and have now taken to some other occupation, such as peddling, only since they have ascertained their lung trouble. These tailors are always more or less in a bent over, cramped position while at work, which to a certain degree causes a flattening of the chest. (3) The emaciation consequent upon the tuberculous infection with its diminution of muscular and adipose tissue, does actually cause a flattening of the chest, especially in young adults unmarred by emphysema. Our forefathers in medicine, unequipped as we are

today with modern instruments of precision, but forced to depend on their sense of observation, had that sense keenly developed and they were not, apparently, in error when they stated that the tuberculous individual frequently has a flat chest.

Lastly, as a diagnostic aid, we may say that the chest index has not aided us materially in clearing up difficult or doubtful cases, and that while a majority of our cases had flat chests, not every flat chest should be taken as an indication of pulmonary tuberculosis.

309 Henry Street.

SURGERY FROM THE PEDIATRIC STANDPOINT

By LE GRAND KERR, M.D.,

Brooklyn, New York.

Pediatrist to the Methodist Episcopal, Bushwick, Williamsburgh and Swedish Hospitals; Consulting Pediatrist to the Rockaway Beach Hospital and Industrial Home for Children

Several months ago the writer was invited to witness an exploratory laparotomy in a child of three years. The question of diagnosis lay between that of tuberculous peritonitis as made by the surgeon and sarcoma as made by one less skilled in operative technique. During the procedure the operator made emphatic complaint about the low temperature of the saline solution which was being freely used in irrigation. Immediately following the operation there were removed from the child several protective towels and a gown which were all well saturated with the saline which had been more or less carelessly handled throughout the operation. Upon looking over the child's chart, it was noted by the writer that a bronchitis had existed for several days, although there was absence of any rise in temperature for a few days preceding the operation. Upon the strength of three facts, namely, the wet dressings, the bronchitis, and the general lowered nutrition of the child, the writer felt justified in expressing the opinion, when it was asked for, that the child would probably die within a few days of pneumonia. While this was not comforting to the operator, the prediction proved true in four days.

This experience is cited to emphasize the fact that while an accurate diagnosis of the existing pathological condition is most important, it is not all-important. There still remains another most important factor and that is this: what will be the probable outcome of the injury or the disease and what estimate can be placed upon the probable course and termination if an operative procedure is undertaken? In this instance these latter considerations were either ignored or reduced to a minor consideration. Is it not true that the tendency is for us to emphasize the importance of accurate diagnoses, and minimize other factors which are at least as important in conserving the morbidity and mortality among children? To appreciate fully what the final outcome may be often entails a close acquaintance with many facts which at first seem to have no direct bearing upon the disease or the injury. However, these may be such as to modify or entirely change the usual interpretation of symptoms.

Thus the nutritional state of the child is of great importance in any surgical disease or injury or when operative procedure is to be undertaken. The tendency has been to somewhat disregard the general condition and nutrition of the child and to give prime consideration to the disease or injury present and to look upon it mainly as a field for operative procedure in the endeavor to make a diagnosis or furnish surgical relief. Such an attitude does not give the surgeon or the child their best chances. Adequate surgical examination in childhood requires a previous intimate knowledge of the normal child at the various periods of its growth and development and without an intimate acquaintance with the morbid tendencies which are peculiar to each of these periods, the unstable equilibrium, the varied and irregular disturbances and peculiar reactions of the child will lead the surgeon into error. There is only one condition under which the surgeon can afford to disregard this, and that is, in emergency surgery.

To the child there should be portioned out every safeguard that an adequate surgical history can supply and the surgeon gains much and gives much, who takes cognizance of the child's organism as a whole. This broader view will aid in the discovery and relief of underlying conditions or the avoidance of unpleasant and sometimes fatal complications during a surgical procedure or convalescence.

This leads us to a consideration of the qualifications of the pediatric surgeon. Naturally the first requirement of the surgeon who hopes to deal efficiently with the surgical affections of children, is a broad clinical experience with surgical conditions and a perfection of technique which has been acquired through actual contact with many cases.

This very clinical experience will teach him that an operative procedure in the very young child requires more preliminary planning, more rapid operating, and infinitely more gentle handling than a similar procedure in an adult. To this knowledge which he already possesses of the details of scientific surgery he must add a further knowledge of and love for children.

There are two ways in which the surgeon may meet the requirements: First, by acquiring a sufficient knowledge of children and their diseases; something that cannot be entirely learned from books, but like his operative skill is acquired through years of experience, and, second, by making use of the trained pediatrist. In fact, if the operative precision and the courage of the skilled surgeon were more often coupled with the knowledge and judgment of the skilled pediatrist the surgical results to the child, as exhibited in diagnosis, treatment, morbidity and mortality, would be better than they are at present.

The writer would not be misunderstood as claiming that every so-called "surgical child" needs the attention of a pediatrist, but in a large number of instances a twofold proposition presents itself.

The attempt of the surgeon to cope with a surgical procedure with which he is entirely familiar in a being with which he is unfamiliar is often as disastrous as would be the attempt of the pediatrist to cope with a surgical procedure with which he is unfamiliar in a being with which he is entirely familiar.

It is well-nigh time that we appreciate and recognize the fact that quantitative considerations are not the only or the chief ones in the surgery of childhood. Recognizing the added difficulties of technique which are offered by the smaller tissues is not sufficient.

We have yet to deal with the larger problem of the entirely different response and reaction of the child's immature organism to injury, disease or infection. And this problem is not a settled one, for

*Read at a meeting of the Medical Association of the Greater City of New York, April 15, 1912.

with the different periods it is an ever-changing one, so that under some circumstances disease or operative interference are tolerated well and under some conditions, as in healing, the child has an advantage over the adult, while under other circumstances a minor interference or injury is fraught with real danger to life.

Further than this there exist during childhood certain factors which have no parallel in adult life. We might mention as types of these the status lymphaticus, the tendency toward early and severe shock from slight causes and the ramifying influences of rickets or other nutritional disease.

Status lymphaticus is greatly dreaded by surgeons and anesthetists alike. And why? Its indefinite etiology, its insidious symptomatology, and its sudden termination of life make it so. And yet if adequate surgical histories were taken it would often be shown that certain children who have been subjected to previous slight injuries have suffered intense shock which was out of all proportion to the injury received. Certainly such a history gives us a clue at least and also a strong and timely warning that any surgical procedure or the administration of an anesthetic will be unpleasantly dangerous. Just as soon as the immediate institution of some surgical procedure is made the paramount consideration in a child whether it is in need of it or not, there is brought into play other factors which may be made more serious by interference or which markedly influence the end results and finally force themselves to attention, although they are treated with scant consideration in the beginning.

It is not a common practice among surgeons to obtain any detailed history of the possibility of exposure to infection previous to an elective operation and as a matter of fact, many have admitted that they are not familiar with the lengths of the various incubation periods of the exanthemata to which children are so constantly exposed. And yet we have observed several serious and some disastrous results which could have been entirely avoided if such a history had been secured in time. It can be readily appreciated that the development of a disease like measles, scarlet fever, diphtheria, or pertussis closely following an operative procedure or occurring during convalescence will materially influence the results. And it is not alone that the complication is of itself serious, but all infections in children are more severe when there is the added depression which must be consequent upon any surgical procedure.

The writer recalls the case of a child with a mild pertussis, from which it had practically recovered. A chronic appendicitis existed and the surgeon insisted upon immediate operation. In this latter proposition he was absolutely right; a chronic appendicitis in a child can only be safely treated by appendectomy and under ordinary circumstances the right time to do it is as soon as it is recognized. But in this instance an unusual element existed; the child was of the neurotic type and was recovering from pertussis. No consideration was accorded to the fact that for several weeks after recovery a child with pertussis is very liable to experience more or less violent spasmodic coughing when something happens to depress it and this is most certain to occur in the neurotic child.

Shortly after the operation the depression of the child's system was such that the spasms of coughing became more and more severe and frequent and the abdominal wound was forced open. For several days the outcome was uncertain, and although the technique was perfect and viewed as a surgical proposition alone, the need for operation was present, a fatal termination was nearly the result, because there was a disregard for other factors.

It is not alone the presence or possibility of other disease being added as a complicating factor, but there are many children who come to the surgeon for the correction of a deformity, the removal of a slow-growing growth or an elective procedure, who are not in good physical condition to stand the ordeal well. These children are operated upon and they do not die. They recover, but what is often the result? The operative procedure suffers in repute because there is not the return to normal efficiency which the parents expected.

This could all be avoided by competent attention to these details before the operative procedure. Such cases leave the care of the surgeon supposedly cured and find their way into the care of some one else afterward and in the minds of the parents the operative procedure has proven a partial failure.

Even under conditions that are apparently entirely surgical the surgeon cannot safely feel the same security in his ability in cases occurring in childhood as he does in adult life. Take as an illustration of this the recognition of acute and chronic appendicitis in children.

In the former instance it is commonly diagnosed when it does not actually exist. This is probably so because the question of appendicitis is so constantly forced on our attention that it is usually the first thing thought of when the symptom of right-sided abdominal pain is presented.

And yet abdominal pain is one of the least important symptoms of acute appendicitis in children. Why give so much prominence to this one disease which causes abdominal symptoms and disregard those less common but just as important other diseases which are frequent in childhood? In looking over my records for the past year I fail to find but one instance in which acute appendicitis actually existed and was not diagnosed either tentatively or positively before my observation, while upon the other hand, there are sixteen instances in which it was positively diagnosed and did not exist. In twelve of the cases the condition present was right-sided lobar pneumonia, in two, an acute indigestion, in one, intestinal parasites, and in another an overdistended bladder. The large proportion of cases of lobar pneumonia should be noted. The writer has known of many of these cases being operated upon and a normal or nearly normal appendix found. Then within a short time the child developed a lobar pneumonia which was attributed to the anesthetic. These are instances of mistaken diagnoses; made because the fact is overlooked that in children the physical signs in the chest are not always necessary for the recognition of the disease. For these errors, however excusable they may be in any given case, the surgeon and not the anesthetist should assume the responsibility.

A large number of the cases of chronic appendicitis in children are unrecognized as such, but are designated as acute exacerbations of some chronic digestive disturbance or are lightly dismissed under the pleasingly popular misnomer of "bilious attacks." If these children were thoroughly examined between their attacks it would often be found that there is a thickening about the appendix which would clear up the etiology and suggest the only adequate measure of relief—opportune appendectomy.

The surgeon does not see many of these cases because the indefinite symptomatology does not emphasize the need of adequate surgical intervention. It is distinctly a problem for the general practitioner, for it is he who observes these cases before they suffer an acute attack, but we should all heed the warning: "Be suspicious of all so-called bilious attacks in children."

And so we might go on and recite experience after experience, but enough has been mentioned to emphasize the following facts. That inaccurate diagnoses in the surgical affections of children are more common than in adults and that incomplete diagnoses are the rule rather than the exception and that both of these are brought about by the lack of an intimate knowledge of children in general and the way in which they react to disease or injury. Now, while it is not so in every instance, yet it is a common experience that an accurate and complete diagnosis is essential to the institution of adequate treatment and that as a consequence children suffer in treatment from too much or too little surgery. The inevitable result is that as far as operative relief is concerned to the lay mind its results are questionable in children.

When an operative procedure is advised in childhood, and this applies with particular force to those of tender years, it is common to observe that there is inadequate preparation of the peculiar patient and his surroundings as is evidenced by the previous examination and observation; that there is inefficient operative care because no special attention is paid to the planning for rapid work, brief and skillfully administered anesthesia, the most efficient assistants and the maintenance of body heat, and last, but far from least, an unpleasant post-operative convalescence is commonly the end of an otherwise perfect procedure because the child has not been understood and safeguarded at every point.

Post-operative complications are not always directly due to the surgical procedure; a prolonged post-operative convalescence is rarely a surgical proposition. Some of our surgeons must realize that they are not fully competent to handle the whole problem because at some time during its course a definite surgical proposition forces itself as an issue.

The surgery of childhood is related to general surgery in about the same manner as the practice of pediatrics is related to that of general medicine. Old traditions and former methods still connect them in the minds of many, but the modern surgeon with all of his courage, skill and mastery of technique, occasionally needs the services of the trained pediatrist and the writer is firmly convinced that the morbidity and mortality among children would be materially reduced if we all gave a much larger place in our deliberations and activities to the broad-minded and widely knowledged general practitioner.

42 Gate Avenue.

A CASE OF DRY NECROSIS OF THE MASTOID CELLS.

By OSCAR WILKINSON, A.M., M.D.,

WASHINGTON, D. C.

On October 26, 1911, Miss A. H., aged 25 years, came to me complaining of terrible headaches, pain back of her eyes, back of her right ear, and at the base of the head. In order to eliminate any ocular association of these symptoms I corrected her error of refraction which consisted of myopic astigmatism; refraction,—50 cyl., axis 180, and at the same time corrected a degree of left hyperphoria. This relieved her of the frontal and basilar headaches, but she still complained of pain in the right ear and especially of pain in and tenderness of the right mastoid bone which was so severe as to cause nausea and vomiting and deprived her of sleep. The drum showed some scars of old perforations of which she gave a history of suppuration at times between the ages of 8 and 15 years but no suppuration had taken place for ten years. She had had this post-auricular pain on several occasions, it lasting for a month or six weeks before being relieved. For twelve months she had had some pain and sensitiveness about the mastoid, and had consulted one or two aurists in regard to this, and had received some middle ear treatment, but without obtaining relief.

I gave her calomel and saline laxatives and ordered ice and counterirritants, placed her in bed, gave her quinine, her temperature being 100° at about the same hour every day which led me to think it might possibly be of malarial origin. Her temperature varied from 98.6° to 100° for two weeks before the operation. I operated with some degree of hesitancy, owing to the fact that the pain and tenderness on pressure and enlargement of a few superficial lymphatic glands were the only symptom of inflammation of the mastoid. I expected to find sclerosis of the mastoid tip with an associated neuralgic condition with a possibility of pus in one of the cells.

On opening the mastoid, the external layer of the bone was found to be more brittle but not harder than the normal tip; there was an entire absence of oozing from the bone. I found the cells dry and friable, apparently as dry as those of a skeleton and much more friable. Not a drop of blood was found from the first chiseling of the first layer of the bone until the aditus ad antrum was reached. There was no pus in any of the cells.

Recovery was uneventful, the symptoms entirely disappearing after the operation.

1408 L Street, N. W.

Infantilism.—M. de Biehler states that infantilism is a condition in which there is an arrest of development and a persistence of childish characteristics, so that the person appears younger than he really is. There are two types of the disease, one in which the individual appears to be a little man instead of a child, with enlarged thorax and small pelvis, and no disproportion between the head and the body; the hairy and genital systems are undeveloped. There may be either anorchidism or cryptorchidism. There are lesions of the heart, vessels, thyroid, and sometimes the eyes. The nervous system is undeveloped and neuroses, hysteria, or chorea may be present. The second form is accompanied by the symptoms of myxedema, with insufficiency of thyroid and hypertrophy of the hypophysis and thymus. Radioscopy shows an arrest of development of the epiphyses and retardation of the points of ossification. Myxedematous infantilism is due to thyroid insufficiency. The thyroid has some influence on the development of the genital organs, and these are also diseased. In the first type the causes mentioned are anangioplasia, alcoholism, tuberculosis, bad hygiene, syphilis, and malaria. In dystrophic infantilism the ossification is normal; in myxedematous infantilism there are bony changes. Contraction of the pelvis and thorax are accompanied by arrest of development of the contained organs. There is no cure for infantilism; all that one can do for these children is to nourish and educate them and protect them from injuries.—*Archives de Médecine des Enfants.*

THE CONGRESS FOR GENEALOGY, HEREDITY, AND REGENERATION

THIS new movement as exemplified in the recent congress held in Germany appears from the interest excited in high scientific circles to be on a somewhat different plane from some of the movements in the interest of eugenics so-called. It embodies the scientific features of the latter but is thus far devoid of a propaganda, and is in fact avowedly committed to a purely scientific research. According to the brief report of the congress in the *Münchener medizinische Wochenschrift* for May 7, a representative body of medical men, scientists, jurists, and genealogists were assembled. To cite a few only of the names best known among the participants we quote Ostwald the physicist, Alsheimer the alienist, and Kurella the disciple of Lombroso. It readily appears that the chief if not the sole reason for the existence of the Congress is the desire to resubmit all our older learning concerning heredity to Mendelian tests. Nothing permanent can be done in the way of race regeneration until we can ascertain to what extent certain outcroppings are inevitable. Of what use to breed eugenically if a Mendelian recessive quality entirely unsuspected in the ancestry is to crop out in a child? Thus our family genealogies must be rewritten, and this can hardly be done in a day, and at best only in prominent families. But a system of records for future use can and should be set in action at once, in connection with public schools, insurance, the army, etc.

The newer movement is in entire sympathy with the Eugenic Movement in England and elsewhere so far as this is carried out along the lines proposed by Galton and his disciples. It would naturally be opposed to hasty and otherwise inadvisable attempts to regenerate the race before the accumulation of necessary data. Certain data from the past are available from the study of the ordinary records of parishes, etc., such as must form the basis of ordinary genealogical research. From these it appears at the outset that families like individuals do not bear prosperity well and deteriorate as their material resources improve, and also that the menace from mating of the unfit is not so great as it might at first thought seem, because here the death rate in the resulting progeny is phenomenally high.

PARASITISM OF THE DEMODEX FOLLICULORUM IN THE DOG

WHEN the demodex was originally discovered in the sebaceous follicles of the face it was very naturally supposed that it was responsible, in part at least, for the occurrence of diseases in those structures, notably comedones and acne. All attempts, however, to show pathogenicity were attended with failure and the conclusion was accordingly reached that the demodex was an absolute saprophyte. Later it was shown that acari practically not distinguishable from the demodex were pathogenic in the dog, and it became apparent, therefore, that differences in pathogenicity might depend on something widely removed from mere morphology, just as in the case of much more lowly organized forms of life.

There has recently been formed in Germany an admirable society for the study of comparative pathology, entitled the Vereinigung zur Pflege der vergeichenden Pathologie in which, possibly for the first time, the leading exponents of human and veterinary pathology in equal representation meet and discuss problems of the utmost importance for mankind—for man must depend largely for his welfare on the complete health of the domestic animals. In a session of this society held last November (*Berliner klinische Wochenschrift*, April 22), an ophthalmologist made the announcement that in trachoma it was possible to find the demodex in such an association that it must be held responsible for the production of some of the secondary effects of that disease. In other words, when the tissues of the eyelids had been sufficiently compromised by the disease trachoma, the parasite became equal to the production of certain lesions which would not have occurred in its absence, and which might consequently be looked on as specific. These lesions represented a perifollicular infiltration of the lanugo hairs and eyelashes.

In discussion Regenbogen stated that he saw annually about 400 cases of diseases in the dog due to the same parasite or one indistinguishable from it. Yet within these limits there were wide differences which appeared to show a very variable pathogenicity by the same species. These differences in pathogenicity very likely depend on differences in the parasite which can be discovered only by prolonged zoological studies. At present there seem to be gross differences in size and shape which may not be accidental. It is of significance clinically that the demodex of the dog has never yet been accused of causing disease in mankind.

THE REPRESSION OF VENEREAL INFECTIONS.

IN all countries of the world venereal affections directly and indirectly lay a heavier toll on the population than any other disease, perhaps, than all other diseases together. It is difficult, almost impossible, to estimate their effects upon mankind. All diseases, with few exceptions, are influenced by venereal infections and its manifestations are protean, insidious, and deadly. Such diseases may be rightly termed the greatest scourge of mankind. Up to re-

cent times, in Anglo-Saxon countries, the venereal infections have been blinked at. The dislike to face this issue squarely is attributed by Anglo-Saxons themselves to the natural reserve of a retiring people, by the inhabitants of other countries to hypocrisy, the wish to pose as more moral than other races. This national characteristic has its drawbacks and advantages. There is no need to blazon forth one's weaknesses or vices, but on the other hand it is folly to try to hide them and to refuse to recognize them, to the detriment of the race. However, in this country at any rate, there has sprung up a tendency to grapple with the matter boldly and no longer to allow self-consciousness and false modesty to work harm. It is freely acknowledged that the canker is at the root of the tree and the only sane course to pursue is to find out the best way to drag it out and as quickly as possible.

In the *Maryland Medical Journal* for May 19, 1912, Lieut. Col. Jefferson R. Kean, Medical Corps U. S. Army, discusses the question and argues that, since prostitution is at the bottom of the evil logically prostitutes should be subject to supervision. Of course, infected men spread disease as well, but certainly as a beginning the regulation of prostitutes should be proceeded with. Unfortunately, in this country of freedom there are strong prejudices against restriction of any kind, even if they be designed for the good of the majority, and women especially are averse to having members of their sex unfairly, as they claim, discriminated against. After all, however, venereal diseases are more widely spread by prostitutes than by any other agency and consequently it seems reasonable to devise and put into effect measures which will tend to prevent this mode of spread.

Kean points out that Norway, Denmark, Finland, Switzerland, and other countries have done away with inscription, casernation, and segregation, yet all are trying to bring about a sanitary supervision of the prostitutes by the health authorities in order to check the spread of venereal disease. In Germany, Austria, France, and elsewhere there is a gradual tendency to break away from the older, more purely police methods of "control" and to substitute sanitary supervision. Finally, Kean thinks that a fair and honest trial of the provisions of a law like the much belabored Page law would be a good beginning of such sanitary supervision, which should be administered without recourse to the police except in the case of those who resist the law. In all parts of America public opinion is aroused with regard to the menace of venereal disease, and it now remains for a widespread movement to be undertaken to fight the evil in a rational manner—whether in the way Kean suggests or not, at any rate in some way.

Interpreters at Ellis Island.

Attention has been called in a previous issue (April 13, 1912) to the necessity of having sufficient interpreters to enable the medical examiners at Ellis Island to converse with any or all incoming aliens, if the inspection for mental disorders is to be in any way effective. It was stated that it was foolish to expect the best qualified alienist to recognize insanity or feeblemindedness when he could not even talk with the person being examined. It was further pointed out that interpreters were needed not only on the primary line inspection but even more in the immigrant hospital and in the medical examining rooms, for the careful and detailed examination of suspects who have been detained. Conditions are still far from satisfactory in this regard, and there seems to be a lack of agreement as to the responsibilty for the appointment of the interpreters. The medical examiners are officers of the Public Health and Marine-Hospital Service, which constitutes a bureau under the Treasury Department. The immigration inspectors are employees of the Department of Commerce and Labor, and are charged by law with the duty of presenting the immigrants for examination and of providing suitable facilities for the conduct of that examination. The interpreters used now in the medical examination are furnished by the immigration officials of the Department of Commerce and Labor, and are sent for individual cases only. Often great difficulty is experienced by the medical examiners in securing any interpreters. The great prominence which has recently been given to mental disorders in aliens, makes it of pressing necessity that every assistance be given the medical examiners in their work. The Marine-Hospital Service has at the Ellis Island station twenty-one medical officers, of whom six have had special training in the diagnosis and care of mental disorders. These six competent alienists are handicapped seriously through inability to talk with many of the immigrants. The decision as to whether the Marine-Hospital Service or the immigration officials should provide interpreters is of purely administrative importance and should no longer interfere with removing this present handicap of the medical officers. The real question at issue is the effective enforcement of the restriction laws. The Marine-Hospital Service is doing good work, and it should be encouraged. It cannot work without facilities and the interests of the country demand that those facilities be provided.

A Double Singing Voice.

At a recent meeting of the Berlin Laryngological Society (*Berliner klinische Wochenschrift*, April 29) a man was shown by Scheier who was able to sing simultaneously in two voices. It was agreed that the phenomenon was absolutely unique. The subject was an opera singer who had long appeared in vaudeville as the "man with the double throat." His normal voice is a baritone of wide range. In singing he is able at will to accompany himself in a higher key. Thus far diplophonia has been regarded as a phenomenon which is purely pathological, and the case in question is the first known exception to this generalization. The singer has been examined by many well known laryngologists, but as yet no light has been thrown on the double voice production. The vocal cords redden during the act. In demonstrating his faculty he sings an air first in the normal, then in the double voice. Unfortunately, when the laryngoscope is in position for study the double singing is produced with great difficulty and the artist would not permit the use of cocaine. The possession of the double voice makes it easy for him to imitate various instruments. As this class of mimetics and also ventriloquists have already been studied profitably with

radiography the thought lay near to use this diagnostic resource in the present subject. The skiagrams showed enough to suggest to Scheier that the double voice was produced by the supraadaction of the vocal cords and epiglottis. Others have suggested that the extra voice might have been produced with the soft palate or ventricular bands. It is highly improbable that it can be produced by the vocal cords alone. As the vibrations cannot be seen their causation must remain conjectural.

Utilization of the Nitrogen of Inorganic Salts by the Animal Organism.

The recent successful demonstrations of the ability of the animal organism to form syntheses from the ultimate cleavage products of protein naturally have prompted the inquiry as to the possibility of utilizing the nitrogen of inorganic salts, notably of ammonia compounds, since similar substances are abundantly produced in the body as a result of catabolic activity. This research is being carried out extensively at the present time by Abderhalden and his students, and doubtless many other laboratories are taking up the subject, which is no less important from the practical viewpoint than interesting in theory. As the recent session of the German Congress for Internal Medicine (*Münchener medizinische Wochenschrift*, May 14) Gruefe announced that it was very probable as a result of his experiments that the animal body could utilize the nitrogen of ammonia and niter. This would not occur under ordinary circumstances but only when there was great nitrogen hunger, as in a rapidly growing puppy when placed on a carbohydrate diet. On several occasions negative N was brought up to equilibrium and even to retention with weight gain by feeding with salts of ammonium. It may not be easy to prove that the N is actually retained as albumin, *i. e.* that a synthesis up to blood albumin has occurred. It is possible that urea after it has been split off from food albumin is in part utilized—as has often been suggested—for if the body could utilize exogenous ammonia it ought also to be able to use its own urea.

News of the Week.

Libel Award.—A libel suit of interest to the medical profession has just been concluded in London with the award by the jury of damages amounting to $10,000 to Dr. Robert Bell, who had sued Dr. E. F. Blashford, director of the laboratories of the Imperial Cancer Research Fund, and the *British Medical Journal*, the former as the author and the latter as the publisher of an article entitled "Quacks and Quackery." The plaintiff charged, and the court very properly sustained his contention, that he was libeled in being accused of quackery and of preying on the credulity of the public in connection with his treatment of cancer by non-surgical methods.

Plague in Trinidad.—The State Department of June 14 received dispatches announcing the appearance of the plague at Port of Spain, Trinidad. Three deaths had occurred at that time.

Urge Bronx Hospital.—A recent report of the Committee on Public Health, Hospitals, and Budget, of the New York Academy of Medicine urges the necessity for the establishment in the Bronx of a hospital for contagious diseases. At present patients suffering from the contagious diseases must be sent to either the Willard Parker or the Kingston Avenue Hospital, Brooklyn. The erection of such a hospital has been opposed by the real estate owners in the neighborhood of the two sites owned by the Department of Health and available for the purpose, who propose the use of North Brother Island. This the committee opposes on the ground that the island is needed for other special hospitals. The rapid increase of population in the Bronx makes the speedy determination of the question desirable, and the committee urges that the money already appropriated by the Board of Estimate be used for the erection of such a hospital on a tract of land in the northern part of the Borough.

New Hospital Planned.—The Federation of Russian-Polish Hebrews of America has prepared plans for the erection of a hospital, to be known as the Beth David Hospital, on the northwest corner of Columbus Avenue and 113th Street, New York. The hospital will be an eight-story building and it is estimated cost about $150,000. The Federation has already established a temporary dispensary at Lexington Avenue and 115th Street, and this will be maintained until the new hospital is ready for occupancy.

Doctor by Aeroplane.—Dr. P. L. Alden of Hammondsport, N. Y., is perhaps the first physician to make use of an aeroplane as a quick means of transportation in answering an emergency call. The doctor was called from his home to Urbana, N. Y., to attend an accident case and made the trip across Lake Keuka in a hydro-aeroplane in record time.

Ban on Public Drinking Cup.—Kentucky is the latest State to fall into line, and on June 10 the public drinking cup was banished from within her borders, the recently enacted statute prohibiting its use becoming operative on that date.

Dr. Eugene Hoffman Porter, Commissioner of Health of the State of New York, received the honorary degree of Doctor of Public Health from Syracuse University at the commencement exercises held on June 12.

Dr. John B. Deaner of Philadelphia received the honorary degree of Doctor of Laws from Franklin and Marshall College at its recent commencement.

Death Rate in London.—During the past six years the health of London has greatly improved, the death rate having fallen 19 per cent, according to statistics recently published. It is computed that this means the saving of the lives of 28,000 Londoners each year. Typhus fever has been banished, smallpox is almost negligible, and the mortality from typhoid fever is very much decreased. On the other hand, however, it is stated that deaths from tuberculosis have increased from 26 to 33 per cent. and that infant mortality has increased 30 per cent.

Preventive Legislation.—Two bills recently introduced into the House of Representatives are designed to regulate the trade in habit-forming drugs. One proposes that the matter should be regulated by international agreement; the other provides for an internal revenue tax of five cents a pound on opium, chloral, and conobis, and a quarter of a cent a pound on cocol leaves. It further provides that importers and dealers in the drugs named shall register with the Commissioners of Internal Revenue, and that the former shall pay a license fee of fifty dollars, and the latter a license fee of ten dollars.

Medical Graduates.—Eighty-two students, two of them women, received the degree of Doctor of Medicine from the Maryland Medical College, Baltimore, on June 3, the exercises being conducted by

the Dean of the College, Dr. W. S. Smith. Congressman William Sulzer of New York made the address to the graduates.

Dr. Samuel J. Meltzer of the Rockefeller Institute, New York, was the speaker of the evening at the annual commencement exercises of the St. Louis University School of Medicine, on May 31, when seventy-six students were graduated.

The College of Physicians and Surgeons of Chicago graduated 145 students at its annual commencement on June 4. The class was presented by the dean of the college, and the degrees were conferred by the president of the University of Illinois, of which the college is a part.

Cornell Medical College.—The class of 1913 which was graduated on June 7 was the first to be sent forth since the college made the bachelor's degree a pre-requisite to the M. D. degree, and numbered only eleven, of whom two were women. Of these all but one has received a hospital appointment, four going to Bellevue Hospital, two to the New York Hospital, two to the Rochester General Hospital, one to the Methodist Episcopal Hospital of Brooklyn, and one to the Erie County Hospital, Buffalo, N. Y.

Unusual Surgical Condition.—A female patient in the Pennsylvania Hospital for the insane recently attempted suicide by introducing a steel crochet needle into her chest. She survived the injury for five days, and on post mortem examination it was found that the needle, six inches long and one-eighth inch in diameter at its thickest, and octagonal in shape, had passed through both ventricles of the heart and had pierced the left lung.

Report from Canal Zone.—The Department of Sanitation of the Isthmian Canal Commission reports that during the month of April, 1912, there were 48 deaths from all causes among employees, of which 37 were due to disease and 11 to violence, making an annual average per thousand of 8.77 and 2.61, respectively, or a total of 11.38. In segregating according to race, the annual average death per thousand among white employees was 5.74, among black, 10.48. During the same month of 1911 the total average was 9.38. There were 9 deaths from tuberculosis and 4 from pneumonia, 4 from heart disease, 2 from chronic nephritis, and 1 each from dysentery, estivo-autumnal malaria, hemoglobinuric fever, and typhoid fever. No cases of yellow fever, smallpox, or plague originated on or were brought to the Isthmus during the month.

Comparative Pathology.—The first International Congress of Comparative Pathology will be held at the Faculty of Medicine in Paris, France, October 17 to 23, 1912, having been organized by the Société de Pathologie Comparée. The subjects for discussion will include the diseases of men and animals and the connection existing between the diseases of different species, and also the possible connection between certain diseases of plants and of animals. The general secretary of the congress is M. Grollet, 42, Rue de Villejust, Paris, to whom all correspondence should be addressed.

Charitable Bequests.—By the will of the late Elizabeth Wharton McKean, of Philadelphia, bequests are made as follows: Children's Hospital, $1,500; Germantown Hospital, $5,000; Maternity Ward of the University Hospital, $3,000; St. Christopher's Hospital, $800.

By the will of the late Samuel Kohn, of Philadelphia, the sum of $50,000 is devised to the Jewish Hospital for the erection and equipment of a surgical building to be known by the name of the testator.

Dr. Charles F. Boldnan has removed to 251 Fort Washington Avenue, New York City.

National Society of Anesthetists.—On June 6 at Atlantic City, during the meeting of the American Medical Association, and following a symposium on anesthesia, the National Society of Anesthetists was organized. Prof. Yandel Henderson of Yale, chairman of the commission on anesthesia of the A. M. A., occupying the chair, those assembled for the symposium acting as a committee of the whole, proceeded to organization and elected the following officers for the year 1912-13: *President*, James T. Gwathmey of New York; *Vice-Presidents*, Charles K. Teter of Cleveland, F. H. McMeechen of Cincinnati, Yandel Henderson of New Haven; *Secretary*, William C. Woolsey, 88 Lafayette Avenue, Brooklyn, N. Y.; *Treasurer*, Harold A. Sanders of Brooklyn. The constitution and by-laws were ordered to be drawn by the executive committee and submitted to the society at its next meeting for adoption; all names submitted for membership, if qualified in the estimation of the executive committee, shall be considered as charter members if presented within a period of sixty days and accompanied by the levied dues of three dollars. The National Society of Anesthetists in this notice calls all those who are actively interested in this work to join its ranks and assist in developing the subject of anesthesia to greater perfection and more uniform safety.

Medical Club of Harrisburg.—At the annual meeting of this club, held recently, the following officers were elected: *President*, Dr. Samuel Z. Shope; *Secretary*, Dr. J. Harvey Miller; *Treasurer*, Dr. John A. Sherger.

Willimantic (Connecticut) City Medical Society.—The following officers were elected at the annual meeting on June 5: *President*, Dr. Louis Irving Mason; *Vice-President*, Dr. Frank E. Guild; *Secretary-Treasurer*, Dr. Laura H. Hills.

Pan-Missouri Medical Association.—The third annual convention of this association was held in St. Louis recently, when officers for the ensuing year were elected as follows: *President*, Dr. J. M. Harris, Sedalia; *Vice-Presidents*, Dr. William H. Mansfee, St. Louis; Dr. T. J. Jackson, St. Charles; Dr. L. B. Bluitt, East St. Louis; *Secretary*, Dr. J. F. Shannon, Kansas City; *Corresponding Secretary*, Dr. F. S. Thurman, St. Louis; *Treasurer*, Dr. O. C. Queen, Hannibal.

Northern Medical Society.—A regular meeting of this society will take place on Friday, June 28, 8.30 P. M., at the Bronx Hospital Dispensary Building, 1385 Fulton Avenue (near 170th Street). The following papers will be read: "Dreams as an Aid to Diagnosis and Treatment," A. A. Brill; "Hormones and Opotherapy," M. Aronson; "Demonstration (on living animal) of the Direct Method of Blood Transfusion," A. L. Soresi; "Tics and Their Treatment: Education *vs.* Hypnosis," J. H. Leiner.

Obituary Notes.—Dr. John Fife of Red Bluff, California, a graduate of the New York University Medical College in 1882, a member of the American Medical Association and of the California State and Tehama County Medical Societies, died at his home on May 29, aged 52 years.

Dr. Harriet C. Hinds of East Orange, N. J., a graduate of the Eclectic Medical College of the City of New York in 1877, and emeritus professor of pediatrics in the same institution, died at her home of paralysis on June 5.

Dr. JOHN COWAN BOYLE of Dansville, Ky., a graduate of the University of Louisville, Medical Department, in 1878, and a member of the American Medical Association and the Kentucky State and Boyle County Medical Societies, died at his home suddenly on May 26, aged 63 years.

Dr. EDWIN T. WOOD of Dansville, Ky., a graduate of the University of Buffalo, Medical Department, in 1888, and a member of the American Medical Association and the New York State and Livingston County Medical Societies, died at Bordeaux, France, on June 7, aged 52 years.

Dr. MYRON W. ROBINSON of Norfolk Tregaron, Conn., physician in charge of Fitch's Home for Soldiers and medical director of the Department of Connecticut, Grand Army of the Republic, a graduate of the Berkshire Medical College, Pittsfield, Mass., in 1861, a surgeon in the United States Army during the Civil War, a member of the American Medical Association and the Connecticut State and Fairfield County Medical Societies, died suddenly at his home on May 27, of heart failure, aged 73 years.

Dr. EDGAR REED HAWLEY of Chicago, Ill., medical director of the Illinois Life Insurance Company, a graduate of the University of Illinois, College of Medicine, in 1892, died in the Chicago Hospital on May 26, from pneumonia, aged 48 years.

Dr. RICHARD E. MCVEY of Topeka, Kan., a graduate of the Rush Medical College, Chicago, in 1861, professor of skin and venereal diseases and of clinical medicine in the Kansas Medical College, Topeka, and a member of the Kansas State and Shawnee County Medical Societies, died at his home on May 23, aged 85 years.

Dr. JAMES MCCHESNEY, a retired physician of Troy, N. Y., a graduate of the Castleton Medical College, Vt., in 1849, died at his home on June 4, aged 89 years.

Dr. BENJAMIN F. BUTCHER of Philadelphia, a graduate of the Pennsylvania Medical College, Gettysburg, in 1861, a veteran of the Civil War, having been commended for daring and bravery, and for forty-five years physician to Moyamensing Prison, died at his home of apoplexy on May 31, aged 73 years.

Dr. CHARLES H. LIEBERT of Philadelphia, a graduate of the Philadelphia University of Medicine and Surgery in 1878, died at his home on May 20 of pneumonia and heart disease, aged 70 years.

Dr. ROBERT F. NOYES of Providence, R. I., a graduate of the College of Physicians and Surgeons, New York, in 1873, formerly on the staff of the Rhode Island and St. Joseph's Hospitals, a member of the American Medical Association, and a member and former president of the Rhode Island State Medical Society and the Providence County Medical Society, died at his summer home in Matunuck Beach, after a long illness, on June 2, aged 62 years.

Dr. NORMAN FREDERIC CUNNINGHAM of Dartmouth, Nova Scotia, a graduate of the Bellevue Hospital Medical College, New York, in 1877, and professor of medicine in the Dalhousie Medical College, Halifax, died at his home after a short illness, on June 1, aged 63 years.

Dr. JOHN MARKS STEWART of Chesley, Ontario, a graduate of Queen's University, Medical Faculty, Kingston, Ontario, in 1882, died at his home on May 25, aged 54 years.

Dr. MAX AXELROOD of Vancouver, Wash., a graduate of Cooper Medical College, San Francisco, in 1881, died at his home of paralysis on May 22, aged 63 years.

Dr. ROBERT A. MILLER of Sebastopol, California, a graduate of the Texas Medical College and Hospital, Galveston, in 1871, an officer in the Confederate Army during the Civil War, died at his home on April 20, aged 81 years.

Dr. JOHN H. MILLER, a retired physician of Littleton, Colorado, a graduate of the Jefferson Medical College, Philadelphia, in 1840, and for many years a resident and practitioner of Denver, died at his home on June 1, aged 92 years.

Dr. JOHN ELY BREADY of Dubuque, Iowa, a graduate of the Jefferson Medical College, Philadelphia, in 1878, a veteran of the Civil War, having interrupted his medical studies begun at the College of Physicians and Surgeons, New York, to enlist in the United States Army, and since 1880 assistant surgeon in the United States Marine-Hospital Service, died at his home on June 5, after a long illness, aged 72 years.

Dr. EDWARD FIELD PARSONS of Thompsonville, Connecticut, a graduate of the College of Physicians and Surgeons, New York, in 1858, died at his home on June 13, aged 79 years.

Dr. JAMES MCFARLAND EVANS of Salem, Iowa, a graduate of the Cleveland Homeopathic Medical College in 1868, a veteran of the Civil War, died at his home after a long illness on June 6, aged 70 years.

Dr. THOMAS JEFFERSON SATCHER of Columbus, Ohio, a graduate of the University of Louisville, Medical Department, in 1887, died suddenly at his home on June 5.

Dr. SAMUEL B. HUNTER of Machias, Maine, a graduate of the Jefferson Medical College, Philadelphia, in 1855, surgeon in the Eleventh Maine Volunteers during the Civil War, and a member of the American Medical Association and the Maine State and Washington County Medical Societies, died at his home on June 2, aged 82 years.

Dr. FYFIELD H. LONGLEY of North Platte, Nebraska, a graduate of the Eclectic Medical College of Cincinnati, Ohio, in 1867, and of the College of Physicians and Surgeons, Keokuk, Iowa, in 1876, formerly a member of the Board of Regents of the University of Nebraska, and for several terms coroner of Lincoln County, and a member of the Nebraska State and Lincoln County Medical Societies, died at his home on May 24, aged 70 years.

Dr. CHARLES W. DOWNS of Omaha, Nebraska, a graduate of the Bennett Medical College, Chicago, in 1888, died at his home on June 2, aged 54 years.

Dr. PURNELL W. ANDREWS of Camden, New Jersey, a graduate of the Homeopathic Medical College of Pennsylvania in 1867, died at his home on June 4, aged 65 years.

Dr. JAMES ROOT FAIRBANKS of Amsterdam, New York, a graduate of the Berkshire Medical College, Pittsfield, Massachusetts, in 1866, consulting surgeon to the Amsterdam City Hospital, a member of the American Medical Association, the New York State and Montgomery County Medical Societies, and the Amsterdam City Medical Society, and a veteran of the Civil War, having served as assistant surgeon in the Tirty-fourth Massachusetts Volunteers, died at his home of pneumonia on June 14, aged 69 years.

Dr. GEORGE PELL CARMAN of Brooklyn, New York, a graduate of the now-extinct United States Medical College of New York in 1870, died at his home from diabetes, after a long illness, on June 8, aged 72 years.

Dr. Jerome Hilton Waterman of New York, a graduate of the Harvard Medical School, Boston, in 1893, president of the Harvard Medical Society, and a member of the New York Academy of Medicine, the American Orthopedic Society, the New York State and County Medical Societies, and the Society of the Alumni of the City Hospital, and attending surgeon to the Hospital for Ruptured and Crippled, died at his home on June 9, aged 41 years.

FAILURE OF THE ROENTGEN RAY IN PROSTATIC HYPERTROPHY.

To the Editor of The Medical Record:

Sir:—Having for some years suffered from prostatic hypertrophy; having tested the various physical agents, including the *x*-ray, and finally having been completely relieved by surgery, I think it a duty I owe to the profession and to the victims of this wretched condition, that I briefly give my experience, especially with reference to the *x*-ray.

The so-called wave current obtained from the static machine and the current of high frequency applied through an ordinary rectal vacuum tube, I was able to manage myself, but after many trials and with no permanent relief, I reluctantly abandoned them. Slightly encouraged by reports of the efficiency of the *x*-ray in this condition, I applied to my friend, Dr. Sinclair Tousey, who kindly agreed to make the test. With thoroughness and skill he gave me some twenty-eight exposures. Each exposure was of seven minutes' duration. The method was to give two treatments a week until seven had been administered, and after an interval of several weeks to begin again.

The results were entirely negative, and a few months after I had discontinued the *x*-ray, Dr. J. Bentley Squier operated by his usual method (suprapubic), which was followed by complete and permanent relief. It seems to me that this case shows as much as any single case can, that the treatment of prostatic hypertrophy by the *x*-ray deserves no greater consideration than does that other electrotherapeutic fiction, the resolution of urethral stricture by the galvanic current, since a careful examination of the removed gland showed that the various methods employed had failed to affect its structure in the slightest degree. In conclusion I may be allowed to say that I would by no means have it understood that I am not now as always a firm believer in the exceeding great value of physical methods of treatment, but I do deprecate the extravagant and ill-considered claims of special pleaders, whose aim too often seems to be not truth, but self-exploitation.

A. D. Rockwell, M.D.

New York

PRECAUTION NECESSARY IN THE TREATMENT OF CARCINOMA BY SELENIUM.

To the Editor of the Medical Record:

Sir:—Different selenium compounds are efficacious in malignant tumors, but to get satisfactory effects it is necessary to have experience in the handling of them. Selenium transforms carcinoma and sometimes sarcoma into fibroma, and then the fibroma may be a more satisfactory object of the surgeon's attention than the previous malignant tumor. The first effect of selenium on the tumor is softening and destruction of the parenchymatous part. There is some edematous swelling of the softened part sometimes with pain in the softening process, lasting about three days. This swelling has caused trouble in rare cases by compression of the esophagus in carcinoma of the cervical glands in such a way that the administering of food became impossible. The latter effect is that the stroma of malignant tumors is changed to dense scar tissue which subsequently firmly contracts. In a case of carcinoma of the cardia the patient could not take food because of constriction of the esophagus by the scar. These few points are very necessary to be observed. The practical use of selenium in the case of man needs more experience than the treatment of artificial mice tumors on external organs. The basis of carcinoma metabolism is decrease of oxidation, especially of sulphur. The chemical effect of selenium is an increased oxidation, especially of sulphur.

F. von Oettle, M.D.

726 East Fifty-eighth Street.

MODIFICATION OF COW'S MILK.

To the Editor of the Medical Record:

Sir:—In response to my comment on the milk formula Dr. Helfgott accuses me of not having consulted someone as to the exact percentage of proteids in whole cow's milk. It is regrettable that Dr. Helfgott did not even consult his own writing before attempting his reply. He based his calculations on 4 per cent. proteid. To obtain the 7½ ounces whole milk Dr. Helfgott divided 30—total percentage of proteids in the mixture—by 4—the proteid percentage, according to his statement, in whole cow's milk. To be exact, Dr. Helfgott had to divide 30 by 3.3 and he would get about 9 or 10 ounces whole milk instead of 7½. The quantity of cream to be added for the supply of the missing fat would also be changed thereby. Assuming that Dr. Helfgott consciously and purposely took the figures 4, 4, 4—proteids 4, fat 4, sugar 4—to avoid the complication of fractions and to facilitate his calculations, I accepted his figures and commented merely upon his formula and his calculations. Dr. Helfgott says: "Two pint bottles of milk cost as much as one quart bottle." How does Dr. Helfgott expect to get 20 per cent. fat in the top 4 ounces of a pint bottle of milk after standing? The total percentage of fat in 16 ounces is: $16 \times 4 = 64$; the top 4 ounces 20 per cent. would contain: $4 \times 20 = 80$. No more fat can rise to the top than the entire quantity of milk contains! If all the fat in a pint of milk rose to the top 4 ounces there would be only 16 per cent. fat; $64 \div 4 = 16$. To make a mixture, consisting of milk and cream, of any desired percentage composition the quantity of cream has to be substituted for the same quantity of whole milk instead of adding cream to the whole milk obtained. Taking Dr. Helfgott's mixture, the calculations are as follows: What is the total percentage of proteids desired? Multiply the number of ounces in the mixture by the percentage of proteids desired, $20 \times 1.5 = 30$. How many ounces of whole milk would supply the total percentage of proteids? Divide the total percentage of proteids by the percentage of proteids in whole cow's milk $30 \div 3 = 10$. (Chapin and Pisek give 3.2, but the small difference may be disregarded.) What is the total

percentage of fat desired. Multiply the number of ounces in the mixture by the percentage of fat desired, 20 × 4 = 80. What total percentage of fat would be supplied by the quantity of the whole milk obtained? Multiply the number of ounces of whole milk obtained by the percentage of fat in whole milk, 10 × 4 = 40. What percentage of fat is missing? Subtract the percentage of fat that would be supplied from the total percentage of fat desired, 80 − 40 = 40. What is the difference in the percentage of fat between whole cow's milk and the top 4 ounces of one-quart bottle of milk after standing? 20 − 4 = 16. How many ounces of cream do we have to substitute to supply the missing fat? 40 ÷ 16 = 2½. How many ounces of whole milk should we take in addition to the cream? 10 − 2½ = 7½. By adding 1 ounce of milk sugar the desired percentage will always be approximately right. The completed formula is: Whole milk, 7½ ounces; top 4 ounces of 1-quart bottle of milk after standing, 2½ ounces; sugar, 1 ounce; lime water, 1 ounce, and water enough to make 20 ounces.

Louis Mock, M. D.

New York.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

BLOOD PRESSURE—PROPOSALS REGARDING THE FEEBLE MINDED—INSURANCE AND FRIENDLY SOCIETIES—OBITUARIES.

London, May 31, 1912.

The sphygmomanometer has not become popular, I think, among general practitioners, but there are not wanting among its admirers those who predict for it a great future. Experts perhaps attach undue importance to its records, while very busy men find it difficult to devote sufficient time to get the best results from its use. The point was brought before the Medical Society of London by Dr. de Haviland Hall, who held that the instrument was of use, not only for definitely recording blood-pressures, but for revealing increases, which would without it escape detection. He quoted from Lauder Brunton the normal standards in young men as 100 to 120 mm.; in middle life, 125 to 135; above 60, 145 to 150 mm. To show the value of the instrument he took a series of consecutive cases and divided them into 6 groups, thus, with arterial pressure of:

	Cases.	Deaths.
120 mm. or below	55	2
121 to 140 mm.	56	2
141 to 160 mm.	34	1
161 to 180 mm.	19	5
181 to 200 mm.	12	5
Above 200 mm.	17	9

He thought the figures showed that the instrument could afford valuable information as to the patient's condition, not only as to prognosis but also as to treatment—indicating measures for lowering tension while enabling the effect of that lowering to be recorded. He could not, however, omit a warning against the incautious use of vasodilators. Sir L. Brunton said he now used an aneroid manometer comparing it, however, now and then with a mercurial one. He thought the systolic pressure most reliable. Pressure below 100 mm. in a healthy man was usually due to tobacco. If not phthisis was to be suspected. In angina prognosis was better for high than low tension as in the latter death was apt to occur unexpectedly. Absence of worry was most important during [illegible] blood pressure.

Dr. Leonard Hill said the instrument had led to many important physiological observations and he regarded it as an accurate means of taking blood pressures. He remarked that in compensated aortic regurgitation the pressure was greater in the legs than the arms—and that as made at from 100 to 150 mm. Dr. George Oliver said he had of late come to consider the diastolic pressure as precise as the systolic and more valuable. Dr. Gossage thought that though the systolic pressure was to-day most useful the diastolic might to-morrow take first place. For recording the latter Dr. Oliver's instrument was by far the best.

Dr. B. Thorne preferred the aneroid, 42 m., of Hill & Bernard. He noted systolic pressure, point of radial occlusion, area of maximum pulsation (this he termed balance-pressure), and migration of needle. Dr. F. W. Price doubted the value of diastolic figures which were always changing and falling. It was important to know the patient's usual pressure previously—in some it was continually fluctuating. The results of the action of drugs on the pressures in the human subject tended to shake his faith in their importance.

The question of how to deal with the feeble minded can scarcely be said to be neglected considering that there are three bills before the House of Commons at the present time. They are practically based on the report of the Royal Commission. One of them, Mr. Stewart's, has attained to a second reading and been referred to a standing committee. This fact seems to have awakened the government to the possibility of adding to the brief list of their proposals for social reforms; and their own bill in its initial stage again appears on their program. But the third scheme, a much more portentous one offered by Mr. Hills, is still in the way with its 252 clauses and six schedules. It proposes to extend to all defectives the care and protection now given to lunatics and imbeciles under the Lunacy and Idiots Acts. Instead of setting up a new authority it would enlarge, strengthen, and modify the existing Lunacy Commission, renaming it the "Board of Control." Locally the asylum committees of county and borough councils would retain the care, training, protection, and control of the mentally defectives in their several areas. These persons are to be regarded as mentally diseased rather than poor or destitute. Hence provision for them is not to be committed to the Poor Law authorities.

The government bill naturally has a better chance of becoming an act than either of the others, but it would be taking an optimistic view to expect it to survive the present session and the public generally would probably rejoice to dismiss the government with this and other promises of benefits that have been sacrificed to political partisanship. The general opinion seems to be that the government is indifferent to this and other social reforms which they might find the House of Commons ready to support, but as to which they are playing the part of the "dog in the manger."

A number of friendly societies have been holding their annual conferences and of course the Insurance Act has occupied much of their attention. The "attitude of the doctors" toward them has furnished a subject to some of the speeches and the views expressed have been various. The Manchester Unity of Oddfellows is the largest of these or-

organizations and its grand master warned the doctors that Parliament would take away their privileges if they abused them. But he kindly told them they were free to adopt trade union methods. The Ancient Imperial order had a meeting of delegates representing 40,000 Oddfellows and its Grand Master said though no satisfactory settlement had been come to he did not mistrust the act and thought six shillings a generous offer for contract attendance when compared with what had in some cases been paid. In another order the act was held to be most beneficial in regard to maternity and sanatorium benefits. In more than one kindly feeling toward the doctors were expressed, and, while considering their own pecuniary liabilities, grand masters and other officials were willing to pay what would be remunerative, though they found a difficulty in estimating what that might be. You will see there are a number of different Orders of Oddfellows as there are of other organizations of the same kind—clubs as they are commonly called—with strange official names and quaintly termed officers: *e.g.* Order of Rechabites, with its high Chief Ruler; Order of Shepherds, with its High Pastor; the High Sanctuary of the Ancient Order of Druids, with its Chief Druid, and so on. They are not exactly competing societies, as the chief object of all is the same, and in the past they have certainly done excellent work in providing for sickness and old age.

The new hospital for research at Cambridge was opened on the 24th inst. by Dr. R. C. Brown, who spoke of the progress of medical science in the last generation and the prospect of its continuance in the next. Dr. Normans Moore, representing the royal colleges, bid the new hospital welcome and referred to rheumatic arthritis as a subject already worked at. Sir C. Allbutt added that some 4,000 cases of that disease had been recorded, many photos and analyses being made. He spoke also of the benefits conferred by the chief supporters of this work.

The death of Surgeon-General W. Judson van Someren, late of the Indian Medical Service, has taken place at the age of eight-eight. He was an Edinburgh University student and graduated there M.D., in 1844, taking the L.R.C.P. the same year. Taking service in the I.M.S. he became a fellow of the University of Madras and Professor of Anatomy and Physiology at the college. He wrote on various subjects connected with public hygiene.

OUR CANADIAN LETTER.

(From Our Regular Correspondent.)

MEETING OF THE CANADIAN ASSOCIATION FOR THE PREVENTION OF TUBERCULOSIS IN TORONTO.

TORONTO, May 24, 1912.

THE week beginning May 20 was a busy one in Toronto in medical circles and for those interested in matters of public health. On Monday and Tuesday, May 20 and 21, the twelfth annual meeting of the Canadian Association for the Prevention of Tuberculosis was held in the Margaret Eaton Hall, Toronto, and on May 21, 22 and 23 the thirty-second annual meeting of the Ontario Medical Association took place in the new medical building of the University of Toronto.

The meeting of the Canadian Tuberculosis Association was markedly distinctive. The number of papers was commendably few, but what they lacked in quantity was more than compensated by the quality of those presented. The papers were all of interest, while some were exceptionally able and to the point.

The president was Dr. George Adami, Professor of Pathology at McGill University, Montreal. Dr. Adami, it may be mentioned, occupied the presidential chair for the fourth year in succession. In his opening address Dr. Adami commented on the fact that tuberculosis has become a well worn subject and rightly said that, as a rule, speeches and papers dealing with the question are rehashes of what has been spoken or written before. He, however, laid emphasis upon the obvious truth, that the main factor in the production and spread of pulmonary tuberculosis is crowded tenements and filthy dwellings. Although it is true that there is little new to be said concerning tuberculosis and its mode of treatment, yet there were two or three papers read which, if not original, at least touched upon certain phases of the problem in a novel way. These papers will be referred to later.

Dr. D. A. Craig, Lake Edward, Que., urged the need for systematic control of tuberculosis. His address was concerned chiefly with the necessity for notification of the authorities of the existence of cases of the disease. In his opinion a notification system could be carried out successfully. Some of the advantages of such a system were that the sufferer was placed at once in a position to receive attention and the patient became, instead of a source of infection, a focus of prevention.

Mrs. Adam Shortt of Ottawa discussed in a really excellent paper some of the social aspects of tuberculosis. The speaker, among other pertinent remarks, said: "The social aspects of the disease involved the study of heredity, eugenics, alcoholism, the feeble minded, and the insane, as well as industrial conditions, immigration, climate, maternity, infant mortality, the meat and milk supply, and the housing problem." According to Mrs. Shortt, the initial step toward the right basis of action in the prevention of tuberculosis is to have thorough and complete medical inspection of school children. Mrs. Shortt attributed a great deal of the delay and the laxity in grappling with the housing problem in the large cities to two obstacles. She said that there were two great giants greater than humanity, the name of the one being Commercial Interests and the name of the other Political Inexpediency. Perhaps the best paper read at the meeting was that of Dr. Hermann M. Biggs, General Medical Health Officer of New York, who treated of the administrative control of tuberculosis. It is needless to state that this paper simply bristled with points and facts and was fully worthy of the greatest master of administrative control of tuberculosis in the world. But it would be carrying coals to Newcastle to set before American medical readers Dr. Biggs' views on the subject. Dr. R. C. Paterson, St. Agathe, Que., read a paper on the importance of the pretuberculous stage and Dr. E. C. Harding, Montreal, contributed a paper on the value of the dispensary to public health.

Dr. Oliver Bruce, London, Eng., then read a paper which was one of the "bonnes bouches" of the meeting. It goes without saying that the question as to what to do with consumptives after their discharge from a sanatorium is one of the most difficult to be faced. Often, perhaps most often, and certainly too often, the consumptive after leaving a sanatorium is not in a fit state to earn his living by manual labor or, indeed, to follow the profession

or trade in which he was engaged on entering the institution. It compelled to work at an unhealthy occupation, which is frequently the case, he soon has a relapse, and the last state of that man is worse than the first. Dr. Bruce's paper, the title of which was the treatment of pulmonary tuberculosis by means of graduated rest and exercise, was a lucid and illuminating exposition of the manner in which this system was carried out in a sanatorium in England over which he has control. Dr. Bruce laid stress on the point that in order to succeed in the carrying out of the graduated labor method a fair considerable amount of experience is absolutely necessary. For, though not perhaps an exact science yet, it has an entirely scientific basis and is merely an empirical one. A thorough knowledge of opsonins is an important part of the scientific basis. For instance, Dr. Bruce and Dr. Inman found out that the opsonic index varies inversely with the temperature. This is an important point, for in regulating the amount of exercise to be prescribed in graduated labor some guide is necessary, some indication as to the amount of protective substances, which are being elaborated as the result of the exercise. This knowledge enables one to substitute the temperature chart for the opsonic index as a guide. Thus there are two main facts to work on, that the amount of opsonin or antibody in the blood can be raised by exercise and that the temperature chart and feelings of the patient are sufficient guides to an experienced observer as to whether the amount of exercise prescribed is too great or too little. Paterson, the originator of the method, has fixed the danger mark, the point signifying excessive autoinoculation at 99° F. in the case of men and 99.6 F. in the case of women. Dr. Bruce in his paper describes the entire system at length. Rest at first to bring down the temperature, and then the graduated exercise. Dr. Bruce emphasizes very strongly the point that the treatment throughout must be strictly supervised by a scientific physician. The results of the treatment under Dr. Bruce's supervision have been most satisfactory, but he draws attention to the fact that in many respects he has been working under very favorable conditions. The sanatorium with which he is connected is an offshoot or adjunct to the Brompton Hospital for Consumption, and consequently from its 300 inpatients there is little difficulty in choosing those most suitable for treatment. Nevertheless, by this method a large number of patients have been discharged able to undertake the most severe manual labor, and if this can be done under favorable circumstances it would appear that it might be worth while to attempt it in this country and in the United States, where the conditions are not so well adapted to the prosecution of similar methods.

Professor Westbrook, University of Minnesota, read a paper on modern public health teaching and practice in relation to the control of tuberculosis. In the course of his address Professor Westbrook severely castigated the faddists with their remedies and prescriptions. It was necessary to realize, too, that the tendency of the disease to spread had no relation to its severity. In the opinion of the speaker we pay a high price in cash and a higher price in health for the complications imposed by society. In the battle of health it was the man versus the microbe or the man versus the environment. Society planned in terms of the mass. Conditions demanded treatment for and by the individual. We came into the world singly and the health of the individual was of public concern, not of mere individual or family interest. He considered that hospitals and sanatoriums should not be regarded as monuments to their donors or as tributes to their architects, but as workshops to restore health and strength. He deprecated the tendency to migrate to cities and stated as his dictum, "the need to unload our cities." Professor Westbrook also had a fling at the lay press and declared that public support ought to be withdrawn from newspapers that continued to furnish impossible news stories with patent medicine advertisements of charlatans and quacks.

Dr. George D. Porter, secretary of the association, presented the twelfth annual report, in which he reviewed in detail the progress of the campaign against tuberculosis throughout the Dominion. He called attention to this very important fact, that the best results had been shown where there had been cooperation between the Government, the municipalities and the local societies. Dr. Porter described the scope and arrangement of work of the various agencies in each province, but said that it must not be supposed that there were sufficient weapons against tuberculosis, for, while its proper care was of the utmost importance and segregation of advanced cases imperative, the disease could not be properly controlled until they had improved conditions favoring its spread.

Dr. C. D. Parfitt of Gravenhurst read a paper on the care of the patient after leaving the sanatorium, which was esteemed so good by those who heard it that a resolution was proposed and carried that it should be printed and distributed to advance the education of the medical profession and the public on the subject.

On the afternoon of the second day of the meeting a clinic was held by Dr. Parsons at the Toronto Children's Hospital, at which he exhibited some splendid x-ray skiagrams presenting pictures of thoracic tuberculosis in infants and children. After the clinic a reception was given to the members of the Canadian Tuberculosis Association and other guests by the Toronto Heather Club in the magnificent nurses' home at the back of the hospital. The reception was largely attended. It may be said that the Duke of Connaught, Governor General of Canada, was the patron of the meeting, but was unable to attend. The Hon. Adam Beck of London, Ontario, was elected president of the association for the ensuing year.

4. Post-Typhoid Dyspepsia. A. Bassler.
5. Causes for Failures in Treatments of Chronic Joint Disease and Some Suggestions How Greater Successes Can Be Attained. H. W. Marshall.

2. Skin Grafting.—J. S. Davis states that in a general way grafts may be divided into thin grafts, where only a portion of the thickness of the skin is utilized, as obtained by the methods of Reverdin and Thiersch; and thick grafts, where the whole thickness of the skin is used. This latter division includes whole thickness sessile flaps and whole thickness pedunculated flaps. Grafts may be further classified into: auto. or homo. grafts, where the graft is obtained from the same individual; iso. or hetero. grafts, where the graft is obtained from

another individual of the same species, and zoo grafts, where the graft is obtained from a lower species. The simplest method of obtaining this graft is by means of Reverdin's method of transferring small bits of epidermis and placing them in rows or clusters over the wound. But this method is tedious when a large area is to be covered. The Thiersch method in its various modifications is that which is chosen by the majority of surgeons. Sliding plastic flaps from neighboring parts are of great value in the treatment of certain defects. As regards iso grafts, it is stated that good lasting results may be secured with these if the grafts are obtained and transplanted with the proper technique. Both thin and thick zoo grafts have been used, and a number of successful cases have been reported in the literature. The skin of dogs, lambs, rabbits, guinea pigs, frogs, etc., has been used. The most uniformly successful reports seem to follow the use of skin from a young pig. The author's results with zoo grafts have been disappointing. Most of the grafts would apparently take and would bleed when cut into, but within a few weeks they would melt away. It is interesting that grafts from a negro which have been successfully transplanted on to a white person gradually fade and assume the color of the host, and vice versa. This has been established by a number of observers, and has also been the experience at the Johns Hopkins Hospital.

3. **Acute Indigestion and Chronic Nephritis.**—M. Seymour states that some of the most important symptoms in the earlier stages of chronic nephritis, before compensatory changes have taken place, are those of the gastroenteric system, and present themselves in a mild form of uremia. These mild symptoms of uremia or toxemia, probably resulting from retained poisons due to faulty metabolic changes, may be so slight, and the increase in severity so slow, that the individual does not think his condition serious. He considers himself a chronic dyspeptic. He frequently complains of nausea, has aversion for food, especially for meat; in fact, he has a poor appetite. He takes bicarbonate of soda after his meals. After no indiscretion in eating or drinking, and after no change in his mode of living, he occasionally has what he terms a "frightful bilious headache," accompanied by nausea and vomiting, and severe epigastric pain. This sudden onset of epigastric pain, nausea, and vomiting is often termed "ptomaine poisoning," and similar mistakes in diagnosis are altogether too frequently made. The trouble may clear up in a few hours, or two or three days, and the patient may go on for weeks or months without a return of any alarming symptoms, or, as is often the case, his condition becomes more serious. The nausea, vomiting, headache, and severe epigastric pain continue, the mental state becomes more involved, coma develops, and death follows in a few hours. The author concludes that loose diagnostic terms, as "acute indigestion," "ptomaine poisoning," and their like, should be avoided. More care should be used in finding a possible cause of gastroenteric disturbances, especially indigestion and dyspepsia. Carelessness in uranalysis may be dangerous, both to the physician and to the patient. "No albumin" does not mean "no nephritis." Increased twenty-four-hour output of urine with persistent low specific gravity, associated with gastric disturbances, should strongly suggest involvement of the kidneys.

1. **Infant Mortality.**—By A. Jacobi. (See MEDICAL RECORD, June 8, 1912, page 1065.)

3. **Deaf Mutism.**—G. H. Makuen states that histological studies of the auditory and phonatory tracts have revealed the morbid anatomy of deaf mutism, and have thus placed one's knowledge of the subject upon a more or less scientific basis, but they have failed utterly to point the way toward any definite conclusions with reference to the etiology of the affection and to its treatment. They do not enable one to distinguish even between so-called congenital and acquired deaf mutism, and there is very little to be found in the pathological processes themselves which is suggestive of the particular disease or diseases which caused them. Inasmuch as the physiology of hearing is still a subject for discussion, it is not surprising that the pathology of deaf mutism should be obscure and unsatisfactory. Deaf mutism is not a disease, but is a result of a disease, or rather it is a result once removed. It is a result of a result, the disease itself having long since run its devastating course and left behind the morbid processes upon which the final result, deaf mutism, depends. Although these morbid processes are plainly visible in post-mortem examinations, they have in themselves no features sufficiently distinctive to enable one to draw any satisfactory conclusions. One cannot always be sure that they are not purely accidental anamolies or merely unimportant variations, and until they are compared and correlated with histological studies of normal auditory and phonatory tracts, and with previous clinical histories of the subjects examined, their value must ever remain exceedingly limited. Future progress in this line of work will come from a closer study of the diseases which are responsible for the morbid anatomy of deaf mutism, rather than from a further study of the morbid conditions themselves.

4. **Alopecia.**—J. Dyer states that one may classify all cases of alopecia under two general types, namely, alopecia idiopathica or primary baldness, and alopecia symptomatica or secondary baldness. The former includes the congenital, the senile, and the premature forms. Symptomatic alopecia includes baldness due to local or to general causes. The local causes are as follows: seborrheic dermatitis (dandruff), seborrhea sicca, eczema, erysipelas, lupus erythematosus, lupus vulgaris, parasitic diseases—tinea tonsurans, favus, impetigo following pediculosis capitis, tinea barbæ (barber's itch), staphylococcic infections, and folliculitis in its various forms—local injuries, burns, etc. The general or systemic causes are: syphilis, psoriasis, fevers (typhoid, etc.), ichthyosis, leprosy, variola, and alopecia areata or neurotica. Treatment generally must be based upon the etiology. When related to particular diseases, these must be treated. Idiopathic baldness is usually permanent and without relief. The following treatment may be adopted in most cases: The frequent washing of the scalp with green soap or tar, resorcin, napthol, and sulphur soap, and the application of stimulating substances. Of these are mentioned chloral hydrate, tincture of jaborandi, spirits of rosemary, cantharides (in tincture and guardedly), tar oils (cade, birch, pine, etc.), castor oil, croton oil (in minute quantity), alcohol, and chloroform. The use of any application should be intelligent; oily substances used when the scalp and hair are dry; desiccating or alcohol preparations when the hair is oily or the scalp greasy. Combinations may be made antiseptic with resorcin (two to five per cent.), salicylic acid (two to five per cent.), lactic acid (two to five per cent.), bichloride of mercury (one to 1,000), or with carbolic acid (not over two per cent.), each of which is also somewhat stimulating to hair growth. The use of the high frequency effluve in some cases of long standing has proved satisfactory

2. Thymol in Uncinariasis.—C. Bozzolo having employed this remedy continuously throughout the past thirty years, and not as a cure for ankylostoma only, considers as somewhat exaggerated the fears expressed by the greater part of those who, while admitting the utility and great superiority of thymol in comparison with other drugs, regard its after-effects as likely to be poisonous, and see danger in the administration of the remedy in large doses or in the contemporaneous administration of some alcoholic beverage, and who advise the substitution of small and repeated doses for maximum ones. In the several cases under his care during the time in which workers on the cutting of the St. Gothard tunnel, suffering from ankylostoma anemia, flocked to Turin, 12 grams of thymol were given in twelve hours, 2 grams every two hours, always well enveloped in capsules, and no serious disturbance was ever noted. In one solitary case throughout his long experience, in a woman, it is possible that thymol, administered in large doses, proved fatal; as a matter of fact, at the post-mortem examination of this woman there were traces of marked enteritis, which had, perhaps, been the cause of death. Before having encountered ankylostoma anemia—that is, before the year 1878—Bozzolo had already used thymol in diabetes with satisfactory results in diminishing the glycosuria, and with no serious after-effects. In these cases, however, the doses were restricted to 3 grams daily. Without therefore exaggerating the fear of the direct drawbacks of thymol in the treatment of hookworm disease, which in Turin has been widely employed in other diseases as well, it may be advisable to administer it in smaller doses (*therapia sterilisans fractionata*) than those originally proposed by Bozzolo in cases of weak persons who have been suffering for a long time, and when the treatment cannot be carried out under direct supervision. In the case of persistent enteric catarrh it is further advisable, whenever possible, to precede the treatment with a dry diet and the administration of tannic acid.

4. Diagnostic Tender Spot in Pulmonary Tuberculosis.—S. T. Harris adds to the usual diagnostic signs of pulmonary tuberculosis a hypersensitive or painful spot. This spot is a manifestation of degenerative changes. It may be due to a reflex from the pneumogastric nerve through the spinal accessory nerve supplying the trapezius, or the third or fourth cervical nerves supplying the levator anguli scapulæ. It may be found by palpating the tip of the superior angle of the scapula with the finger and riding over it with more or less inward pressure. It is best to palpate both sides at the same time, exerting the same degree of pressure, but not enough to produce pain in a normal individual. The pain may be quite severe, causing [illegible] wince, or it may be one only of [illegible] with that obtained in the normal side. [illegible] and neuritis, as well as rheumatism, [illegible] excluded.

5. Contributions by the United States Public Health and Marine Hospital Service.—J. F. Anderson states that these contributions have been along two main lines: first, research work in the laboratories of the service; and second, the application of new as well as older methods in the control of certain diseases. The two lines, however, at times necessarily merge. The measures instituted during the past summer may be considered under three general heads: (1) Quarantine measures enforced at foreign ports. (2) Quarantine measures enforced during the voyage. (3) Measures enforced at ports of arrival in the United States. The measures adopted in the suppression of bubonic plague in San Francisco have conclusively shown that it is possible to eradicate this disease even when it has obtained a foothold in a large city. The work on typhoid within the past few years, including a prolonged and intensive study of the disease in the District of Columbia, investigations of numerous outbreaks in towns and cities, and studies of rural typhoid in different sections of the country, has contributed materially to the knowledge of the epidemiology of the disease. In the past year studies have been made on measles, as a result of which has been obtained the first definite knowledge as to the susceptibility of the monkey to infection with measles. It has been shown that the virus of the disease is present in the blood at least some hours before the eruption appears and for about thirty-six hours after. The behavior of the virus to various physical and other influences has been tested. Experiments made to determine whether the scales are infectious have justified the opinion that the desquamating epidermis in measles does not of itself carry the virus of the disease. They conclusively demonstrated that the infective agent of measles is contained in the nasal and buccal secretions during at least the first forty-eight hours of the eruptive period; and in no instance have the secretions, collected at a later period, been found to be infective. Other contributions pertained to the standardization of drugs, especially digitalis, ergot, and thyroid preparations; the study of embalming fluids and methods of preparing dead bodies for interstate shipment; the disposal of sewage; laboratory and field studies on hookworm and other intestinal infections, etc.

8. Auricular Fibrillation.—J. D. Heard states that this is a condition in which the auricles no longer contract coordinately, but are constantly in a position of diastole, while individual groups of fibers are in ceaseless activity, causing frequent and disorderly impulses to be transmitted to the ventricle, which responds by contracting without any rhythm. When this is the case the disorderly ventricular contraction impairs the efficiency of the heart, which is somewhat enlarged, and unless proper treatment is instituted, the ventricle is gradually exhausted. A disturbance of conduction, if present, is exaggerated, and partial or complete block may follow, though with this the clinical condition of the patient may improve. The condition is induced by myocardial affections, notably the postfebrile infections, though other causes may occur. Overstrain may be a predisposing cause, and the use of the drugs of the digitalis group may bring it on in the predisposed. Organic changes in the auricle seem to be essential, but the pathological histology needs more study. Mackenzie's estimate of 70 per cent. of all cases of heart failure being due to auricular fibrillation or aggravated by it, may be accepted. Subjective symptoms may fail for some time when compensation is maintained, but this is not the rule. There may have been

precede attacks of tachycardia, and the signs and symptoms of the early stage are those of broken compensation. In severe cases there may be orthopnœa, cyanosis, dropsy, hemoptysis, local pain, and albuminuria. The pulse is usually rapid and disorderly, and gives the usual evidence of hypertrophy and dilatation. The presystolic murmur of mitral stenosis is absent. The affection may be transient or permanent, and one attack predisposes to another. If the condition is permanent the prognosis depends on the rate of pulse and the response of the heart to treatment. Auricular fibrillation is not incompatible with long life. A slow pulse is more favorable than a rapid one, and the prognosis depends in great measure on the ability to lower the rate. The one sovereign remedy is digitalis, but it usually fails where the pulse is regular and is contraindicated in cases accompanied by partial block.

6. Two Cases of Mercurial Poisoning. A. J. Hall.
7. Acute Focal Encephalitis. G. W. Watson.

2. **Treatment of Cholelithiasis.**—P. Mayer states that (1) acute cholecystitis should be treated medically; only the most severe form, cholecystitis acutissima, belongs to the surgeon; (2) chronic relapsing cholecystitis should be treated by operation only when all the suitably employed agencies of medical therapy have failed; (3) operation should be performed in chronic obstruction of the ductus choledochus if two or three months of medical treatment are without effect. In cases with prolonged remittent fever, rigors, and bad general condition the operation is unquestionably indicated; (4) hydrops vesicæ felleæ demands operation only if there are persistent and very severe irritative phenomena; (5) empyema of the gall-bladder and all suppurating processes in the region of the gall-bladder and in the liver should be operated upon; (6) adhesions about the gall-bladder should be treated medically as long as the inconvenience produced is not marked. In the most severe cases operation is required; (7) acute and chronic pancreatitis resulting from cholelithiasis belong to the surgeon. In the author's experience of all the substances recommended for the treatment of cholelithiasis he can attribute a genuine value to salicylic acid only. Salicylate of soda with extract of belladonna are often found valuable in practice. The chief influence of salicylic acid is upon the inflammatory symptoms. The author has seen the best results with salicylic acid in acute and chronic cholecystisis, especially with simultaneous rest in bed and the application of hot compresses. In such cases he gives from two to four times a day a powder of sodium salicylate 0.5 gram, and extract belladonna 0.01-0.02 gram, dissolved in warm water. He has used calomel for years according to the recommendation of Sacharjin in severe cases of biliary colic accompanied by constant pain and high fever. He gives 0.06 gram every hour for the first three to five doses, according to the nature of the case, and afterwards every two hours until the first typical calomel stool appears. Striking results are frequently obtained by this treatment, since the pains often cease at once, the fever gradually diminishes, and the whole severe symptom-complex completely disappears in a few days. The bile can be made more liquid by giving the patient an abundance of fluid. Excesses in eating must be avoided. All food difficult of digestion must be strictly forbidden. Food should be taken minced or in the form of puree. The patient should be kept in bed for several days after each attack of biliary colic, and in severe cases as long as there are inflammatory manifestations and as long as tenderness on pressure over the gall-bladder remains. In the absence of these symptoms physical excesses are not only indicated, but constitute one of the most important factors in treatment. Deep breathing exercises are valuable.

4. **General Infection by the Influenza Bacillus.**—J. M. Clarke reports the case of a girl aged thirteen years who had a purulent discharge from the left ear at times for some years. The onset of fever was gradual, so that the precise day of onset could not be fixed, but it occurred between two and three weeks after an operation for removal of enlarged tonsils. After admission to the hospital the ear discharge yielded a pure culture of Pfeiffer's influenza bacillus. Cultures from the blood taken towards the end of the second week of the fever, and after the occurrence of two rigors, also gave a pure culture of the same bacillus. The inference would seem to be that the bacillus was present in the ear discharge, and obtained entrance to the blood through the open wounds left by removal of the tonsils, and produced an acute septicemia. This appears to be a striking example of the tonsillar route for a general infection. The resulting septicemia was of gradual onset, and was a very severe one. For two or three weeks the prospect of recovery appeared dubious. If the foregoing view is correct, the case would appear to show the course of a direct infection of the blood by the influenza bacillus through a lesion in a mucous membrane. The fever was irregular throughout, and the course of the illness was five weeks. Injections of an autogenous vaccine were given in the third week, and during, and for three days subsequently to, their administration the fever became higher than it had been during the previous week and showed more extensive daily variations. From the course of the fever alone, however, it is difficult to say whether the vaccines had any effect on the disease, and no certain effects could be traced from them on the local or general symptoms, with this exception, that the aural discharge rather suddenly ceased and did not recur.

7. **Acute Focal Encephalitis.**—G. W. Watson states that encephalitis is now recognized as a sequela of several infections, notably influenza, diphtheria, and typhoid fever. It has occurred also apparently as a result of syphilis, but here probably the affection is usually subacute or chronic rather than acute, and is associated with disease of the membranes, being essentially a meningoencephalitis. Certain toxic agents, especially alcohol and more rarely lead, have been held responsible for the causation in some instances. Of all these causes, however, there is no doubt that influenza is the precursor in the great majority of cases. The inflammation of the brain is a nonsuppurative one and may affect any part of the organ. If the brain is extensively affected the condition is regarded as a diffuse encephalitis. It is in cases of this kind that the greatest difficulty is experienced in diagnosis, as the acute onset, associated with fever, intense headache, delirium, and drowsiness deepening into coma, may in the possible absence of signs of paralysis suggest nothing more than an intense toxemia. The inflammatory process may, on the other hand, be limited to some local area of the brain, and when this is the case, although both gray and white matter may be affected, it is usually the gray matter of the mid- and hind-brain (that of the cranial nerve nuclei and the cerebral cortex) which is involved. Consequently this type of the disease, known as acute focal encephalitis, is usually associated with paralytic symptoms, and is easier of diagnosis. Not only is the area of disease more limited in this than in the diffuse form, but as a rule the intensity of the inflammation is less, the general toxemic symptoms are not so severe, and the prognosis is much more hopeful.

The pathological changes in both forms [illegible] consisting of vascular distention and thr[illegible] rhagic extravasations, and exudations of [illegible] lesion is typical of an acute inflammation [illegible] of the causative organism has not been [illegible] termined.

5. The Bactericidal Action of the Cresols and Methods of the Best Means of Employing Them. F. W. [illegible]

2. The Autoinoculation Test in Tuberculosis. W. Crowe states that Freeman found that massage to a diseased joint was followed by an increase [illegible] of toxin in the circulation, demonstrable by a very accurate fluctuation in the opsonic index, provided only that the index was determined with respect to the causal organism. This he termed an artificial or induced autoinoculation, and he was able to utilize his discovery to elucidate the nature of joint troubles of doubtful origin. The example he first quoted was that of a knee joint said to be tuberculous; after massage the tuberculo-opsonic index did not fluctuate, while the index determined with respect to the gonococcus gave a marked and typical fluctuation. The inference drawn by Freeman was that the disease must be gonorrheal and not tuberculous. Hereupon Wright and his collaborators, following out the same line of experimentation, showed that a very considerable number of agencies, such as exercise, operation, Bier's bandage, and even physical examination of the chest, were capable of inducing autoinoculation. Patterson elaborated his treatment for phthisis, consisting of the scientific induction of autoinoculation by carefully graduated labor, and in connection therewith Inman found that as long as disease was still present the varying grades of work produced fluctuations in the opsonic index, while in those apparently cured the most arduous labor was followed by no fluctuation whatever. By means of an apparatus used for testing the vital capacity of the lungs, forced respiration continued over a period of some minutes can be used to induce autoinoculation in a tuberculous lung. The presence or absence of such autoinoculation is then determined by measuring the opsonic index before and at varying periods after the exercise. On the basis of an experience drawn from about sixty cases the author concludes that in the autoinoculation test one possesses the means of diagnosing tuberculosis in its earlier stages, that this test is so extraordinarily reliable that on its verdict alone treatment may be confidently applied or [illegible] confidently omitted, and, lastly, that it is of utility in directing the course of treatment and in deciding the moment when cure is complete.

3. Paths of Rheumatic Infection in Children.—J. R. Mackenzie states that the *Micrococcus rheumaticus* takes the path of least resistance. This may be an unhealthy throat, absorption from which frequently gives rise to general rheumatic infection, including peritonitis and appendicitis, directly through the vascular system. Or it may be localized in the bronchial tubes and give rise to pneumonia, with polyarthritis and endocarditis. An unhealthy condition of the intestinal wall may excite to activity the rheumatic agent, setting up acute rheumatic phenomena with peritonitis or appendicitis as part of a general infection. A mild catarrh is produced at the seat of inoculation, and one or more of three factors in each case are present and promote the inroads of the micrococcus. Either the physical resistance or the protective properties of the local tissue, or the defensive agencies of the blood are below [illegible] stinction between acute and subacute or late [illegible] is mainly due to general infection with the [illegible] atic agent in the former and with the toxin[illegible] latter.

June 3, 1

Cases of Disturbance of Inter[illegible] tions.—Under this title Bittorf relates several [illegible] hard and fast lines of diagnosis were not [illegible] der the better to give an idea of the depend[illegible] toms on disturbed hormone action. The [illegible] man aged thirty-eight, showed some of the [illegible] acromegaly. The hands and feet had been cl[illegible] twelve years. The nose, tongue, and chin were s[illegible] fected, but a number of the classic symptoms of ac[illegible] k were absent. The eyes were beginning to be [illegible] omised. There was failing vision (binasal hemianopsia) due to opticus atrophy at the nasal side. The thyroid was normal. Eosinophilia and alimentary glycosuria alike pointed to disturbed internal secretions. Wassermann reaction was positive. The peculiarities of the case were due doubtless to the fact that syphilis had attacked the base of the brain with independent lesions of the hypophysis and optic chiasm. The lesions of the optic nerve were not of the type due to compression of an enlarged hypophysis, for in the latter we commonly see bitemporal hemianopsia. The patient improved upon KI. The second patient was a girl of marked infantile habit who was first treated for anemia. Later she complained of failing vision and was found to have choked disks. There was some headache, nausea, and vertigo. The *x*-ray showed enlargement and arrosion of the sella turcica. The condition of the patient pointed to dystrophia adiposogenitalis. The hypophysis was evidently affected, but the author does not believe that a lesion of the latter is wholly responsible for the clinical picture. The actual state of affairs is doubtless highly complex. No doubt a polyglandular insufficiency is present in which hypophysis, thyroid, and ovary are like involved. The treatment consisted in feeding with thyroid and ovarian tablets and some improvement followed. The third patient, a man aged twenty-eight, was an alcoholic, and presented a long and complicated history of invalidism. From a multitude of symptoms the following facts stand out in relief: The patient at one time had put on fat at a phenomenal rate, with symptoms (chiefly blood pictures) pointing vaguely to dysthyroidism. He improved under thyroidin, losing his fat and improving as to blood count. The presence of a period of somnolence was also attributed to hypothyroidism. The patient's viscera were badly damaged, probably from alcohol. Whether the lesion of the thyroid could have been due to the latter is not discussed.

Neurofibromatosis and Acromegaly.—Wolfsohn and Marcuse report a case in which von Recklinghausen's and Marie's diseases appear to have coexisted. As far back as 1903 no less than 447 cases of the former had been placed on record and carefully analyzed, and hence it is safe to say that this coincidence can only be accidental or at least due to nothing further than the rare occurrence of a lesion of neurofibroma in the sella turcica. A careful study of von Recklinghausen's disease shows the possibility that four other cases may have presented acromegalic symptoms, but that the reporters in describing these cases had evidently had no suspicion of the latter. Any attempt to explain neurofibromatosis by anomalies of internal secretion is evidently foredoomed to failure.

Prognosis of Puerperal Fever.—Rosenthal states that for two years the antitrypsin reaction has been used in the Budapest obstetrical clinic for the diagnosis of pregnancy. The elevation of the index persisted into the puerperium, vanishing about the fourteenth day. From

another quarter came the report that the same reaction was being employed in the prognosis of puerperal sepsis. The author had already remarked that should a puerpera have fever this fall to normal did not take place. In fact not until the fever subsided did the elevation of the index subside. To make of this behavior any trustworthy prognostic sign can hardly be warranted. There is no parallel between the height of the index and severity of the infection.

May 21, 1912.

Rachitis and Hypophysis Medication.—Klotz first refers to a prevalent past and present belief that rickets and osteomalacia are one and the same morbid process. The latter affection is now reputed to be favorably influenced by pituitrin and therefore the latter may be also indicated in rickets. Hypophysis extract is quite rich in phosphorus, which substance is often of use in the said bone affections. Cod liver oil may also contain phosphorus from the fish liver as an impurity and it is also of value in rickets. The author has separately tested lecithin on account of its assimilable phosphorus and believes that rickets tends to improve decidedly but not very rapidly upon this resource. He then further gave tables of pituitrin whereupon the benefit was accelerated. Believing that the phosphorus in the hypophysis would be sufficient for the purpose he has since given the pituitrin substance alone. Thus far he has treated four cases of infantile rickets for the space of five or six weeks with notable improvement in the state of nutrition. His theory is that the disease or diseases are due to a disturbance of the phosphorus metabolism, which the pituitrin is able to correct. In other words the disease may be determined originally by hypophysis insufficiency, which disappears under feeding with the substance, as myxedema improves under thyroid feeding.

Perforation of the Rectum by a Proctoscope.—Schmitt relates an accident which occurred in his own practice. In depressing the handle of the instrument while in position in order to bring a certain area into the field of vision the top of the instrument perforated the rectal wall and a piece of omentum entered the gut. The patient, an elderly man, was at once placed on his back and laparotomized and the rent repaired. The latter had occurred just where the peritoneal fold is formed. On the fourth day there developed symptoms both of peritonitis and ileus. The abdomen was at once reopened, when it was found that a kink had been caused in the small intestine by new adhesions. A fistula was established but the patient succumbed to peritonitis.

Anaphylaxis from Homologous Albumin.—Wolf-Eisner and Vertes appear to have established the fact that albumin anaphylaxis is not due necessarily to heterologous albumin. Homologous albumin is of course introduced from within, but there appears to be no essential difference in the anaphylaxis. Disease phenomena set down hitherto to bacteria toxins may after all be found to be due to one's own albumin. Every exudate absorbed may be a possible source of danger should the event be repeated. Our knowledge of autointoxication and of hormone action may have to be rewritten, for what we have regarded hitherto as common poisoning may prove to be anaphylactic, as may also the supposed overaction of internal secretions.

Operative Cure of an Acute Unilateral Septic-infectious Nephritis.—Ritter reports a case in several ways unique. The patient, a school girl aged seven, was seized suddenly with the symptoms of urinary irritation associated later with right lumbar pains and fever. As an exanthem, with conjunctivitis and bronchitis was superadded, a diagnosis of measles had been made by the first attendant. As a tumefaction began to appear in the right flank patient came under surgical care. The diagnosis was cystitis with simultaneous complication of the right kidney. Upon cutting down, none of the affections suspected was found to exist. There was neither paranephritic abscess nor any suppurative process involving capsule or renal parenchyma. The organ was simply much enlarged and hyperemic. An ascending pyelonephritis must have occurred as sequela of a vesical infection. The operation of decapsulation was performed and patient made an excellent recovery. The author does not believe that the patient had measles at all. The renal symptoms antedated the rash by a number of days and the picture of measles was doubtless due to a septic outbreak. The infection doubtless began in the bladder from bacteria introduced from without. It has been shown abundantly that this accident readily occurs through the short female urethra. The author seemingly made no bacteriological studies whatever.

Pituitrin as an Oxytocic.—Hofbauer, who was one of the first, if not the first to report on hypophysis extract as an oxytocic (Jan., 1911) has continued to use this agent in Winter's clinic, and now announces his more mature conclusions concerning its usefulness. It is, he states, the best oxytocic we have and his opinion as originally pronounced, has been sustained by practically every one who has tested pituitrin on large material. It is in fact the first practicable oxytocic ever found. It materially shortens labor and hence must diminish the chances of infection and exhaustion of the mother and asphyxia of the infant. It also cuts down considerably the necessity for operative intervention, as shown by records of clinics since its introduction.

Priority as to Arteriovenous Blood Transfusion.—R. T. Frank of New York in a letter commenting on a recently published article by Prof. Payr asserts that he and G. Baehr reported practically the same technique in the United States in 1909. Dog's carotid, hardened in formalin and kept in paraffin was used to make the communication. Prof. Payr used calf's artery and a somewhat simpler technique, and there is no attempt to deprive him of any credit, but the contrary is implied. Prof. Payr replies that he with many others has made use of Carrel's and Guthrie's labors on arterial segments for some years, and that his use of a calf's artery was only an application of their teachings. He was aware at the time that Frank had made use of fresh dog's artery and gave him credit. The second paper in which Frank reports the use of pressed dog's artery had been unknown to him.

May 23, 1912.

Early Symptoms of Organic Nervous Disease.—Heilbronner enumerates a number of early symptoms of organic cerebral and spinal diseases as follows: Purely subjective sensations often bring the patient to consultation. The testimony of the attending physician is often important in such cases because he can inform the neurologist as to whether or not the patient has a tendency to exaggerate his sensations and whether there is any motive for simulation. Special sense disturbances may be controlled with the needle and esthesiometer, ophthalmoscope, etc., but much still depends on the trustworthiness of the patient's testimony. It must be borne in mind that in organic as well as functional nervous diseases the patient usually places more emphasis on his subjective sensations than on the objectives, for, according as the former improve or become aggravated he believes himself to be improving or retrograding as the case may be. Headache is the most important subjective manifestation, and if without any apparent cause it sets in or becomes

worse or chronic, or returns without ca[illegible] mis-sions there is good reason to suspect or[illegible]ase. When vomiting is superadded we think [illegible] of renal insufficiency, especially if there is a [illegible]ing of the mental processes. Next to uremia [illegible] to bear in mind other types of organic headache including migraine, and exclude the latter, cerebral [illegible] abscesses, and (in children) hydrocephalus. The ophthalmoscope must be used in all these cases as ch[illegible] disk, etc., may accompany headache of intracranial [illegible]. Vertigo associated with headache suggests cerebellar and labyrinthine involvement. Next in importance to headache is neuralgia, especially sciatica, which is very often due to some form of organic disease. Disturbances of micturition, defecation, and sexual potency are of great significance in organic disease of the spine. Disturbances of vision with normal fundal finds suggest hysteria, but owing to the fact that multiple sclerosis is so intimately associated with hysterical symptoms the presence of the latter often make it imperative to exclude the possibility of organic disease.

A Neglected Resource in the Chemotherapy of Cancer.—Freund, who as far back as 1878 was a pioneer in abdominal hysterectomy for cancer, has for years been experimenting along a particular line of work in which it was intended to flush out the blood vessels of a diseased organ or limb and inject under pressure fluids designed to cause pressure necrosis of cancer tissue. It is assumed to be necessary to deplete the organs of blood. After numerous animal experiments the author in 1892 tested the method on a cancerous uterus. The nutrient blood vessels were isolated and washed out with saline infusion until the venous blood came away a pale pink. The solutions were forced in under increasing pressure (200 mm. mercury). The pelvic connective tissue became edematous and the uterus itself became very hard to touch. At that time no attempt was made to inject any therapeutic principle. The author's idea was solely to cause pressure necrosis of the cancerous mass. This appeared to be what was taking place when death suddenly supervened from cardiac collapse. As there were found numerous glandular metastases of the cancer it was clear that the patient could not have survived long. The local result was satisfactory, as shown by autopsy, but the death *en masse* of a uterine cancer would hardly help the chances of recovery owing to the danger of sepsis. However, the combination of emptying the blood vessels and local injection of a chemotherapeutic solution into the artery might prove a practical resource in connection with the latest work of Ehrlich and others with selenium and eosin.

Death Following Intravenous Injection of Hormonal.—Jurasz reports a case of this accident, the first to go upon record, although a number of instances of collapse have been reported. Patient was a woman aged forty-three, who had suffered for eight years with cholelithiasis. Attacks of colic were becoming more frequent and severe and eventually perforative peritonitis resulted, for which she was laparotomized. The gall bladder, sclerotic, was extirpated and the peritoneal cavity irrigated and drained. On account of the high degree of meteorism, which could not be controlled an enterostomy was performed and followed with an injection of 20 c.c. of hormonal into a vein. At the moment in which the Esmarch bandage was removed, profound collapse developed and patient became pulseless. Not for fifteen minutes did she rally, under camphor and adrenalin. In an hour she again showed evidences of collapse and in two and a half hours after the injection was dead. There could be no doubt that the hormonal was responsible. The "vasodilatatin," which is contained in the substance (Popielski) is responsible for the sudden lowering of blood pressure. The heart was evidently a damaged organ, able to respond but feebly to analeptics, and the sudden removal of the bandage threw extra work upon it. The [illegible]ever use hormonal again in peritonitis, for in [illegible] the heart often suffers. This, however, is [illegible]ate of affairs in which hormonal was believed [illegible] its chief usefulness.

Syphilitic Reinfection after [illegible]arsan Cure.—Stumpke cites a case which illus[illegible]edly salvarsan may cure a patient (unless of [illegible] to believe that the attack was self-limit[illegible] highly improbable). It is not the first examp[illegible] during the short time that the drug has been [illegible]. The patient had a chancre about July, 1911, and [illegible] by the writer September 20. He was a vigorou[illegible] who had never been ill, and was then sound with the [illegible] of a few early syphilides and mucous papules in the fauces. On October 3 salvarsan was injected into a vein, and this procedure was repeated two weeks later. He improved, but as the Wassermann was still positive a course of calomel injections was begun. By November 6 he was free from all symptoms, including enlarged lymph nodes, and the reaction had been negative for some days. He was seen again in March, 1912, with a lesion on the lower lip bearing every resemblance to a primary lesion. There was a localized adenopathy. Any evidences of a relapse of the original syphilides were quite lacking. There were numerous spirochetes in the lesion and the Wassermann reaction, negative at the outset, soon became positive. Under salvarsan the chancre and adenopathy began to subside and the Wassermann became negative. There was no eruption of secondary manifestations and the inference is that these were aborted. While the case is not a perfect one and naturally requires further study, it seems evident that a patient can contract syphilis as early at least as four months after a clinical cure, so that a past attack gives very little protection under the complete modern treatment.

Fatty Stools in Graves' Disease.—Bittorf, the well-known authority on affections of the ductless glands, says it has been noted in at least six cases of Graves' disease that fatty stools coexisted with alimentary glycosuria. In other words, there was an association here which pointed plainly to a pancreatic disorder or insufficiency affecting both its external and internal secretions. The patients improved remarkably under the internal administration of a pancreas preparation. The rationale is of course by no means clear, but the simplest assumption is that the pancreas insufficiency is determined by the hyperthyroidism. This applies to the failure of the external secretion. The participation of the internal secretion is open to some doubt. Fatty stools are rare in Graves' disease, while glycosuria and alimentary glycosuria are not infrequent.

Green Teeth, Subsequent to a Prolonged Jaundice in the First Weeks of Life.—H. Thursfield reports the case of a boy who was first seen at the age of 3 weeks. The history was that he had been jaundiced from birth, or possibly from the third day of life only, and that during the first week he had passed very black stools, and had a purulent discharge from the navel. When seen the umbilicus was perfectly healthy; the liver and splen were not enlarged, and the child, though small—6 pounds 5 ounces—seemed quite healthy. The jaundice was at this time deep, and remained so for the next seven weeks, slowly disappearing. When it had gone the boy put on weight rapidly and at 4 months of age weighed 9 pounds. He was not seen again till he was 9 months old, when he was brought again for an attack of diarrhea. The two lower central incisors were then a vidid yellow tint, which had become now green. The tint varied considerably; it was occasionally quite bright, at other times dull.—*Proceedings of the Royal Society of Medicine.*

Insurance Medicine.

Chronic Diseases of the Lungs and Longevity. Dr. Arnold Chaplin discusses the desirability, and otherwise, of cases of chronic lung disease for life insurance. He excludes chronic pulmonary tuberculosis from the discussion and considers fibroid cirrhosis of the lung and chronic pleural conditions. The first one is also known as Corrigan's cirrhosis, chronic pneumonia, etc. The condition is not as rare as taught by some, Dr. Chaplin having met with some 300 examples in two decades. The greater number of such cases usually owe their origin to acute pulmonary affections of childhood, bronchopneumonia following measles or whooping-cough being the chief exciting cause. The duration of the disease is much shorter than taught by some authorities who claim that it has little, if any, effect upon longevity. Dr. Chaplin's cases began for the most part before the age of ten, and the great majority of them came to a fatal termination by the end of the third decade. Cases beginning late in life have a worse prognosis, ten years being the average duration of the disease. From the life insurance aspect, cases with limited disease at the base of one lung have a relatively good prospect, but even then it must be remembered that the disease is one of slow progression. The commonest modes of termination are acute bronchitis, sepsis from absorption of fetid material gathered in dilated bronchi, tuberculosis, and metastatic abscess of the brain. Fibroid disease of the lung, usually beginning before the age of ten and ending before thirty, is therefore unfavorable from the life assurance point of view.

Chronic inflammatory conditions of the pleura frequently follow serous or purulent pleural effusions. Dr. Chaplin does not share the opinion of most writers who look upon the great majority of pleural effusions as due to tuberculosis. He thinks that if the attack has taken place a number of years before the person's application for insurance, such application should not be immediately refused. Chaplin is inclined to regard it as a good sign that the applicant may have had a minor attack of tuberculosis and have recovered from it many years ago, as he was perhaps rendered quite immune to severe form of lung tuberculosis.

Cases with purulent effusion in which operation was done should be differently treated. The main point here is the amount of damage to the lungs from collapse and the consequent lowering of the individual's vitality. Those empyemata which occur and are treated before the age of twenty, offer a much better prospect of complete recovery than those occurring after that period. Of course, the actual physical findings, the extent of falling in of the chest wall and the condition of the lung underneath must be considered in each individual case. Patients who have had the affection after their youth usually remain chronic pulmonary invalids for life; they may be insured for short terms only and with an extra premium of a substantial kind. —Proceedings of Life Assurance Medical Officers' Association, London, England.

Some Impositions Practised on the Doctor.—Under this rather strong title, T. J. Dunn discusses what he regards as an unfair burden placed upon the physician by life insurance companies with reference to death claims. The rule that "claimants are bound to produce, at their own expense, such medical testimony as to cause of death, duration of disease, etc., as may be required by the company," also imposes a burden upon the beneficiary. A striking contrast is furnished by the attitude of an insurance company upon the entrance of an applicant to that upon his exit by death. In the former case the companies show the most solicitous care as to the medical examination. They do not trust the family physician to do this work. Sometimes the medical examiner telephones or writes to the family physician to get a little inside information about the individual seeking insurance. The fact that the family physician is not compensated for any information which he may vouchsafe is regarded as an imposition practised by the insurance companies. The applicant contributes his yearly premium for a number of years, and when he dies, according to the author, the companies that entered into an agreement with him and took his money on the strength of it, are entitled to know that he is actually dead, but that is all, and this information is contained in full in the death certificate filed with the health authorities. But the companies are not satisfied with this information; they seek a mass of privileged information from the medical attendant who is not in their employ, and who is not justified in telling the things he has learned in a confidential way about the deceased. About one-half of the statement they require consists of questions on this order, and at times the answer may put the medical man in the unfortunate position of having acted the spy upon his patient for the benefit of the company. The author states that at one time his answer to the question: "For what diseases have you at any time attended the deceased and what was their duration?" formed the basis of refusal by a certain company to pay a death claim where the man had been insured for thirteen years. The law was invoked and finally the company paid one-half the claim. This question is No. 9 on the blank of one of the largest companies. Question 10 is as follows: "Did you ever attend or prescribe for deceased, except as stated in answer to No. 9?" This might be taken to mean that having prevaricated in answer to No. 9, the physician would tell the truth in No. 10. Still other questions are: "Was deceased afflicted with any infirmity, deformity, or chronic disease?" "Did deceased suffer from phthisis?" "Did any members of his family die of consumption?" All these questions are regarded by the author as manifestly unfair questions to put to the family physician and are all calculated to serve the interest of the company and to develop some contradiction in the statement made by the insured on entering. Under certain conditions, it is asked, could a medical man honestly and conscientiously answer some of these questions? For instance, knowing that the patient died of cerebral hemorrhage and that such hemorrhage was secondary to cerebral syphilis, how could one answer the question, "Did he have any chronic disease?" Would the physician conceal the fact and deceive the company, or disclose his knowledge and then possibly have the company refuse to pay the insurance, and meanwhile be sued himself for having disclosed privileged information? In the latter case the physician would be betraying confidences which have been given to him as a sacred trust.—*New York Medical Journal*, June 8, 1912.

The Report of the Mutual Life Insurance Company for 1911 shows that there was paid to policy holders and their beneficiaries in death claims, endowments and dividends, $57,353,726. This was $599,050 more than was paid out in the previous year.

Society Reports.

MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, April 15, 1912.

THE PRESIDENT, DR. REYNOLD WEBB WILCOX, IN THE CHAIR.

Abbott's Method of Correcting the Fixed Lateral Curvature.—Dr. DEXTER D. ASHLEY read a paper on this method. He said, was not a cure for all forms of scoliosis, but was especially adapted to the acquired forms, when not too rigid, severe, complicated by structural changes from bony ankylosis. The postural, habitual, and functional varieties were readily treated by exercises. The importance of finding a way to correct the fixed curve had long been felt, and research had been active in regard to the pathology and mechanism of the condition. All orthopedists now recognized that it should be possible to correct the curve and overcorrect, and that, according to Wolff's law, it should stay corrected; but the technique had been missed. The correction of a deformity of the body necessarily meant the ability of the surgeon to make an overcorrection, as in bow legs, knock knees, club feet, and wry neck, but until Abbott, so far as he knew, no one had shown us an overcorrection of a fixed spinal curve as recorded by the *x*-ray. In correcting a scoliosis it was evident to all who had studied the subject that the twisted spine, with the vertebral bodies rotated to the side of the convexity, must be reduced by causing these bodies to pass back to the normal position by the same route through which they had moved into the position of deformity. Abbott's work was based upon the theory that the concave side has swung forward in a circle to the right (in the ordinary right dorsal, left lumbar deformity). All previous efforts had been founded upon the idea that there was rotation backward of the convex side, and heretofore in our endeavors to forcibly correct the spine we had been making pressure upon the prominent angle of the ribs. Lovett had shown that a force or forces applied at or beyond the angle of the ribs would cause the spine to be forced forward, or into superextension in the direction of least resistance, carrying the bodies further forward in rotation and deformity. This would explain why a fixed or severe curve had resisted our best efforts and become progressively worse with treatment. Abbott's conception was that in correction the bodies must move to the concave side and backward. Since the deformity was produced by flexion and side bending toward the convex side, the correction and overcorrection must take place in the same position of flexion and side bending to the other side. To obtain this effect he flexed the spine with pressure over the lower ribs, with side bending, the arm on the depressed side being brought high up and forward and the arm on the convex side well down and backward. To facilitate the holding of the patient in this position of extreme flexion while applying the plaster jacket he placed him on his back in a hammock suspended from a frame. Ample felt pads, three-eighths of an inch or more in thickness, were fitted over the angles of the ribs on the convex side and prominent ribs in front, as well as the crests of the ilia, and a large felt roll was placed over the concave side, to be removed through the large fenestra in the back when trimming the jacket. After all had been adjusted upon the hammock the lower limbs were flexed in order to overcome the lordosis and the foot of the frame was elevated to an angle of 30° to 60° to further utilize the weight of the pelvis and lower limbs. Three strong muslin bandages were then adjusted, making side pulls, and a broad bandage was anchored to the frame on the convex side and passed across the lower prominent ribs. From this was suspended a weight of 25 to 50 pounds to force the patient still further into flexion and side bending and depress the prominent ribs. The plaster jacket, which extended about 1½ inches below the anterior superior spines, was made rather higher above the symphysis pubis than was usual because of the flexed position of the thighs, while behind it reached well down over the base of the sacrum, to prevent the erect position. The plaster was carried high up under the arm on the convex side and well down on the concave side, permitting the high shoulder to fall backward and downward, and in some instances it was advised to apply a strip of plaster to hold this shoulder down and back. The body in flexion, the jacket was made roomy in front over the upper part of the sternum, to relieve the elevated breasts and permit the body to fall further forward in flexion, but still give high thoracic breathing space; while over the lower ribs it was made close, to compress. four fenestræ were cut out, to permit further flexion and side backward. Two were in base of the breasts and extended from five to eight inches, to allow adjustment of pads, and the fourth was made on the side, to better control any crushing or bending which was to be avoided. During the wearing, which would vary from two to eight months, to the severity of the case, the patient should do dumb-bell exercises, leaning forward in order to keep up the muscular tone and assist in maintaining the flexibility of the spine. The jacket was worn in the position of overcorrection until structural changes were established and the position became a habitual one for the patient. After the removal of the jacket he should remain much of the time in bed and should exercise the muscles of the spine daily. Sometimes it was advisable that a brace or corset should be worn. Very few had any idea of the complete plant and earnest corps of workers which the State of Maine had furnished in support of Abbott's general work. As Dr. Abbott turned over ream after ream of *x*-ray prints of cases treated when Dr. Ashley visited him he was much impressed with the completeness of his work, and he said that he considered his discovery one of the greatest advances in orthopedic surgery in ten years. In connection with the paper Dr. Ashley presented several patients in course of treatment and showed *x*-ray pictures and photographs of them before treatment and at different stages.

Dr. REGINALD H. SAYRE said there could be no question that this was a most intelligent way of improving the condition of the spine. In his own practice one of the most satisfactory things that he had done in the treatment of scoliosis was to have his patients go through movements like those of sailors hauling up a heavy cable, which had the effect of arching up the spine. What he had done for only a very short time each day Abbott had now succeeded in keeping up for the whole twenty-four hours. There was no question in his mind that Abbott had made a great advance when he found out how to keep his patients in a posture which might very well be compared to that of cats on the back yard fence with their backs up. It was extremely difficult, however, to apply our pressure to so many vertebral bodies in one direction and yet not affect in any way the other vertebræ. The state of affairs was different from that met with in club foot, where the problem was much simpler, and he was therefore not so optimistic as Abbott appeared to be. There were, he believed, certain cases which could not be improved.

Dr. ASHLEY said that "Keep your back up like a cat" was exactly what he had been telling his patients. The arching of the spine was what was required, and Dr. Sayre's remarks had shown how many of us approached the idea in different ways. Personally he had often thought that if he could only hold his patient in the desired position he could effect a cure, but before Abbott's discovery he had lost faith in the possibility of doing this by means of a plaster-of-Paris jacket.

The Female Perineum from a General Surgeon's Standpoint.—Dr. ROBERT T. MORRIS said that many years ago he became impressed with the fact that most of the perineal operations dealt with fascia alone, and did not appeal to the general surgeon, who liked to have muscles actually in sight when any repair was to be made. Dissections he had made of ruptured perineums showed that atrophy of most of the muscles and fascia took place rather rapidly after the perineum was torn. The pubo-coccygeal portion of the levator ani muscles, however, remained plump and in good condition because of their continued action in other work. In ordinary cases of ruptured perineum he made a horseshoe incision with the arms extending between the labia, placed a finger in the vagina, and felt the large, round portion of the levator ani, stabbed a pair of scissors through one side of the horseshoe incision down to this point, opened the scissors *in situ*, repeated the process on the opposite side, cut the intervening fascia, and then sutured the levator ani muscles in the midline with three or four interrupted kangaroo tendon sutures. A continued suture next united the fascia which carried any remains of the transverse perineal muscles and of sphincters. Where the external sphincter was completely torn he made a second horseshoe incision, with the arms pointing downward, exposed the blunt ends of the torn sphincter ani and united them with one or two kangaroo tendon sutures; after which he completed the regular operation. This made a very strong, durable, and accurate perineal repair, which could be performed

easily in ten minutes without any hurry. The perineum should be repaired before degenerative changes had taken place in muscles and fascia which had been thrown out of commission. Immediate repair of the recently torn perineum could not be made so accurately because of the bruised and torn tissues. In these cases immediate repair was desirable, however, because we usually got primary union if there was a good flow of normal lochial fluid, nature's antiseptic, which bathed the parts freely. If union were missed, or if it were not attempted at this time, the accurate anatomical operation was to be done later.

Dr. Ransford E. Van Gieson said that prevention was sometimes better than cure. Many years ago he had suggested and carried out a little procedure designed for the protection of the perineum, though he had never published this. In cases in which it seemed probable that rupture would occur he passed two or three sutures along through the perineal body beforehand. If rupture did occur the stitches were drawn up, but if there was no rupture they were simply taken out. Within the last three or four years this plan of procedure had been advocated in the medical press.

Surgery from the Pediatric Standpoint.—Dr. Le Grand Kerr read this paper. (See page 1186.)

Dr. Godfrey L. Pisek said that, particularly in New York City, we had a chance to accomplish some of the things spoken of in the paper. There was a distinct surgery of childhood, and he did not doubt that in the future we would have in our medical colleges a chair of Surgery of Children. Even the anatomy of the child varied from that of the adult, and the surgeon should be always ready to recognize congenital abnormalities. The man who regarded the child as a little adult was not fit to practise surgery among children. He believed that the surgeon had taught the pediatrist to be a conservative because he (the surgeon) had not been careful enough in regard to details. The surgeon should not be alone a mechanic. It was not right for him, when called in, merely to say: "Tell me what you want done and I will do it." He should know something about children and their ailments: for instance, that a female child might have a pyosalpinx, resulting from a gonorrheal vaginitis. Possibly there might be present a hemophiliac condition, which it would be of vital importance to recognize. Then, as to the matter of feeding, all the benefit of an operative procedure might be lost by mistakes in this particular. In this connection it was interesting to note the different results which had been reported after the operation for pyloric stenosis. Some men had had a large mortality and others few or no fatal cases, and it could scarcely be doubted that the manner in which the infants were fed had had much to do with these results. Having referred to the importance of *x*-ray examinations, Dr. Pisek concluded by saying that we should always keep in mind the fact that from a surgical point of view, as well as others, the child was an entirely different proposition from the adult.

Dr. Franz Torek said that the importance of thoroughly investigating the general condition of the patient applied to all surgical cases, whether in the child or the adult. Dr. Kerr had done well in telling us not to forget that a child upon whom it was desired to operate might possibly be in the incubation stage of some infectious disease, and it was certainly advisable always to inquire carefully whether the child or any of the family had been exposed to the risk of contagion. Sometimes, however, in spite of all precautions, these infectious diseases took us by surprise. As to the diagnosis of appendicitis, he had been called upon to operate in at least six cases where he found, instead of appendicitis, some pulmonary trouble, perhaps more frequently pleurisy than pneumonia. Even left-sided thoracic disease had sometimes been mistaken for appendicitis. In all of these cases of mistaken diagnosis which he had personally seen the patients were adults; therefore this matter applied to adults as well as to children. As to the question of shock, he could not quite agree with the reader of the paper. He had been brought up to be greatly in fear of shock, but as time went on and his experience increased it had lost some of its terrors for him. He thought that if in the case of children we were to substitute for shock the word hemorrhage it would be getting nearer the truth. The losing of blood was a matter of the gravest import to a young child, and it was therefore highly desirable that in operating on such subjects surgeons should be extremely careful to prevent all bleeding. He believed that if this were borne in mind we would hear less about shock.

Dr. William Shannon said he thought the most expert surgeon could not take offense at anything which had been said this evening. Due credit had been given to skill and technique. He did believe, however, that the pediatrist could often be of service. In one case where he himself was called in an abdominal operation had been performed on a child three or four days before, and on account of the appearance of alarming symptoms the surgeon had been asked to open the abdomen again. There was incessant vomiting and the temperature had risen to 105°. Dr. Shannon found, on investigation, that there had been wrong feeding. He corrected this, and within twenty-four hours the temperature had fallen to normal. Here the whole trouble was that the surgeon did not understand the proper feeding of his little patient, and there were many such instances in which surgeons had profited by advice from the pediatrist. A correct diagnosis was essential not only for medical, but for surgical, therapeutics. A little over a year ago a child who was believed to be suffering from appendicitis was brought on from Boston, to be under his observation for a couple of months. There had been eight acute attacks, and after the arrival of the patient in New York he himself witnessed two distinct attacks. After a careful study of the case, with repeated examinations, he came to the conclusion that the trouble was of digestive origin, and expressed the opinion that no operation was called for. He prescribed an appropriately regulated diet, and during the fourteen months which had now elapsed there had been no relapse. Just the opposite of this case was often true, for, as Dr. Kerr had said, there were many instances where chronic appendicitis was mistaken for other troubles. In all cases of appendicitis in children he believed that operation should be resorted to just as soon as the diagnosis had been made.

Dr. A. Ernest Gallant said that in 1891 he had spent some time at the country branch of the New York Infant Asylum at Mount Vernon, where there were some 400 children, ranging in age from ten days to four years, and as a result of the knowledge of children and their ailments which he gained from this experience he believed that he had since lost a number of surgical fees. A man who had not thus spent some time working among children would certainly sometimes perform operations which were not called for, and, in his opinion, any one who did not understand children was not fit to do surgical work on them. He was very glad to hear Dr. Pisek speak of the anatomical differences between the child and the adult. There was a great lack of knowledge regarding the anatomical peculiarities of early life, and it was also very difficult to secure such knowledge. He had discovered this when, some time ago, he was trying to learn something of the comparative anatomy of the adult and the child, for he could find very little upon the subject in the whole library of the Academy of Medicine. As to the matter of shock, he had always supposed that children stood shock well. It was true that he had seen some nearly killed by chloroform, but he would not consider this as shock. He still believed, however, that in the case of children chloroform was preferable to ether as an anesthetic. The surgeon, in his opinion, should make his own diagnosis. In a number of instances where he had been called in the attending physician had told him what was the matter with the patient and what he wished done, but while he was willing to take into consideration the points thus given him he always liked to form his own opinion of a case. The main point in Dr. Kerr's paper was that the surgeon and the pediatrists ought to get together. He believed that he was right, and that when there was more of this coming together there would be fewer mistakes and also fewer operations.

Dr. Alfred Kahn said that in every case we had to be guided by the conditions present, and that we could not always tell what was going to be the result. Reference had been made to the status lymphaticus. Who could say whether this was going to occur from the anesthetic? In the future he believed that the surgeon would be more of a mechanic, to be called in to do a special thing. As to the general condition and requirements of the child, the best judge undoubtedly was the general practitioner, who had known and cared for it from infancy.

Dr. Kerr, in closing, said in reference to Dr. Torek's point that infectious diseases sometimes came upon us as a sudden surprise, that this was because the child had not been under sufficiently careful observation. All children were liable to contract the exanthematous diseases, and in every instance the question of exposure should be considered. In order to avoid shock in cases requiring manipulations of considerable length, such as extensive burns or scalds, he thought that several short periods of anesthesia were much better than one long, dangerous one. One of the most common causes of shock was the pulling and handling of the tissues, as in the careless use of hemostats, etc., during an operation. He was glad to say that in two

of the hospitals with which he was connected [illegible] now saw all cases under twelve years of age [illegible] medical or surgical; in the latter conferring with the surgeon. As one result of this plan there had not been in the two years since its adoption a single operation for appendicitis in either of these institutions where appendicitis was not really present. In another hospital where he served, however, only the medical cases under twelve, but not the surgical, were allotted to the pediatrist, and here there had been a number of instances in which mistakes were made. He had taken care to observe the work of a number of careful and conscientious surgeons, and he had convinced them of the need of cooperation in children's cases.

NEW YORK ACADEMY OF MEDICINE

SECTION ON SURGERY.

Stated Meeting Held May 3, 1912.

DR. LUCIUS W. HOTCHKISS IN THE CHAIR

Echinococcus Cyst of the Thigh.—Dr. EMILY DUNNING BARRINGER reported the case of an Italian woman sixty-four years old, who was admitted to the hospital May 3, 1911, with a diagnosis of osteosarcoma of the thigh with metastasis in the neck. The family history was negative and there was no history of malignancy. The patient had had the usual diseases of childhood, but otherwise had been perfectly healthy. The menopause occurred ten years ago and in all respects was normal. The history of the present condition dated back six years, when she first noticed a small lump on the outer side of her right thigh which was painful; this swelling grew gradually, becoming more and more painful until at the time of her admission to the hospital she was very much incapacitated and walked with great difficulty. The physical examination showed the lungs and heart to be normal; the examination of the abdomen was negative; there were no enlarged lymph glands with the possible exception of one infraclavicular gland on the left side, and there arose the question as to whether there was a metastatic involvement in this. The right thigh showed a large tumor mass on the anterior and exterior aspects which extended down to within 5 cm. of the upper part of the patella. The tumor was not hard but lobulated and somewhat cystic in various areas. The skin over the tumor was fairly normal in appearance.

Arteriovenous Aneurysm (Facial Vessels) Following a Bullet Wound.—Dr. JOHN J. MOORHEAD reported this case. The patient was shot with a .38 revolver, the bullet making an exit at the angle of the lip. Two days after this occurrence he was admitted to the Post-Graduate Hospital with a large hematoma which had a decided pulsation and gave all the characteristic signs of an arteriovenous aneurysm.

Obliteration of Douglas Cul-de-sac for Rectal Prolapse.—Dr. DE WITT STETTEN presented this patient. He said that two years ago Quenu and Duval had suggested a form of treatment in rectal prolapse which with some modification he had tried in this case. On the assumption that the pouch of Douglas represented the hernial sac, they had advocated the obliteration of the cul-de-sac. Colopexy could be added to this procedure. The patient was 27 years of age and unmarried. She had had colitis two and one-half years ago which lasted eight months, and for six months prior to the operation had noticed prolapse of the rectum when her bowels moved, and suffered very severe pain so that at times she almost fainted. The examination showed a good sphincter ani. With slight pressure the patient was able to extrude about three inches of rectum in its entire thickness. In November, 1911, Dr. Stetten operated through a median incision with the patient in the extreme Trendelenburg position. The uterus was drawn out of the very deep cul-de-sac and pulled taut. The sigmoid was likewise pulled taut. A purse-string suture was then applied to the lowest possible point in the cul-de-sac, only peritoneum, of course, being included. A second and a third purse-string suture were applied in the same manner until the cul-de-sac was completely obliterated, the last suture bringing it to a level with the pelvic brim. The sigmoid was fastened to the posterior wall of the uterus with a few sutures so that it ran transversely across from right to left. Then the peritoneum over the left psoas was divided and the sigmoid was sutured to the muscle. Finally a ventrosuspension of the uterus was done in the usual fashion. The patient made an uneventful recovery and there had been no trace of prolapse since. There had been no interference with the function of the bowels notwithstanding the extensive plastic operation. It was too soon to be certain of the end result, but, if there should be a recurrence, Dr. Stetten believed that a simple perineal operation would be sufficient to bring about a permanent cure. The case simply showed that this operation was absolutely safe and the temporary result perfect.

Ligation of Branches of the Pulmonary Artery for Bronchiectasis.—Dr. WILLY MEYER, after a few introductory remarks regarding bronchiectasis and the difficulties of its medical as well as surgical treatment, referred to the experiments of Sauerbruch and Bruns regarding the effect of ligation of the pulmonary artery and the subsequent shrinking and connective tissue proliferation in the lung and then reported the case of a man 17 years of age, in whom he had ligated the branches of the right pulmonary artery that ran to the middle and lower lobe on that side. The patient was kept in a slight Trendelenburg posture for two days prior to operation, so as to have him cough up as much as possible of the retained secretion. One hour before operation he was given 8 minims Magendie plus 1/150 of atropine. The negative chamber was used. The operation was done under regional anesthesia, novocaine and suprarenin being injected into the fourth to the eighth thoracic nerve near the spine; then the field of operation itself was anesthetized and prepared. An intercostal incision was made in the fifth space, from the vault of the axillary cavity forward as far as possible, avoiding the internal mammary artery. Firm adhesions were found from the lower and middle lobes to the diaphragm, posteriorly in the complementary space, and anteriorly. It was decided to loosen the adhesions, which was accomplished with some difficulty. Still, the lung could not be well moved, the cause being a firm band of adhesions which fixed the apex. With the left fore and middle finger around this band a long curved pair of scissors were introduced and the band clipped. Now the entire lung could be well brought forward and inspected. It had been the intention to enter the interlobar space in order to reach the divisions of the pulmonary artery, but this space had evidently been entirely obliterated by the former attacks of pleurisy; a fine line showed the union between the lobes. It therefore, became necessary to reach the artery more centrally. The lung was turned outward and the bronchus of the middle and lower lobes carefully palpated; the adhesions there present were loosened with a piece of gauze on a long handle. It was not easy to definitely make out the pulmonary artery. The inferior vena cava was distinctly recognized by virtue of its rhythmic distention and collapse with respiration. Alongside the upper border of the bronchus of the lower lobe the pulmonary artery could be definitely made out; this was isolated and surrounded with a silk ligature. When pulled upon, it was observed that about one inch further up another branch was given off from the pulmonary artery, evidently the one to the middle lobe; this was also ligated with silk. The pleural cavity was cleansed and the wound closed in the usual way, without drainage.

The patient stood the operation nicely. He was returned to the ward and made an uninterrupted recovery. He was out of bed on the fifth day. An effusion into his pleural cavity proved to be sterile on bacteriological examination. The patient has very much improved since the operation and the amount of expectoration has become reduced from ten to twelve ounces to less than one ounce.

Incision of Pulmonary Artery in a Dog for Supposed Pulmonary Embolism (Trendelenburg's Operation).—Dr. WILLY MEYER presented a dog in whom he had done the incision of the pulmonary artery, for supposed pulmonary embolism (Trendelenburg's operation). As was well known, Dr. Trendelenburg conducted his experiments for this deadly occurrence in his 64th year and had the courage to try the operation on human beings a short time afterward. He had written Dr. Meyer lately that, although none of the 12 patients who were operated upon by himself and his assistants, in the Leipsic Clinic had survived, he nevertheless would continue to try the method as it offered the only chance of relief in this otherwise usually fatal accident. Dr. Meyer showed the dog to prove that, with the help of differential pressure, the operation lost a great deal of its magnitude, for dogs were generally believed not to be good objects for this kind of operation. Trendelenburg tried it successfully on a calf, imitating the embolism by a piece of lung which had been put into the internal jugular vein and which, after producing the embolism, was attacked and successfully extracted, the animal making a final recovery.

Dr. Meyer has tried the operation three times on dogs, using Trendelenburg's instruments, which were too large, as they were designed for human beings. Still, he succeeded in pulling through two out of the three dogs in which the pulmonary artery was incised. The forceps was intro-

raced into both branches of the vessel and the vessel then closed by interrupted sutures. The dog that died was a small animal and the forceps proved too large, interrupting totally the communication between the right and left ventricles of the heart.

A Contribution to the Study and Surgical Treatment of Oblique Inguinal Hernia.—Dr. Franz Torek read this paper. (See page 1174.)

Membranous Perienteritis.—Dr. Archibald F. Isaacs read this paper. He stated that this condition was, in many cases, the cause of symptoms on which a diagnosis of chronic appendicitis had been made. Though frequently associated with chronic inflammation of the appendix or other viscus, and probably secondary to it in many cases, it developed into a distinct process with manifestations of its own which were usually sufficient to distinguish it from appendicitis or other inflammatory conditions, even if such were present at the same time. The term membranous pericolitis had been applied to the condition, but as the process might occur about various other organs it should be termed perienteritis. While the condition had been referred to by earlier writers, Jackson, in 1909, had written the first real description, and the one which had called the attention of the profession to the frequency and importance of the condition. Observation on the living subject had shown the frequent presence of what might be called a pseudo-peritoneal membrane, lying over and loosely attached to the serosa of the gut, and generally extending to the parietes, thus limiting the normal mobility of the viscus. The appearance of the membrane was usually that of a very delicate, veil-like, transparent film, with its main strands running in a general direction across that of the axis of the gut on which it lay. These bands were comparatively firmly attached at their ends, but the body of the membrane was attached so loosely to the serosa that the gut was freely movable under it. In this delicate mesh of membrane there were often one or more bands of dense tissue attached by one end to the abdominal wall, from whence they radiated over the intestines, or, beginning at the intestine, radiated over the abdominal wall. These bands were likely to cause obstruction by kinking the gut, or by constricting its lumen, or by drawing it into rotary displacement, or by any combination of these effects. The veil-like membrane might have a similar effect in a milder degree, or might form a pouch within which the intestine was freely movable but confined. Again, it might not surround the intestine, but, attached to the parietes on one side, it might extend over a portion of the gut circumference and thus bind it down with rotary displacement and diminution of the caliber of the gut. The anterior longitudinal band of the ascending colon seemed to be the favorite seat for firm attachment of the more dense bands. From here they usually ran outward and upward to be again attached to the parietal peritoneum at a much higher level than that of their origin on the colon. In cases where the transverse colon turned down the hepatic flexure to run back parallel to the ascending colon, the greater omentum, on a line near its origin from the transverse colon, would be found attached to this same longitudinal band by new membrane holding the two sections of the colon together. This doubled colon was then enveloped in a pouch of perienteric new membrane, attached to the outer parietes which limited the normal mobility and caused kinking at the hepatic flexure, very often sharp enough to cause partial obstruction of the lumen. The etiology of the production of this membrane was not yet settled. From his own experience the writer believed that the formation of the membrane was secondary to ulceration or inflammation in the gastrointestinal tract, or in other peritoneum covered viscera. It resulted from the reaction of the peritoneum to the irritation of septic material carried to it, through the lymphatics, or directly from the transvisceral lesion. A mild grade of productive fibrinous peritonitis was set up and organization of the exudate formed this filmy membrane, which contracted in its development. The continuance of the irritation kept up the process with the additional organization of new tissue and the denser and more contracted fibrous bands were formed. The theory that the process was due to irritant absorption from intravisceral sources was supported by the fact that the regions in which it was most frequently found corresponded to the regions where ulceration of the gastrointestinal mucosa were most common. These regions were about the appendix, along the large intestinal tract, the distal portion of the ileum, and about the region of the duodenum and pyloric end of the stomach. The author reported several cases which seemed to show the evident relationship between intraenteric ulceration and perienteric new membrane, or at least showed the coexistence of both under circumstances where cause and effect seemed evident. The cases might be divided into four classes according to the location of the membrane, and, incidentally, in relation to its cause: 1. Membrane about the appendix and neighboring portions of the cecum and ileum. 2. Membrane about the ascending colon, extending to the cecum below and to the region of the flexure above, with bands in advanced cases binding the gut down, reducing its caliber, and rotating on its axis. In these cases the irritation must come from the colon. 3. Membranous adhesions of the transverse colon to the ascending colon, the former being displaced so as to run parallel with the latter, and both being held in an investment of new membrane. 4. Membrane extending from the gall-bladder and liver to the duodenum and pyloric portion of the stomach, and from there to the transverse colon, and usually across the hepatic flexure to the ascending colon. These cases were secondary to duodenal or gastric ulcer, or to cholecystitis. This classification did not include Lane's kink. The pathologist reported that the membrane removed from three cases consisted entirely of connective tissue and blood vessels. The diagnosis could not be made in the early stages, but later there were a few main factors to be relied upon. The history was usually that of vague and annoying pains in the right side of the abdomen for months or years. Constipation was usual, at times followed by painful diarrheal discharges. Gassy distention of the cecum, or of the cecum and ascending colon, with a comparatively collapsed condition of the descending colon would be found. Tenderness about the right half of the abdomen not limited to the appendical region, especially when it extended up over the ascending colon and the hepatic flexure. In the treatment the first requisite was the removal of the cause. To treat the membrane alone and to neglect the cause would be to invite its recurrence. In operating for chronic appendicitis, if the ascending colon would not come down into the wound, it was fair to assume that there were perienteric membranous adhesions about it, and it should be explored. The proper treatment for the membrane was not yet definitely established. It seemed rational to remove as much as possible of the new tissue, and, if in doing so the serosa was damaged by the firmness of the adhesions, such deficiencies might be closed by a few Lambert sutures. The membrane should be divided across the direction of its fibers, which with the expansion of the confined gut would likewise retrace to either side. Even if the membrane did not seem to kink or constrict the gut, it should be treated by division or removed, for, if left, its tendency to contraction might be the cause of future trouble. When it became necessary to cover a defect in the serosa, the line of sutures should, if possible, be at right angles to the incision so as to spread the divided ends of the constricting fibers still further apart. When practicable, the membrane should be peeled off, and either entirely removed or folded up and sutured to its parietal attachment. The results of treatment had been generally good, though not invariably so.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Board of Medical Examiners in the State of Washington.

January, 1912.

ANATOMY.

Twelve questions; answer ten.

1. Name the bones of the cranium. Give the anatomy of the inguinal region and the perineum.
2. Give the contents of the nine regions of the abdomen.
3. Give origin, course, and distribution of sciatic nerve.
4. (*a*) Name the branches of the aorta—ascending, arch, and descending. Give course and distribution of the carotid. (*b*) Give and describe the blood supply of the stomach and bowels. Describe the pulmonary artery.
5. Name the muscles of the abdomen and give origin and insertion.
6. Name and give relation of the important organs, vessels, nerves, muscles and structures of the neck.
7. Give origins and insertions of muscles of the shoulder.
8. Give muscular and tendinous attachments of patella.
9. Give the course of the external and internal saphenous veins.
10. Describe the portal circulation.
11. Describe the sympathetic nervous system.
12. Give anatomy of ear and mastoid and their relations.

HISTOLOGY.

Twelve questions; answer ten

1. Name and describe the membranes of the [illegible].
2. Describe red-blood corpuscle and tell some [illegible] regarding.
3. Give structure of human skin.
4. Describe the appearance of healthy adult liver [illegible] by the microscope.
5. Locate and give structure of Peyer's patch.
6. Name, describe and locate two types of epithelium.
7. Where are the nerve cells found?
8. Locate the thyroid gland and describe its structure.
9. Name the layers of the retina.
10. Name the varieties of muscle and state difference between them.
11. Describe nonmedullated fibers and where occur.
12. Give histological difference between the pyloric and cardiac end of stomach.

PHYSIOLOGY.

Twelve questions; answer ten.

1. Name the principal groups of the normal constituents of the body and give illustrations of each.
2. What are carbohydrates, and what part do they take in the general metabolism?
3. What is the distinguishing element of (*a*) albuminous substances? (*b*) Hydrocarbonaceous substances?
4. Why is an exclusive diet of (*a*) animal food not suited to man's needs? (*b*) Vegetable substances?
5. Name the fluids secreted by the digestive apparatus. Where secreted, and reaction of each?
6. Describe the gastric juice; its action and the product of gastric digestion.
7. Describe the chyle, and how does it enter the general circulation?
8. Describe briefly the phenomena of the coagulation of the blood.
9. What are the *glandulæ solitariæ* or solitary glandules? Where found? Their function?
10. Describe the iris and give its function.
11. Describe the composition of the blood and the functions of its component parts.
12. What is the physiological significance of diabetes, or sugar in the urine?

CHEMISTRY.

Twelve questions; answer ten.

1. What is urea? How would you determine the amount?
2. What degree Fahrenheit is 95° C.?
3. Write the formula of (*a*) baking soda, (*b*) lunar caustic, (*c*) cream of tartar, (*d*) chloride of lime, (*e*) fire damp.
4. Give the chemical difference between calomel and corrosive sublimate.
5. What is (*a*) water of crystallization, (*b*) efflorescence, (*c*) deliquescence?
6. What are proteids? (*b*) From what they derived? (*c*) Name the chief proteids.
7. Describe H_2O_2. (*b*) its properties. (*c*) What is the purest natural H_2O?
8. Name the halogens. Give their symbols and atomic weights.
9. Describe the various allotropic forms of carbon.
10. What is meant by a volatile liquid? Name one and give its formula. (*b*) Same question relative to a fixed liquid.
11. Define (*a*) calorie, (*b*) synthesis, (*c*) molecule, (*d*) fusing point, (*e*) osmosis.
12. Complete the following equations and write the name of each resulting compound under its formula:

$$HgSO_4 - Hg + 2NaCl$$
$$NaC_2H_3O_2 - NaOH$$
$$As_2O_3 + 3H_2S$$

TOXICOLOGY.

Twelve questions; answer ten.

1. Define a poison. Give methods in which they may be introduced into the organism.
2. Give classification of poisons.
3. Give effects local and remote of poisons in general and indicate the particular poisons that affect particular organs or structures.
4. What are ptomaines?
5. Give symptoms of mushroom poisoning.
6. Name the poisonous gases most commonly met with and give their symptoms.
7. Give symptoms of poisoning by arsenic; (*b*) give symptoms of poisoning by phosphorus.
8. What diseases may follow [illegible] on eating pork? Describe them.
9. Describe idiosyncrasy and tolerance and state what effect they may have on poisoning.
10. Does the habitual taking of poisonous drugs diminish the risk of the latent or insidious remote effects.
11. What is wood alcohol? How may it be recognized from grain alcohol? Describe symptoms of poisoning by same.
12. What is denatured alcohol? Is it a poison? In what kind of poisoning may a scarlatina-like rash appear?

PATHOLOGY.

Twelve questions, answer ten.

1. What are the characteristics of a growth which make one pronounce it malignant? What are the principal subdivisions of malignant growths, and how do you distinguish them?
2. Give the pathological appearance (macroscopical and microscopical) of the kidney of chronic interstitial nephritis and give the urinary findings.
3. Describe carefully the condition of the arteries in arteriosclerosis and describe how the heart is affected by it.
4. What is the pathological condition in diabetes mellitus?
5. Describe carefully the appearance of the lung (macroscopical and microscopical) in acute lobar pneumonia.
6. Describe carefully the various steps in the formation of a tuberculous cavity in the lung.
7. What tissues are affected and in what manner are they affected in diphtheritic paralysis of the legs?
8. Describe the gross and minute appearance of the typical alcoholic liver.
9. Describe the lesions in acute cerebrospinal meningitis (epidemic form).
10. Describe the pathological conditions present in exophthalmic goiter.
11. Describe the tissues affected and give the microscopical appearances of the blood in pernicious anemia.
12. What tissues are affected in rheumatoid arthritis? Describe the joint lesion.

BACTERIOLOGY.

Twelve questions; answer ten.

1. Define bacteria and classify them according to form, habitat, and oxygen requirements, describing each classification and giving examples.
2. Discuss microbic association. Give examples.
3. What is the chemical nature or composition of bacteria? What is a pathogenic germ? Toxicogenic?
4. Tell what you can of lactic acid fermentation—in the mouth, the stomach, in milk. Give its cause and the material acted upon.
5. What is necessary to demonstrate the causal relation of a microorganism to a given disease? (*b*) Give the four rules of Koch.
6. What are the water-borne diseases? How would you determine the presence of pathogenic bacteria in water? Distinguish between typhoid and colon bacilli.
7. A sample of sputum is brought to you. How would you determine the presence or absence of the tubercle bacillus? What is tuberculin?
8. What are toxins? Antitoxins? Distinguish between active and passive immunity. For what diseases are antitoxins known and used?
9. Tell all you can about diphtheria antitoxin. How is it made? How standardized?
10. Tell all you can about bubonic plague.
11. Describe Widal's reaction.
12. Give the principle for the Pasteur treatment for rabies.

GENERAL DIAGNOSIS.

Twelve questions; answer ten.

1. Differential diagnosis of intracapsular fracture and dorsal dislocation of head of femur.
2. Give in detail tests to determine the cause of coma in a patient whose history is unobtainable.
3. Give the symptoms and physical signs of aortic insufficiency in the stage of failing compensation.
4. Association of physical signs: (*a*) Solidification of pulmonary structure; percussion; auscultation of respiration; vocal fremitus. (*b*) Large cavity with elastic walls; percussion; auscultation of respiration; vocal fremitus. (*c*) Effusion into pleural sac; percussion; auscultation of respiration; vocal fremitus.
5. Give and define four pathognomonic symptoms of locomotor ataxia—how distinguish multiple neuritis from locomotor ataxia.

6. Define pemphigus; sycosis vulgaris; herpes zoster. A description of the eruption in each case is especially desired.

7. Causes and symptoms of decubital gangrene—how prevent?

8. Diagnose between tetanus, hysterical tetanus and strychnine poisoning.

9. In what lobe is almost always situated a cerebral abscess due to ear disease?

10. Give symptoms of cerebral abscess following empyema of the mastoid.

11. In abdominal operations it is frequently necessary that the large intestine be recognized with certainty or the small bowel be positively identified. Give differences.

12. How many forms of non-malignant stricture of the rectum? How far above the anus is usually situated a simple stricture?

GYNECOLOGY.

Twelve questions; answer ten

1. Give differential diagnosis between appendicitis and right-sided adnexal inflammation.

2. Name varieties of fibroids, most frequent location of each, and diagnose from an unruptured ectopic gestation.

3. At what age does carcinoma of the cervix most frequently develop? Give prognosis, method of dissemination, and differential diagnosis from cervical erosion.

4. Name varieties of menstrual abnormalities. Describe and give etiology of each.

5. How is the uterus normally protected from infection by pathogenic bacteria?

6. What is pelvic hematocele? For what is it most likely to be mistaken? Give etiology and symptomatology.

7. What is vaginismus? Bartholinitis? Pyosalpinx? Coccygodynia? Hematometra?

8. Give distinguishing symptoms between a four months' pregnancy, a uterine fibroid and an ovarian cyst.

9. Describe normal menstruation and the changes that take place in the endometrium at that time.

10. What is subinvolution? And what are its chief etiological factors?

11. How would you distinguish between a case of amenorrhea, the menopause, or a three and one-half months' pregnancy?

12. Give symptoms and diagnosis of gonorrhea in the female. Why is it so serious in the female, and what are its sequelæ?

OBSTETRICS.

Twelve questions; answer ten.

1. Name in order the things to be determined on visiting a patient supposed to be in labor?

2. Define the first, second and third stage of labor, and give the mechanism of breech presentation?

3. Give the definition of pseudocyesis and name other conditions from which to distinguish it, and give the differential diagnosis?

4. What is eclampsia, its frequency, time of occurrence, and effect on mother and child?

5. Define premature labor and abortion, naming the most constant causes of each in order of importance and frequency?

6. Describe fully the obstetric forceps and cranioclast, and name the indications for their use.

7. What do you understand by accidental concealed hemorrhage? Give the causes, symptoms and prognosis?

8. Define version, name the kinds, and tell when indicated?

9. What is puerperal infection? Give a clinical picture of a case, including causes, symptoms, and pathology?

10. Define hydatidiform mole and give symptoms, frequency, pathology, and prognosis?

11. Name and describe four of the most common abnormalities of the female pelvis?

12. Name conditions occurring during labor which jeopardize the life of the child.

HYGIENE.

Twelve questions; answer ten.

1. Name the food principles and state in what proportion they form a balanced ration. Is there any one food which contains all the principles in the proper proportion? What is the effect of living upon a single article of food?

2. What is the chief cause of high infantile mortality? Give directions for the proper care of milk at the time of milking and until it is fed to the child. Are preservatives in milk ever justifiable? Why?

3. Why are patent medicines dangerous? What is the effect of alcohol taken in large amounts (*a*) upon the stomach; (*b*) upon the liver; (*c*) upon the susceptibility to disease; (*d*) upon the capacity for work; (*e*) upon the intellectual capacity?

4. What constitutes a safe and suitable drinking water? What are the best methods of purifying a water supply?

5. What are the best methods for the disposal of sewage? Garbage?

6. Give fully the hygienic measures for tuberculosis both for the care of the patient and for the protection of others.

7. What are the best means for the disinfection of rooms? Clothing? Hands? Sputum? Excreta? Dishes?

8. What constitutes air suitable for breathing? What are the chief impurities of bad air, and what are their effects? How much air space does the individual need?

9. Of the clothing fibers, which is best protection against sunlight? Against cold? Which is best for underclothing? For foot wear? Give reasons.

10. Discuss ventilation and heating of homes from standpoint of hygiene.

11. What are the requirements of a physician and others to prevent the spread of disease?

12. If you were a meat and food inspector what requirements would you make of the dealers in these things? Give reasons.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS IN THE STATE OF WASHINGTON.

January, 1912.

ANATOMY.

2. The regions of the abdomen and their contents are shown in the following table. It is to be remembered that the contents will vary according to the position of the lines drawn; these are arbitrary, and nearly every writer differs from every other. In the following table the superior horizontal line extends between the cartilaginous ends of the tenth ribs, the inferior between the anterior superior iliac spines. The vertical lines pass upward from the iliopectineal eminences, at right angles, to the upper horizontal line.

The viscera situated in each region are as follows:

RIGHT HYPOCHONDRIAC	EPIGASTRIC	LEFT HYPOCHONDRIAC
Liver.	Liver.	Stomach.
Right kidney.	Stomach.	Spleen.
Hepatic flexure of the colon.	Gall-bladder	Left kidney.
	Duodenum.	Splenic flexure of the colon.
	Pancreas.	
RIGHT LUMBAR	UMBILICAL	LEFT LUMBAR
Right kidney.	Transverse colon.	Small part of left kidney.
Ascending colon.	Duodenum and small intestines.	Descending colon.
Ileum.	Great omentum.	Small intestines.
RIGHT ILIAC	HYPOGASTRIC	LEFT ILIAC
Cecum.	Small intestines.	Sigmoid colon.
Appendix.	Bladder in children.	Small intestines.
Last coil of ileum.	Distended bladder in adults.	
	Pregnant uterus.	
	Sigmoid colon.	

4 *Branches of ascending aorta.*—Right coronary and left coronary; of *arch of aorta*: Innominate, left common cartoid and left subclavian; of *descending aorta (thoracic)*: Bronchial, esophageal, pericardial, mediastinal, intercostal, subcostal and superior phrenic; *of descending aorta (abdominal)*: Celiac axis, inferior phrenic, suprarenal, renal, spermatic (or ovarian), superior mesenteric, inferior mesenteric, lumbar, middle sacral, and common iliacs.

HISTOLOGY.

2. The *red blood corpuscles* are biconcave discs, about 1-3200 of an inch in diameter; they are nonnucleated, and there are about 4,500,000 or 5,000,000 of them in each cubic millimeter of blood. They are elastic and soft, and their shape is changed by pressure, but is promptly regained on the removal of the pressure. Their color is yellowish. They contain hemoglobin. They originate in the red marrow of bone, spleen, and liver.

6. TWO KINDS OF EPITHELIUM. (1) *Simple Squamous*, consisting of a single layer of flattened cells, each with a large nucleus. Found in the kidney (in the descending

limb of Henle's loop, and the capsule of Bo[illegible] the alveoli of the lungs, ventricles of the brain. [illegible] *tified Squamous*, consisting of several layers o[illegible] the lowest being columnar, the next polygonal, and [illegible] superficial layers becoming flattened or squam[illegible]ous; in the epidermis, mouth, pharynx, esophagus, [illegible] and anus.

9. The *layers of the retina*, from without inward [illegible] are: (1) Layer of pigment cells; (2) layer of rods and [illegible]s; (3) the external limiting membrane; (4) the outer [illegible]ar, or granular, layer; (5) the outer molecular, or reticular, layer; (6) the inner nuclear, or granular, layer; [illegible] inner molecular or reticular layer; (8) the layer of gang[illegible]lion cells; (9) the layer of nerve fibers; and (1[illegible] the internal limiting membrane.

10. *Voluntary* muscle is striated, has long narrow fibers with cross striations and many nuclei beneath the sarcolemma. *Involuntary* muscle is nonstriated, has spindle-shaped fibers, one nucleus centrally located, and no sarcolemma. The great exception is cardiac muscle, which is involuntary and also striated. *Voluntary muscle* is found in all the skeletal muscles, pharynx, diaphragm, larynx, external ear, and eye. *Involuntary muscle* is found in the alimentary tract from the middle third of the esophagus to the anus, in the ducts of glands, in the trachea and bronchial tubes, within the eyeball, the internal urinary and genital systems, circulatory (except the heart) and lymphatic systems, and the capsules of some organs.

PHYSIOLOGY.

1. *Epithelial tissues*, on the skin, lining the digestive and respiratory tracts, lining the vascular and lymphatic systems, and in various glands.

Connective tissues, in tendons, bones, cartilage, fascia, ligaments, etc.

Muscular tissues in voluntary and involuntary muscles.

Nerve tissues in nerve cells and fibers.

2. *Carbohydrates* were formerly defined as substances of unknown constitution containing carbon, hydrogen and oxygen. The molecule of carbohydrate contained six atoms of carbon (or some multiple of this number), and the hydrogen and oxygen were present in the proportion required to form water. While this definition is not, to-day, scientifically accurate, it suffices to "label" a definite class of compounds containing the sugars and starches.

Carbohydrate metabolism.—"The carbohydrates pass into the liver by the portal circulation as dextrose, and are partly stored up in the liver cells as glycogen, to be given off as sugar in the periods between digestion, to be used up when a sudden demand is made by the starving or working body. Carbohydrates may also be derived from proteids. The dextrose is used up by the muscle- and gland-cells being oxidized, the carbon going off as carbon dioxide. As to amount of carbohydrates, only 500 grams can be consumed without digestive disturbance. The carbohydrates are found in small proportions in flesh-foods, such as glycogen, and in milk in the form of lactose. By far the greater proportions of carbohydrates are obtained from the vegetable kingdom. In vegetable foods they occur as starches and sugars. An animal that is fed upon carbohydrates exclusively dies of starvation on account of want of proteid. The saving of proteid increases proportionately with the quantity of carbohydrates ingested. This is an important fact, since the digestive juices are capable of digesting them in large quantities." (Ott's *Physiology*.)

3. The distinguishing element of albuminous substances is nitrogen; of hydrocarbons, both carbon and hydrogen.

4. *An exclusive animal food* would not include enough carbon (unless the victim of the experiment took far too much nitrogen). So on this diet, there is a choice between too much nitrogen and too little carbon. Scurvy and other disorders would also result.

5. An *exclusive vegetable diet* would not include enough proteid, unless enormous quantities were eaten; this overeating would produce digestive disturbances.

FLUIDS.	WHERE SECRETED.	REACTION.
Saliva.	Salivary glands.	Alkaline.
Gastric juice.	Stomach.	Acid.
Succus entericus.	Small intestine.	Alkaline.
Pancreatic juice.	Pancreas.	Alkaline.
Bile.	Liver.	Alkaline.

6. *Gastric juice* is a thin, colorless fluid; acid in reaction; specific gravity about 1002 to 1010; and containing about 1 per cent. of solids. The daily secretion amounts to 10 or 15 pints. It contains: Water, pepsin, rennin, hydrochloric acid, chlorides (of calcium, sodium, and potassium), and phosphates (of [illegible]um, and iron). Its action is to change proteo[illegible]oses and peptones, and to curdle the caseo[illegible] also slightly antiseptic, and inverts cane [illegible] dextrose and levulose.

The pepsin and rennin come fr[illegible]ural cells in the cardiac glands and from the cell[illegible]ne glands. In both of these glands the pepsin [illegible] pepsinogen. The hydrochloric acid is formed by [illegible]ells. Just how a free acid is formed from the [illegible]n blood and lymph is not known. It has been suggested that it may occur as follows:

(1) $2Na_2HPO_4 + 3CaCl_2 = Ca_3(PO_4)_2 + 4NaCl + 2HCl$ or (2) $Na_2HPO_4 + H_2O + CO_2 = NaHCO_3 + NaH_2PO_4$; and then $NaH_2PO_4 + NaCl = Na_2HPO_4 + HCl$.

The product of gastric digestion is called *chyme*.

7. CHYLE. *Composition*: Water, proteins, fat, cholesterin, lecithin, and inorganic salts.

Properties: Chyle is a clear, colorless or slightly yellow fluid, alkaline in reaction, coagulable; during absorption it becomes creamy, owing to the presence of fat; its specific gravity is about 1006 to 1022.

It is taken up by the lacteals from the intestine during digestion, and finds its way to the lymph stream, then to the receptaculum chyli, then to the thoracic duct, and thence into the blood at the junction of the left subclavian and internal jugular veins.

8. When blood is withdrawn from the blood-vessels of the living body it first becomes viscid, then sets, and is converted into a jelly-like mass. This is due to the formation of fibrin. The jelly contracts, forming the clot; and at the same time the serum is squeezed out from the clot. Various circumstances and conditions will hasten or delay the process of coagulation. In man, the blood generally becomes viscid in from two to three minutes; it forms the jelly-like mass in from five to six minutes; a few minutes later the serum begins to appear; and the whole process is completed in from twenty-four to thirty-six hours. The clot then floats in the serum. The process is thus summed up by Halliburton: In the plasma a proteid substance exists, called fibrinogen. From the colorless corpuscles a nucleo-proteid is shed out, called prothrombin. By the action of calcium salts prothrombin is converted into fibrin ferment, or thrombin. Thrombin acts on fibrinogen in such a way that two new substances are formed: one of these is unimportant and remains in solution; the other is important, viz., fibrin, which entangles the corpuscles and so forms the clot.

10. *Functions of the iris:* To regulate the amount of light which falls upon the retina; to minimize spherical aberration; and to aid accommodation in the production of distinct vision for near objects.

11. *Physiological composition* of the blood:

1. Plasma.
2. Corpuscles { Colored. / Colorless. / Blood-plates.

The *plasma* consists of water and solids (proteins, extractives, and inorganic salts). The *red corpuscles* consist of water and solids (hemoglobin, proteids, fat, and inorganic salts). The *white corpuscles* consist of water and solids (proteid, leuconuclein, lecithin, histon, etc.).

Functions: The *red blood cells* carry oxygen from the lungs to the tissues. The *white blood cells:* (1) Serve as a protection to the body from the incursions of pathogenic microorganisms; (2) take some part in the process of the coagulation of the blood; (3) aid in the absorption of fats and peptones from the intestine, and (4) help to maintain the proper protein content of the blood plasma. The function of the *platelets* is not determined; it is possible that they take some part in the coagulation of the blood. The *plasma* conveys nutriment to the tissues; it holds in solution the carbon dioxide and water which it receives from the tissues, and takes them to be eliminated by the lungs, kidneys, and skin; it also holds in solution urea and other nitrogenous substances that are taken to and excreted by the liver or kidneys.

12. *Physiological significance of diabetes:* "Diabetes has usually been associated with derangements of the glycogenic function of the liver, though doubtless derangements of other organic functions will produce the same condition. At the present time it is believed that the excretion of sugar by the kidneys depends on two causes: (1) An ineffectual abstraction and storage of sugar due to some impairment in the activity of the liver cells; (2) a rapid cleavage of the protein constituents of the tissues, in consequence of some profound alteration in the nutritive process, whereby their glucose radicals are liberated in unusual amounts. The physiological mechanism by which the normal metabolism of the carbohydrates is regulated

is unknown. That it is complex in character is shown by the phenomena which follow not only puncture of the medulla, but also removal of the pancreas and the administration of various toxic agents."—(Brubaker's *Physiology.*)

CHEMISTRY.

1. Urea, $CO(NH_2)_2$, is the end product of the proteid metabolism of the body.

A comparatively easy test for *urea* is that of Fowler, based upon the loss of the specific gravity of the urine after the decomposition of the urea by hypochlorite. "To apply this method the specific gravity of the urine is carefully determined, as well as that of the liquor sodæ chlorinatæ (Squibb's). One volume of the urine is then mixed with exactly seven volumes of the liquor sodæ chlorinatæ, and, after the first violence of the reaction has subsided, the mixture is shaken from time to time during an hour, when the decomposition is complete; the specific gravity of the mixture is then determined. As the reaction begins instantaneously when the urine and reagent are mixed, the specific gravity of the mixture must be calculated by adding together once the specific gravity of the urine and seven times the specific gravity of the liquor sodæ chlorinatæ, and dividing the sum by eight. From the quotient so obtained the specific gravity of the mixture after decomposition is subtracted; every degree of loss in specific gravity indicates 0.7701 gram of urea in 100 c.c. of urine. The specific gravity determinations must all be made at the same temperature; and that of the mixture only when the evolution of gas has ceased entirely."—(Witthaus' *Manual of Chemistry.*)

2. Since $\frac{9}{5}C^\circ + 32 = F^\circ$.

$$\left(\frac{9}{5} \times \frac{95}{1}\right) + 32 = F.$$

$$171 + 32 = 203^\circ.$$

$$\therefore 95^\circ C = 203^\circ F.$$

3. Baking soda is $NaHCO_3$; lunar caustic, $AgNO_3$; cream of tartar, $C_4H_5O_6HK$; chloride of lime, $CaCl(ClO)$; fire damp, CH_4.

4. *Corrosive mercuric chloride*, $HgCl_2$. Corrosive sublimate is heavy, white, and crystalline; it has a strong, acrid, styptic taste, and is soluble in water, in alcohol, and in ether; it is decomposed by exposure to light.

Mild mercurous chloride, Hg_2Cl_2 calomel, is a heavy, white powder, amorphous, tasteless, and odorless; it is insoluble in cold water and in alcohol, and very slightly soluble in boiling water; when exposed to the light it becomes discolored (first yellow, then gray) and partially decomposed; it sublimes without fusing.

5. *Water of crystallization* is the water taken up by certain substances when they assume the crystalline form; this water is necessary for the maintenance of the form (and sometimes the color) of the crystal.

Efflorescence is the sudden change of a crystalline substance into a powder by the loss of its water of crystallization.

Deliquescence is liquefaction of a substance due to absorption of moisture from the atmosphere.

6. *Proteids* are organic substances of very complex composition, and of unknown constitution, which are indispensable to all animal and vegetable life. They are composed of carbon, hydrogen, oxygen, and nitrogen; some of them also contain sulphur or phosphorus, or some other element. They are formed by living matter. The chief proteids are the albumins, albuminates, globulins, nucleoproteids, proteoses, peptones, and coagulated proteids.

7. *Water*, H_2O, is the monoxide of hydrogen. It is a colorless liquid, a good solvent, a necessary component of the human body (about two-thirds of the body being water), it boils at 212° F., and freezes at 32° F. The purest natural waters are rain water and melted snow, provided they are uncontaminated.

8

HALOGENS.	SYMBOLS.	ATOMIC WEIGHTS.
Fluorine	F.	19
Chlorine	Cl.	35.5
Bromine	Br.	80
Iodine	I.	127

9. *The various allotropic forms of carbon* are: (1) *Diamond*, usually colorless or yellowish, but may be blue, green, pink, etc.; it is the hardest substance known, and the one which refracts light the most strongly. It is brittle, a bad conductor of heat and electricity; when very strongly heated it burns, without blackening, to carbon dioxide.

(2) *Graphite* is a form of carbon almost as pure as the diamond, capable of crystallizing in hexagonal plates; dark gray in color, opaque, soft, and a good conductor of electricity. It is also known as black lead or plumbago.

(3) *Amorphous carbon* is met with in a great variety of forms, natural and artificial, in all of which it is black, more or less porous, and a conductor of electricity.—(From Witthaus' *Chemistry.*)

10. A *volatile liquid* is one that passes into vapor at ordinary temperatures; example, Chloroform, $CHCl_3$.

A *fixed liquid* is one that does not pass into vapor at ordinary temperatures; examples, Water, H_2O.

11. *Caloric* is the amount of heat required to raise the temperature of one gram of water from 4° to 5° C.

Synthesis is the building up of a compound out of elements or simpler compounds.

Molecule is the smallest quantity of a substance (either element or compound) that can exist in a free state.

Fusing point is the temperature at which a given substance begins to melt.

Osmosis is the process by which certain fluids and substances in solution pass through a membrane or other porous substance.

12. $HgSO_4 + Hg + 2NaCl = Hg_2Cl_2 + Na_2SO_4$.

$NaC_2H_3O_2 + NaOH = C_2H_4O_2 + Na_2O$.

$As_2O_3 + 3H_2S = As_2S_3 + 3H_2O$.

TOXICOLOGY.

1. A *poison* is a substance which, being in solution in, or acting chemically upon the blood, is capable of producing death or serious bodily harm.

Poisons may be administered by the mouth, rectum, skin, vagina, lungs (by inhalation), by hypodermic injection into the circulation, by being applied to a wounded surface.

2. *Classification of poisons:* I. Corrosives. II. Poisons: Mineral, Vegetable, Animal, and Synthetic.

3. The local action of corrosives is severe, and the remote action is slight; with true poisons the reverse of this is the case. Corrosives decompose the tissues with which they come in contact; they also produce irritation and inflammation.

"Concerning the method of action of poisons upon cells and tissue elements or their constituents but little is known. A few poisons are, however, known to cause changes in the composition, chemical changes, in certain constituents of the tissues and fluids which render them unfit to perform their normal function. Thus carbon monoxide combines with the red coloring matter of blood corpuscles to form a compound more stable than that which the same pigment produces with oxygen, and thus extinguishes life by interference with the transfer of oxygen from the lungs to the tissues. It has also been suggested that the poisonous action of arsenic is due, in part at least, to interference with normal chemical processes brought about by modifications of oxidation. . . . . Recent investigations of the actions of those organic poisons whose chemical constitution is known indicate that their toxic activity depends upon their molecular structure, and in the case of certain series of related or homologous compounds is increased or diminished by introduction of certain groups or atoms, or in the case of isomeric bodies by variations in their positions." (Witthaus' *Toxicology.*)

Poisons that act on the brain: Opium, belladonna; *on the spinal cord:* strychnine, brucine, thebaine; *on the heart:* aconite, hydrocyanic acid, digitalis, strophanthus, nicotine.

4. *Ptomaines* are basic, nitrogenous compounds, produced from protein material by the bacteria which cause putrefaction.

5. *Symptoms in poisoning from mushrooms:* Sudden onset, great prostration, cold perspiration, headache, fever, rapid and feeble pulse, pain in abdomen, diarrhea, cyanosis, urine scanty or suppressed and albuminous or bloody; stupor and delirium.

6. *Poisonous gases most commonly met with:* Carbon monoxide, hydrogen sulphide, sulphur dioxide.

7. The *symptoms of acute arsenical poisoning:* "In acute cases the symptoms usually begin in from 20 to 45 minutes. Nausea and faintness. Violent, burning pain in the stomach, which becomes more and more intense, and increases on pressure. Persisting and distressing vomiting of matters, sometimes brown or gray, or streaked with blood, or green (Paris green). Purging. More or less severe cramps in the lower extremities."

In *chronic arsenical poisoning:* "Inflammation ... junctive with intolerance of light. Irritation of ... with eruption (eczema arsenicale), local paralyses ... weakness and emaciation, exfoliation of the skin, and falling out of the hair." (Witthaus' *Essentials of Chemistry.*)

Symptoms of acute phosphorus poisoning: "Eructation of gas having the odor of garlic. The mouth, when observed in the dark, is frequently faintly luminous (phosphorescent). After several hours, pain in the throat, a sense of heat in the epigastrium, nausea, and vomiting. The vomited matters are sometimes bloody, and frequently luminous when agitated in the dark. The abdomen is tender, and there are diarrhea and colicky pains. After one or two days these symptoms cease, there remaining only pain in the back and limbs and a feeble pulse. Death sometimes occurs suddenly in from two to four days. Usually about the fourth day the patient becomes jaundiced, suffers from headache, insomnia, and retention of urine, rapidly becomes delirious and comatose, and dies." (From Witthaus' *Essentials of Chemistry.*)

8. Ptomaine poisoning and trichiniasis.

9 and 10. *Idiosyncrasy.* "Many persons are peculiarly susceptible to certain poisons, requiring a very small dose to produce serious symptoms. Others suffer serious illness from eating certain articles of food which are noninjurious to most persons, as oysters, lobsters, and other shell fish, strawberries, etc. In others, certain odors, as of musk, certain flowers, etc., produce unpleasant symptoms. In other cases ordinary medicines have an unusual effect (opium causing persistent wakefulness, arsenic producing narcotic symptoms, etc.). Idiosyncrasy rarely takes the form of increased tolerance of poisons. Occasionally a case is met with where a small dose produces serious symptoms in a person who has formerly taken much larger doses without injury. This is probably due to some obscure physiological or functional change, brought about by the former use of the drug, or it may be due to some of the causes previously mentioned relating to changes in the reaction of the contents of the stomach, or lack of uniformity of composition, etc., of the drug itself."

Tolerance: "Many persons habitually use certain poisons (tobacco, morphine, cocaine, alcohol, etc.), and thus acquire a tolerance for doses which would prove quickly fatal to ordinary persons. This is true, however, of organic poisons alone. No well authenticated case has been recorded of a similar tolerance of a mineral poison. This tolerance of organic poisons shows itself in the increased doses that must be taken to produce the desired effect. It does not mean that the use of the poison is not followed by injury. The evil effects may not manifest themselves at once, or in a marked manner, but the constitution is being undermined, and the injury, though insidious, is none the less destructive. The general health is always impaired." (Riley's *Toxicology.*)

11. *Wood alcohol* is methyl hydroxide, CH_3OH. It can be distinguished from grain alcohol by its lower boiling point and higher specific gravity. *Symptoms of poisoning* "Vertigo, headache, progressive emaciation and great muscular weakness, accompanied in most cases by amaurosis, owing to degenerative or inflammatory changes in the optic nerve. This impairment of vision may improve for several days, then sink again, pointing to atrophic changes following inflammation. Neuritis affecting other parts of the body is sometimes developed." (Riley's *Toxicology.*)

12. *Denatured alcohol* is ethyl alcohol to which methyl alcohol has been added to make it undrinkable; other chemical substances are also added, and it is not subject to the internal revenue tax.

It is poisonous.

A *scarlatina-like rash* appears in poisoning by: Belladonna, stramonium, chloral hydrate, hyoscyamine, morphine.

BACTERIOLOGY.

1. *Bacteria* are minute, unicellular vegetable organisms, devoid of chlorophyl, non-nucleated, and multiplying by poison. *According to form, bacteria may be classified* as: (1) *Cocci*, which are round or oval, and may appear singly, in pairs, in chains, or in groups; example—streptococcus of erysipelas. (2) *Bacilli*, which are rod shaped, with the longer sides parallel and the short ends either straight, rounded, or concave; example—bacillus of tetanus. (3) *Spirilla*, which are spiral; example—spirillum of relapsing fever.

According to habitat, as: (1) *Saprophytes*, which live on dead organic substances, and (2) *parasites*, which live on some other living organism. *With regard to oxygen requirements*, they are: (1) *Aërobic*, such as require the presence of oxygen in order to live and grow; most bacteria are aërobic. (2) *Anaërobic*, such as require the absence of oxygen, as tetanus.

2. *Microbic associations* ... of bacteria in nature naturally carries wit... neous presence of many species in all places ... conditions have provided a favorable environme... h. Thus bacteriological investigation of wat... ure, soil, or organic infusions, always reveals ... of a large number of different varieties with ... substance. If the food supply in such a natur... at all limited in quantity, or the removal of w... ts is prohibited, it will usually be found that ... the numbers of varieties will diminish and a te... , or even only one will prevail. In a case of in... stance, after standing for three or four days at ... m temperature, two or three varieties will be found ... ave taken the place of the twenty or thirty, which may have been present originally. This behavior is due to the influences which various microorganisms exert upon each other and is known as *antagonism*. Such antagonism probably depends upon the fact that the metabolic products of the predominant species (the one or ones for whom the special cultured conditions are most favorable) inhibit the growth of the less vigorous varieties. Many examples, experimentally supported, of such antagonism, can be given. Thus, the gonococcus is distinctly inhibited by the soluble products of *Bacillus pyocyaneus*, while in the presence of pyogenic cocci it develops luxuriantly, and the bacillus of plague is completely inhibited when streptococci are present in the culture. When the simultaneous presence of two bacterial species within the same environment favors the development of both species, the condition is spoken of as *symbiosis*. Such dependence is not so frequent as antagonism, but it does occur. Examples of such a condition have been observed in cultures containing diphtheria bacilli and streptococci, and have been frequently observed in cultures containing both aërobic and anaerobic bacteria, where the former favor the development of the latter by monopolizing the supply of oxygen." (Hiss and Zinsser's *Bacteriology.*)

3. *Chemical composition of bacteria:* Chiefly water (80 to 90 per cent.); the ash contains phosphorus pentoxide. There are also found sulphur, potassium, calcium, chlorine, and nitrogenous compounds (such as nuclein, guanin, and adenin).

Pathogenic bacteria are such as produce disease.

Toxicogenic bacteria are such as produce poisons.

4. *Lactic acid fermentation:* Monosaccharides are directly fermentable, by several schizomycetes of the mouth, into lactic acid: caries of the teeth may be caused thereby. Lactic acid fermentation of carbohydrates takes place spontaneously in the mouth and in milk.

Lactic acid fermentation may continue in the stomach till the percentage of HCl reaches 0.16. If too little HCl is secreted, or too much food is taken, the fermentation may last some time.

"Under normal conditions milk always undergoes a process which is popularly known as souring and curdling. This is due to the formation of lactic acid from the milk sugar and is the result of the enzymatic activities of several varieties of bacteria commonly found in milk. Most common among these bacteria is the so-called *Bacillus lactis aërogenes*. The transformation of lactose into lactic acid may occur either directly by hydrolytic cleavage:

$$C_3H_6O_3 + H_2O = 4CH_4O$$

or indirectly through a monosaccharid:

$$C_6H_{12}O_6 + H_2O = 2C_6H_{12}O_6 = 4CH_4O."$$

(From Hiss and Zinsser's *Bacteriology.*)

5. To *prove that bacteria cause disease* it is essential: (1) That the microorganism be found in the tissues, blood, or secretions of a person or animal sick or dead of the disease; (2) the microorganism must be isolated and cultivated from these same sources; it must also be grown for several generations in artificial culture media; (3) the pure cultures, when thus obtained, must, on inoculation into a healthy and susceptible animal, produce the diseases in question, and (4) the same microorganisms must again be found in the tissues, blood, or secretions of the inoculated animal. These are called the rules or postulates of Koch.

6. *Water borne diseases*, are: Typhoid, cholera, dysentery, and some gastrointestinal disorders.

The presence of pathogenic bacteria may be determined (theoretically) by making cultures from the water. But practically there are no reliable methods of doing this. The "colon test" is often used.

To distinguish the typhoid bacillus from the colon bacillus: (1) On gelatin plates, the colonies of typhoid develop more slowly than those of colon bacillus. (2) The colon bacillus causes fermentation with production of gas in media which contain sugar; the typhoid bacillus does not. (3) The colon bacillus produces a strong acid reaction and

coagulates milk within twenty-four to forty-eight hours; the typhoid bacillus does not coagulate milk. (4) In peptone solution the colon bacillus produces indol; the typhoid bacillus does not. (5) The typhoid bacillus gives the Widal reaction with typhoid serum; the colon bacillus does not.

7. To demonstrate the existence of *tubercle bacilli* in the sputum: The sputum must be recent, free from particles of food or other foreign matter; select a cheesy-looking nodule and smear it on a slide, making the smear as thin as possible. Then cover it with some carbolfuchsin, and let it steam over a small flame for about two minutes, care being taken that it does not boil. Wash it thoroughly in water and then decolorize by immersing it in a solution of any dilute mineral acid for about a minute. Then make a contrast stain with solution of Loeffler's methylene blue for about a minute; wash it again and examine with oil immersion lens. The tubercle bacilli will appear as thin red rods, while all other bacteria will appear blue.

Tuberculin is a preparation made from cultures of the *Bacillus tuberculosis*.

8. *Toxins* are the products of pathogenic bacteria or of ptomaines and leucomaines, and are actively poisonous.

Antitoxins are substances formed in the body, of a protective character, and capable of rendering inert the poisonous products of bacteria.

Active immunity follows an attack of a certain disease and secures immunity for that alone; or it follows inoculation of a virus weaker than necessary to cause the typical disease; or it follows inoculation by bacterial products apart from the organisms themselves.

Passive immunity is the term applied to the effect of a serum derived from an immunized animal and injected into one not immune.

Antitoxins are used in: Diphtheria, tetanus, anthrax.

9. *"Diphtheria antitoxin is obtained* from the horse, the animal having been rendered artificially immune by repeated injections extending over a period of several months of gradually increasing quantities of the strongest diphtheria toxin. As the bacilli themselves are not injected, the horse does not become infected with diphtheria, but he gradually acquires a tolerance for the toxins of the disease and develops in his blood a substance (antitoxin) which has the power to neutralize those toxins. At the proper time, when it is thought that his blood has acquired the requisite degree of potency, the animal is bled, and the serum—the part of the blood containing the antitoxin—is carefully separated from the clot, filtered, and standardized. The last procedure is accomplished by determining the quantity of antitoxin serum required to offset the effects of the minimum quantity of toxin necessary to kill a guinea-pig in a definite time. The strength of the antitoxin is measured in units, a unit containing the amount of antitoxin required to save the life of a guinea-pig which has been injected with 100 fatal doses of toxin."—(Stevens' *Materia Medica*.)

11. *Widal's test:* Three drops of blood are taken from the well-washed aseptic finger tip or lobe of the ear, and each lies by itself on a sterile slide, passed through a flame and cooled just before use; this slide may be wrapped in cotton and transported for examination at the laboratory. Here one drop is mixed with a large drop of sterile water, to redissolve it. A drop from the summit of this is then mixed with six drops of fresh broth culture of the bacillus (not over twenty-four hours old) on a sterile slide. From this a small drop of mingled culture and blood is placed in the middle of a sterile cover-glass, and this is inverted over a sterile hollow-ground slide and examined. A positive reaction is obtained when all the bacilli present gather in one or two masses or clumps, and cease their rapid movements inside of twenty minutes.

4. *Association of physical signs*:

PERCUSSION.	AUSCULTATION OF RESPIRATION	VOCAL FREMITUS.	PHYSICAL CONDITIONS.
Dull	Bronchial or harsh respiration.	Increased	Solidification of pulmonary structure.
	Absent respiration.	Diminished or absent.	Effusion into pleural sac.
Amphoric or metallic	Amphoric or metallic.	Mostly diminished.	Large cavity with elastic walls.

(From Hughes' *Practice of Medicine*.)

GENERAL DIAGNOSIS.

6. *Pemphigus* is an inflammatory disease of the skin, either acute or chronic, characterized by the development of a succession of rounded, irregularly shaped blebs or bullæ, varying in size from a pea to an egg. These appear in successive crops, each crop lasting from three to ten days.

Sycosis vulgaris is a chronic inflammatory disease of the bearded region due to invasion of the hair follicles by pus-producing microorganisms, characterized by papules, pustules, and tubercles.

Herpes zoster is an acute inflammatory disease characterized by the development of groups of firm and distended vesicles situated upon inflamed bases corresponding to a definite cutaneous nerve, and accompanied by more or less severe neuralgic pains.—(From Hughes' *Practice of Medicine*.)

7. Decubital gangrene is bedsore.

9. Cerebral abscess due to ear disease is almost always in the temporo-sphenoidal lobe.

11. The *large intestine* has three teniæ or bands, is sacculated, and has appendices epiploicæ attached to it. The *small intestine* has none of these characteristics.

12. See Rose and Carless' "Surgery" (1911), page 1166; or Da Costa's "Surgery" (1911), page 1181.

GYNECOLOGY.

1.

APPENDICITIS.	ADNEXAL INFLAMMATION.
1. No previous local disturbances.	1. Genitourinary functions previously disturbed. Usually a history of gonorrheal or puerperal infection.
2. Chill usually absent.	2. Chill may precede fever.
3. Pain in right iliac region, sudden onset, acute, and not radiating to thighs.	3. Gradual onset, pain dull, continuous, and radiating.
4. Fever of variable degree.	4. Fever often entirely absent.
5. Muscular rigidity on right side of the abdomen.	5. No muscular rigidity unless complicated by peritonitis.
6. Inflammatory exudate about appendix three to five days after onset of symptoms.	6. Inflammatory exudate in the pelvis felt by vaginal examination at the onset of the symptoms.
7. Vaginal examination is rarely painful in appendicitis.	7. Always painful in tuboovarian disease.

—(Findley.)

2. FIBROIDS. *Varieties:* (1) Subperitoneal or subserous; (2) interstitial, in the uterine tissue; and (3) submucous in the endometrium.

3. Carcinoma of the cervix most frequently develops between the ages of 35 and 50. The prognosis is unfavorable unless a radical operation is performed. It is disseminated by the lymphatics, and also spreads by a continuous chain of infiltration in the connective tissue. In *carcinoma of the cervix*, the cervix is hard and nodular, and the mucous membrane seems immovably fixed to the underlying tissue. The nodules break down, the entire cervix becomes ulcerated, or large cauliflower-like masses may fill the upper part of the vagina. The diseased tissue is friable, and bleeds when touched. In *erosion* the pain and general symptoms are less, the eroded portion seems to disappear when the lips of the cervix are brought together. The microscope will show characteristic differences.

4. MENSTRUAL ABNORMALITIES. (a) *Amenorrhea* is absence of menstruation during the period of sexual activity. (b) *Menorrhagia* is a condition characterized by excessive loss of blood during the menstrual periods. (c) *Metrorrhagia* is a hemorrhage from the uterus at other than the menstrual periods. (d) *Dysmenorrhea* is painful menstruation.

AMENORRHEA is *physiological:* Before puberty, during pregnancy and early lactation, and after the menopause. It may also be due to: Absence or imperfect development of the generative organs; also to operative removal of the uterus or its appendages. Other causative factors are: Acute infectious diseases, anemia, chlorosis, obesity, drug habits, alcoholism, overstudy, lack of exercise, exposure to cold, and various emotional causes. CAUSES OF MENORRHAGIA. Purpura, scorbutus, hemophilia, hepatic cirrhosis, overindulgence in food and alcoholic drinks. Uterine congestion and displacement, endometritis, subinvolution, fibroids, and other tumors. CAUSES OF METRORRHAGIA. Disease of uterus or appendages, polyps, extrauterine gestation, the hemorrhages in connection with pregnancy.

CAUSES OF DYSMENORRHEA: Pelvic congestion, pelvic inflammation, malnutrition, overwork, lack of development,

neuralgia, stenosis or obstruction of the cervix, [illegible] or displacement of the uterus.

5. The uterus is normally protected from infection by the muscular constrictions which divide it from the Fallopian tubes and also by a similar arrangement at the internal os, and at the external os. The acidity of the vaginal secretion is also a protective factor.

6. *Pelvic hematocele* is an accumulation of blood in the pelvis, due to rupture of a blood-vessel; it is generally due to rupture of a tubal pregnancy, or to a tubal abortion. *Symptoms*: Pain, which is sudden and severe, over abdomen and pelvis; nausea, cold perspiration, cold extremities, pulse rapid and weak, pinched features, and shock. It is most likely to be mistaken for an ectopic gestation.

7. *Vaginismus* is a condition of painful and spasmodic contraction of the vaginal orifice, rendering coitus difficult or impossible. *Bartholinitis* is inflammation of the vulvovaginal glands. *Pyosalpinx* is an accumulation of pus in the Fallopian tube. *Coccygodynia* is pain in the region of the coccyx (found in parous women more frequently than in multiparæ). *Hematometra* is an accumulation of blood in the uterine cavity.

8. *Pregnancy:* the tumor is hard and does not fluctuate, is situated in the median line, and may give fetal heart sounds and movements; the cervix is soft, and the other signs of pregnancy are present. The rate of growth of the tumor, and the general condition of the patient's health may also help in arriving at a diagnosis.

Uterine fibroid: menstruation is irregular and sometimes very profuse; absence of the signs of pregnancy; the tumor is nodular, firm, irregular in outline, and while generally placed somewhat centrally is not in the median line, and is not symmetrical; the rate of growth is irregular, being, as a rule, slow, but sometimes extending over years.

Ovarian cyst: absence of the chief signs of pregnancy; there may be the characteristic facies, the tumor is soft, fluctuating, is more to one side, and does not show fetal signs.

10. *Subinvolution* is delay in, or failure of the uterus to return to its normal condition after labor. *Its chief etiological factors* are: Lacerations of the cervix; absorption of septic products; mismanagement of the convalescent stage of the puerperium, chiefly too early rising; tedious labors; misplacement of the uterus; retained clots or membranes; tumors of the uterus.

11. In *Amenorrhea*, from other causes, also in the *Menopause*, all the other signs of pregnancy will be absent.

12. GONORRHEA. *Symptoms:* Pain and burning in the vulva; pain and burning on micturition; dyspareunia; yellowish or greenish discharge, in which the gonococcus can be found; the vagina is hot, red, swollen, and tender. *Possible results:* Cystitis, urethritis, vulvitis, endometritis, salpingitis, septic peritonitis, sterility, condylomata of vulva, abscess of Bartholin's glands. *Diagnosis* is made from the symptoms, particularly from finding the gonococcus in the discharge. It is *so serious*, on account of the possible results, enumerated above; it often leads to chronic invalidism, and may be the cause of death.

OBSTETRICS.

12. *Conditions occurring during labor, which may jeopardize the life of the child:* Delayed, or prolonged, or precipitate labor; uterine inertia; hemorrhages; eclampsia; rupture of the uterus; maternal death; faulty presentation or position; prolapse of cord; rupture of cord.

HYGIENE.

1. The *food principles* are: Proteids, fats, carbohydrates, salts, and water. In a balanced ration, the proteids, fats, and carbohydrates are given (by Ranke) in the proportions of 1:1:2½. Milk contains all the food principles in nearly the proper proportions for an adult. The effect of living on a single article of food is either overeating or partial starvation, with lack of nutrition, indigestion, diseases, inability to work.

2. The chief cause of high infant mortality is improper feeding. *Essentials for the production and preservation of pure dairy milk:* Vaughan's rules are as follows: "(1) The cows should be healthy, and the milk of any animal which seems indisposed should not be mixed with that from the healthy animals. (2) Cows must not be fed upon swill or the refuse from breweries or glucose factories, or upon any other fermented food. (3) Milch cows must not be allowed to drink from stagnant pools, but must have access to fresh, pure water. (4) The pasture must be freed from noxious weeds, and the barn and yard must be kept clean. (5) The udders should be washed and then wiped dry before each milking. (6) The milk must be at once thoroughly cooled. This is best done in the summer by placing the milk can in a tank of cold water or ice water, the water being of the same depth as the milk in the can. It would be well [illegible] the tank could be kept flowing, and this will [illegible] less ice water is used. The tank should be [illegible] ged each day to prevent bad odors. The [illegible] n uncovered during the cooling, and the milk [illegible] ntly stirred. The temperature should be reduced [illegible] , or lower, within an hour. The can should [illegible] water till ready for delivery. (7) Milk should [illegible] ed, during the summer, in refrigerated cans or [illegible] t which ice is packed during transportation. [illegible] ceived by the consumer it must be kept in a [illegible] ld at a temperature some degrees below 60° F.

The addition of preservatives is not [illegible] because (1) they are not necessary, and (2) they are [illegible] armful.

3. *Patent medicines are dangerous*, because (1) They are generally taken without professional advice or sanction, but at the whim of the purchaser, solely on the recommendation, or druggist interested in the sale of the stuff. (2) They often contain powerful and harmful ingredients. (3) They are generally issued by irresponsible parties whose sole interest is in their sale. (4) Their exact contents are not always known, and are often variable.

Alcohol taken in large amounts may cause gastritis, cirrhosis of liver, increased susceptibility to disease, lowered capacity for work, and diminished intellectual capacity.

4. *Characteristics of a good drinking water:* (1) It should be clear and limpid. Cloudy and muddy waters should be avoided. (2) It should be colorless. A greenish or yellowish color is usually due to vegetable or animal matter in solution or to organisms. (3) It should be odorless; especially free from sulphuretted hydrogen or putrefactive animal matter. (4) It should not be too cold, but should have a temperature of from 40° F. to 60° F. (5) It should have an agreeable taste; neither flat, salty, nor sweetish. A certain amount of hardness and dissolved gases give a sparkling taste. It should contain from 25 to 50 c.c. of gases per liter, of which 8 to 10 per cent. is carbon dioxide and the rest oxygen and nitrogen. (6) It should be as free as possible from dissolved organic matter, especially of animal origin. (7) It should not contain too great an amount of hardness. A certain quantity of saline matter is necessary, however, to give it a good taste. It should not contain over three or four parts of chlorine in 100,000 parts of water.—(From Bartley's *Chemistry*.)

The best methods of purifying a water supply are filtration and distillation.

5. The best method of sewage disposal is by the bacterial or biological processes. Garbage should be burnt.

6. Hygienic precautions to be taken in treating a case of tuberculosis: "The patient's quarters should be free from dust and admit of spending many hours daily in the open air in all weathers, properly sheltered, and, if very ill, lying wrapped in a hammock or reclining chair. His bedroom should be well aired at night, draughts being avoided. The room should be uncarpeted and free from hangings. It should be often cleaned and periodically disinfected. All sputum should be collected in paper spit-cups, which should be burned daily. Smoking should be forbidden. Harm is done by any exercise which results in fatigue, and while fever exists it should not be attempted at all. Patients should be taught the necessity of practicing lung gymnastics and breathing only through the nose, which should be kept clear and free from occlusion by secretions, or an hypertrophied catarrhal mucosa. * * * The clothing should be woolen, but not too heavy, or sweating is increased; and a flannel nightgown and loosely knit leggings should be worn at night in cool weather. The skin should be cleansed by daily sponge-baths of lukewarm alcohol and water."—(Thompson's *Practical Medicine*.)

7. In *disinfection of rooms*, use formaldehyde gas; *clothing*, use solution of phenol (5 per cent.) for an hour, then boil for an hour; *hands*, wash in soap and water, then with cresol or carbolic acid solution; *sputum*, use chloride of lime; or better, burn it; *excreta*, should be passed into vessels containing dilute solution of formalin, of greater quantity than the expected excretion; *dishes*, should be boiled.

8. Air suitable for heating should consist of about 21 per cent. of oxygen and about 79 per cent. of nitrogen. The chief impurities of bad air are excess of carbon dioxide, crowd poison, and organic impurities, bacteria, etc. Their effects are: Drowsiness, headache, digestive disturbances, mental dullness, and disease. An individual needs about 3000 cubic feet of air per hour; hence, he should have about 1000 cubic feet of space, with ample ventilation.

9. The best protection against *sunlight* is afforded by some *white* material, the *color* is more important than the texture. Against *cold*, the best fiber is *wool*. The best

her is underclothing is wool, because it is a non-conductor of heat, and is absorbent. For footwear, leather is best; it is warm, and keeps out some moisture; it has also good protective properties, and is durable and pliable.

10. *Ventilation:* "The principal means of ventilation in most houses are the windows, doors, and the artificial openings especially made for the purpose. The occasional opening of doors and the opening of windows greatly assist the exchange of air in ordinary dwellings, with not too many persons in the rooms and with but ordinary illumination and heating. When the number of persons in rooms is large and the number of lights increased, the windows and doors may not be sufficient for adequate ventilation, and special artificial openings may be needed. The number and character of such openings vary in size, location, shape, character, etc. The openings may be in the shape of tubes or boxes placed within the windows, the sashes, the panes, the walls at different points, the ceilings, or the floors. All such openings communicate with the external air, and serve as air inlets, or outlets, and may also be provided with adjustable gates, so that they may be closed up when not wanted. The number of ventilating devices is very large; their value depends on their location and size and character. Where local heating is used within the house, ventilation is aided by the necessary chimney and flue openings, and by the use of grates and stoves. The advantages of mechanical ventilation are the constancy of the exchange of air, the independence from any other means, the perfect control of the velocity and volume of the supplied air, the possibility to accurately regulate the temperature, quantity, moisture, and purity of the incoming air. Mechanical ventilation is, as a rule, carried on from a central point, and is of three kinds: *plenum*, or propulsion method, in which pure air is driven into the house from outside; *vacuum*, or exhaustion method, in which the impure air is withdrawn from the house; and the *combined vacuum and plenum* methods."—(Price's *Hygiene and Public Health.*)

"The principal methods of heating houses and rooms are: 1. Open fires. 2. Stoves. 3. Furnaces. 4. Hot-water pipes. 5. Steam pipes. The method most applicable in any particular case will depend upon the size of the room and the number of rooms in the building. In general, it may be stated that the smaller the space, the more simple the method. For a single room, an open fire or a stove will be sufficient; for a small house, stoves or a furnace; for a large one, one or more furnaces or hot-water or steam apparatus; and for large buildings—office buildings, for instance—'direct' or 'indirect' steam."—(Harrington's *Hygiene.*)

11. *To prevent the spread of disease:* Communicable diseases should be reported to the proper authorities; patient should be isolated when necessary; visitors must be kept out; the patient and his immediate family should be instructed in methods of prophylaxis; there should be proper sanitary supervision of food, milk, water supplies, schools, factories, etc.; proper provision should be made of excreta and sputum; and disinfection should be thoroughly performed.

12. Animals should be inspected before they are killed; meat should be inspected before it is offered for sale; slaughter houses should be public rather than private, and should be often and thoroughly inspected. "There are a number of ways in which dishonest traders often attempt to pass inferior meat on the market, such as: (1) Meat of animals which have died from disease, or from an accident, as by drowning. (2) Meat of animals killed and bled when there is no hope of recovery from illness. (3) Meat of animals which have been the subject of infectious disease, as foot-and-mouth disease, anthrax, etc. (4) Meat of tuberculous cattle, the lungs and pleura being removed. (5) Meat containing encysted parasites. (6) Meat beginning to decompose. (7) Horseflesh to be sold as beef; young goats for lamb."

With regard to *milk*, see above QUESTION 2. Other foods should be free from adulteration, sold in proper weight or quantity, and should generally conform to the standards of purity fixed by law or recognized by custom. The reasons can be summed up as a protection of the public health.

Prophylaxis of Diseases Acquired from Eating Oysters.—Bodin, after examining the various methods which have been advocated for the purification of oysters, recommends the simple and efficient solution suggested by Fabre-Domergue, Inspector of the Fisheries. Oysters are kept for a week or ten days in tanks filled with filtered sea water constantly renewed, where they gradually lose all their septic bacteria. Filtered sea water may be replaced by artificial sea water, and thus Fabre-Domergue's plan may be carried out as well in towns far from the seashore.—*Progrès Médical.*

Medical Items.

The Cause of Death in Pancreatic Necrosis.—Dario Maragliano describes the symptoms of pancreatic necrosis as violent abdominal pain, localized in the epigastrium and followed by vomiting. The pulse becomes small and frequent, and a condition of collapse is reached in from ten to twelve hours from the beginning of the disease, followed by death. The autopsy shows hemorrhagic exudation in the abdomen and a pancreas that is large, friable, and cyanotic. In the peripancreatic fat are found areas of steatonecrosis. The basis of the whole trouble is more or less extensive pancreatic necrosis, the other findings being secondary. This inflammation, followed by necrosis, is not of bacterial origin. The author has made experimental researches as to the causation of pancreatic necrosis in animals, as a result of which he believes that the causation is as follows: Death from pancreatic necrosis is due to a form of poisoning; the poisons are not due to soaps, nor ferments, nor the products of pancreatic autolysis; the poisons must be sought in special toxic substances which develop from the products of the autolysis of the pancreas and the fats of the organism.—*Il Policlinico.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended June 7, 1912.

Place	Date	Cases	Deaths
CHOLERA			
China: Amoy	June 3.		Present
Dutch East Indies: Celebes, Ilam	Mar. 10.	5	2

NEUROSES DEPENDENT UPON ERRORS OF INTERNAL SECRETION OF THE DUCTLESS GLANDS.*

By M. ALLEN STARR, M.D., LL.D.,

NEW YORK.

PROF. OF NEUROLOGY, COLLEGE OF PHYSICIANS AND SURGEONS.

It has been my fortune in the past twenty years to study a considerable number of cases of myxedema and of Basedow's disease, and to observe the effect of treatment of the first condition by thyroid extract and of the second condition by removal of the thyroid gland.

In both of these conditions there are numerous nervous symptoms which are very marked in addition to the characteristic features of the disease. The appearance of similar nervous symptoms in lesser degree, without the characteristic symptoms of either myxedema or Graves' disease, or combined with slight evidences of either of these diseases, has suggested the possibility that in various neuroses there may be an element of functional insufficiency or of hypersecretion in the thyroid gland.

The recent studies of Harvey Cushing in regard to the influence of the pituitary gland not only on the growth of the bones but also on carbohydrate metabolism and on the nervous system and the presence of nervous symptoms in diseases of the pituitary gland have suggested a similar hypothesis with regard to the influence of this gland in the production of certain neuroses. We know† that after thyroidectomy the pituitary gland enlarges and its colloid secretion from the anterior lobe is increased, hence it compensates for the loss of the thyroid. The effect of its secretion cannot therefore be very different from that of the thyroid gland.

The very marked neurotic manifestations which occur at the menopause or which occur after the removal of the ovaries and which are undoubtedly due to the inactivity of these ductless glands affords another line of argument for the marked influence of a lack of secretion of a ductless gland in the production of nervous disease.

Considerable experience derived from these four lines of study, together with its application in the treatment of some neuroses by means of glandular extracts, has made it seem worth while at the present time to collect the data and present them to the consideration of this society. I shall deal with the four conditions considered in turn.

I.—NEUROTIC SYMPTOMS SUGGESTIVE OF MYXEDEMA, AND CURABLE BY THYROID EXTRACT.

a. *Mental Symptoms.*—In a well-marked myxedematous condition it is well known that the patients are extremely depressed in their minds almost to the verge of melancholy although they have none of the self-accusation and despair characteristic of a true melancholia. They are extremely sluggish in their thought, unable to remember recent events, indifferent to their surroundings, lacking any interest in their personal and family or business affairs, and present in a slight degree the general characteristics of dementia. They take an unfavorable view of their own condition. They have no hope of recovery. They have no desire to make an effort to recover. Their will power appears to be impaired. There is not only a physical weakness which renders them averse to any effort, but there is also a mental inertia which leads to an undue sense of fatigue on slight mental or physical exertion. The powers of perception are all dulled and hence the interest in things about them is impaired. They are inclined to be sleepy and often sleep heavily both day and night, but awake without any sense of refreshment or invigoration.

b. *Physical Symptoms.*—These are even more marked than the mental symptoms. There is a peculiar dryness of the skin and of the hair even when there is no myxedematous thickening of the subcutaneous tissue. The skin does not perspire, it is rough and scaly, sometimes presenting an appearance as if recently powdered, especially on the arms and legs. It becomes pigmented so that the hands look dirty, though washing does not clean them. The scalp is particularly liable to show a white dandruff. The hair falls or becomes gray and is wholly lacking in the natural oil. In some cases an abnormal growth of hair appears especially in women, in front of the ear and possibly on the face. On the other hand in the axillæ and upon the pubis the hair is liable to come out.

The surface of the body is uniformly cold, the hands and feet are constantly cold, and the patient feels a shivery sensation down the back and all over the body on any exposure to draught or to cold in a way which was different from his or her normal state. This sensation of cold may be attended by a depression by a half or one degree of temperature of the body.

The appetite and digestion are always impaired. Assimilation is imperfect and constipation is the rule. There is very often a swelling of the mucous membrane of the nose and of the throat which is visible which has led to the supposition that a similar condition is present in the stomach and intestines. It has been ascertained that there is a direct interference with the calcium metabolism so that the elements which normally lead to a proper clotting of the blood are absent. The progressive gain in weight in many of these patients is suggestive also of a change in the carbohydrate metabolism such as is known to occur in disease of the pituitary gland though this has not yet been investigated.

Now in many cases of socalled neurasthenia and

*Read at a meeting of the Practitioners' Society, held February 2, 1912.

†Rogowitch: Ziegler's Beiträge zur path. anat. iv, 453.

nervous exhaustion with depression of spirits and sluggish mentality, some or all of the physical symptoms above-mentioned are occasionally found to be present.

It has been noted in cases of myxedema that a very common complaint is severe and more or less constant pain in the muscles and in the bones. Ordinary rheumatic remedies have no effect upon this pain and it is only when the patient recovers from his myxedema, under thyroid treatment, that these pains disappear. It has been noted by Levi and Rothschild* that in a great many cases of chronic arthritis and of chronic muscular rheumatism, thyroid treatment is more efficacious than any other method. Under it the hard deposits about the joints are absorbed and the muscular pains cease. It seems reasonable to suppose, therefore, that the error of metabolism consequent upon a lack of thyroid secretion may be responsible for a pseudorheumatic condition present in many persons.

Many neurasthenics are habitually complaining of sensations of cold, of nervous chills, and are found to have cold hands and feet, to lack in perspiration, to have many irregular muscular pains in the muscles and bones, to have a great sense of physical exhaustion in addition to the mental inertia. These symptoms of exhaustion are, however, not attended by any objective signs of heart weakness, though tests demonstrate the rapid onset of fatigue if measured by the dynamometer or the ergograph.

In this class of neurotic individuals I have found by experience that the ordinary treatment for neurasthenia by hydrotherapy, rest, diet, and nerve tonics, is very much aided by the addition of small amounts of thyroid extract to the patient's food. It is not necessary to give more than one grain twice or three times a day, and it is wise to keep watch of the weight of the patient, and if it is found that a loss of weight occurs, it is wise to reduce the dose of thyroid, but very many patients can take as high as 2½ grains of thyroid extract twice a day, not only with a relief of these various symptoms, but also with a marked gain in weight. The thyroid is best given with the meals or if it is preferred it may be given in a single dose at night on retiring. The effect should be evident in about 10 days in a lessening of the dryness of the skin, in a relief from the sensation of cold, and in a decided improvement in the mental activity. It may then be omitted for a week, but resumed, and thus continued with intervals.

I may mention here also a class of cases of mental sluggishness in young girls with symptoms that some might class as belonging to dementia precox. In two such cases I have seen very marked and continued improvement, after the use of thyroid extract, and these cases at the end of the second year are enjoying a fair degree of mental health and activity, when formerly they were considered as incurable cases of weak mindedness. In neither of these cases were the symptoms sufficiently marked to warrant the diagnosis of myxedema, but in both of them the dry scaly skin, the dryness of the hair, and the continued coldness of the body suggested the propriety of the trial of thyroid extract.

II.—Neurotic Symptoms of Basedow's Disease.

As it is generally admitted that this affection is due to an excessive secretion of the thyroid gland, it is to be expected that the nervous symptoms present are exactly the converse of those already studied. The nervous excitability, the very active mentality, the tremor, the muscular irritability, and the quickness of thought in Basedow's disease are generally recognized.

It is perhaps not generally known that in a number of cases of Basedow's disease the nervous and mental excitement may go on to a state of active mania. I have had one such patient in whom the maniacal symptoms lasted seven months but finally subsided during the remission of the active symptoms of Basedow's disease. All writers on Basedow's disease admit the possibility of maniacal occurrences.

It is not to these cases, however, that I wish to call particular attention, nor to the nervous symptoms present in Basedow's disease. But what I wish to emphasize is the fact that an excessive function of the thyroid gland, not sufficient to produce exophthalmos or goiter, or a very rapid pulse, may nevertheless produce symptoms of a nervous character complicating a neurasthenia.

Certain neurasthenics are extremely restless. They cannot keep quiet, must be in active movement and declare that it is impossible for them to lie down or to rest. They are active mentally as well as physically. They are unable to keep their minds upon any one subject for any length of time, but nevertheless are sufficiently active mentally to keep them busy on many subjects. They are usually anxious about their own condition. They realize that the train of thought is unusual and abnormal and they fear insanity. The physical symptoms in this condition are usually a sense of heat in the body, a desire for cool air and fresh air which prevents them from going to theaters or churches or remaining in hot rooms. A burning sensation of the body which leads them to sleep with exceedingly light bed-clothing, and very frequently leads to excessive perspiration.

The appearance of these patients is more or less characteristic. Their eyes are bright, their skin is shiny and moist, the hair is also moist and glossy, and they are usually thin. There is often a tremor about the hands, and an exaggeration of the knee jerks. They are subject to abnormal sensations of hunger. They are not satisfied after a meal and have a craving for food within two hours of a meal. They are subject to diarrhea and in women the menses are excessive. They sleep badly, wake easily, are hypersensitive to sounds and very often complain of sudden flashes of heat. The pulse is very often more rapid than normal, running between 80 and 90.

When these conditions are present in a case of neurasthenia, it awakens a suspicion that there is an excess of secretion of the thyroid gland. Thyroid secretion may be modified by the use of belladonna or of hydrastis. In extreme cases rodagen or thyrodectin, which appear to decrease the secretion of this gland, may be employed. All these remedies given in conjunction with the treatment for a neurasthenic condition are often of more benefit than other forms of treatment. Ergot and bromide may also be employed and in some cases the application of ice to the thyroid gland for half an hour three or four times a day will be found to diminish its activity. These cases are never severe enough at the outset to warrant surgical removal of the thyroid gland, and many of them never go on to develop a true Basedow's disease.

*Nouvelles Etudes sur la physiopathologie du corps thyroide. O. Doin, Paris, 1911.

III.—Neurotic Symptoms Dependent Upon Errors in the Pituitary Secretion.

The researches of Harvey Cushing have proven that certain disorders may be due to either a defective secretion of the pituitary gland or to a hypersecretion of this gland. But inasmuch as the symptoms of these two probably separate conditions are often intermingled, he prefers to term the condition dyspituitarism.

In the extreme cases as in myxedema, the symptoms are so marked as not to be easily mistaken. They consist of the phenomena known as gigantism or acromegaly on the one side and on the other side a condition of very great increase in the fat of the body, a craving for sweets with a disturbance in the carbohydrate metabolism with subnormal temperature, slow pulse, dry skin, loss of hair, rather suggestive of myxedema. In some cases this latter condition develops without any increase in the growth of the bones.

Sexual infantilism is a marked symptom of this state, a complete lack of sexual desire and impotence, and along with it there are certain characteristic mental changes which lead to a peculiar psychical condition, a lack of ambition, an indifference to matters of importance, an inability to do ordinary work to which the individual is accustomed, and a state of mind which is suggestive of a form of intoxication not unlike the indifference which one sees in the chronic opium habitué.

While these extreme forms are easily recognized it is not at all unlikely that very many conditions developing in so-called neurasthenics have their origin in the disturbance in the functions of this gland. The metabolism in neurasthenia has not been sufficiently studied, but every clinician will recognize the fact that there is a certain type of neurasthenic who is abnormally fat, who is constantly gaining in weight, and suffers from a marked lack of ambition together with many other neurasthenic symptoms. These patients have the abnormal craving for sweets already mentioned, and it seems not at all unlikely, although I have no proof to bring forward, that some of the nervous manifestations may have their origin in an error of the secretion of the pituitary body. In two or three such cases with marked headache, although there has been no indication of atrophy of the optic nerve or of the hemianopsia which are present in extreme cases, a marked improvement has occurred after the use of pituitary extract and many of the nervous symptoms have subsided coincidentally with the improvement. It is also possible in these cases to improve the symptoms by the use of thyroid extract, which, as we have already seen, is not unlike the pituitary extract in its effects. The doses in these cases should be small—not more than 1 or 2 grains a day for ten days, then an intermission of five days. Under its use many of the symptoms subside.

IV.—Neuroses Connected with Ovarian Atrophy.

The neurosis of the menopause is a well marked and well recognized condition. It partakes of many of the characteristics of hysteria and of neurasthenia, both mental and physical symptoms occurring in great variety. The mental irritability is perhaps the most distressing symptom. The sense of apprehension, the inabilty to control the temper, the nervous restlessness leading to all sorts of foolish undertakings never carried to completion, states of depression amounting at times to suicidal impulses, defects of judgment and memory, and a marked lack of self-control, are symptoms which are familiar to the general practitioner and which in despair of relief he is prone to refer to the specialist.

The physical symptoms are equally marked. Intense headache, especially pain in the back of the head and in the neck, sudden flushing of the surface with the sense of heat and general swelling of the tissues, leading to a tightness of the rings and clothing, a sensation of pressure in the head, irregularities of digestion and irritability of the bladder with general indefinite pains throughout the muscles, are all symptoms that will be recognized.

These symptoms seem to be periodically increased every month at a time coincident with what should be the normal period, but are more or less present all the time for two years after the suppression of the function of the ovary. Inasmuch as these symptoms also appear when ovaries are surgically removed at any period of life, it is evident that they are due either to the suppression of an internal secretion or else to an excessive activity, in other glands, especially the thyroid which is known to have a complementary relation to the ovary. In fact, many of the symptoms appearing at the menopause are suggestive of a hypersecretion of the thyroid gland, as they are similar to symptoms occurring in Basedow's disease, but they are not wholly due to such a hypersecretion, as is proven by the fact that the administration of lutein or of ovarian extracts to these patients causes a marked improvement. The mutual interaction of the thyroid gland and the ovaries is demonstrated by the swelling of the thyroid on the first day of menstruation, by its swelling during the first weeks of married life and by its swelling during pregnancy. It would seem function there may be either a compensatory hyperemia is attended by a similar condition of the thyroid. When the ovaries cease to perform their function there may be either a compensatory hypersecretion of the thyroid leading to the sense of heat, the flushes, the rapid pulse, and the mental irritation, or there may be a cessation of its function leading to an accumulation of fat, a sluggish state of metabolism, and a depression and partial dementia. These conditions, then, can be met to some extent by treatment; the first by the use of lutein continuously given for many weeks, the latter by the use of thyroid extract in small doses for a long period of time.

I have called attention to these varying conditions of neurosis because it seems to me that in too many cases we are satisfied by the diagnosis of neurasthenia, although every clinician will admit that there are very few so-called diseases which present so many clinical varieties, and acquire such careful analysis to reach their etiology.

RICE IN THE DIETARY OF THE DIABETIC

By HEINRICH STERN, M.D.,

NEW YORK.

Sooner or later the economy of every diabetic requires some starchy material. This carbohydrate must be metabolizable to a certain degree and should not unduly activate a dormant or intensify an existing glycosuria. At the same time it should exhibit antiacetonemic qualities.

In the milder forms of diabetes practically all starches are tolerated in amounts of from 50 to 100 or more grams per day. Here the ingestion of from three to six of the usual slices of wheaten or rye

bread is either not followed by any sugar excretion at all or gives rise to an insignificant glycosuria only. For these mild cases of diabetes the question of nourishment in general and of carbohydrates in particular virtually resolves itself into the determination of the tolerance for "the staff of life" itself, because wheat and rye are as well tolerated in these cases as are the other nutriments rich in carbohydrate.

In the graver types of diabetes, on the other hand, the problem of nutrition is fraught with many difficulties. It is a continuous navigating between the Scylla of the proteids and the Charybdis of the carbohydrates. Most clinical pilots have taken to the apparently safer side of the carbohydrate Charybdis and prescribe the oat cure of v. Noorden for their grave cases of diabetes. It almost seems that the antiquated notion that a cure must be disgusting to be effective is still alive. Why must it be exclusively oats by which starch is to be introduced into the diabetic organism, and why must it be first brought into the form of v. Noorden's hotch potch? Let me reiterate what I said about the latter eight years ago[1]; "the oat cure is not only disgusting to the patient, but also does not uphold the claims of its author. Oats, in my experience, are not any better tolerated by the diabetic exhibiting acetonemia than other amyloid substances, as buckwheat or rice. Again, the very large amount of butter, 250 to 300 grams daily, which is to be incorporated into the oat groats contradicts the rationale of acidosis therapy. Half a pound of butter or more ingested daily is certainly apt to yield large quantities of acetone bodies in the diabetic; as a matter of fact, I have seen a case (numerous cases now after eight years) in which the intensity of the acetonuria had not only not diminished, but had been appreciably augmented after restriction to the oats-fat-albumin compound for some days. In his oat cure, v. Noorden (who himself has shown that the ingestion of more than 150 grams of unwashed and of more than 180 grams or 200 grams of washed butter—by the washing process butter loses its low fatty acids—is liable to be followed by an increased production of acetone bodies) orders the addition of from 250 to 300 grams of butter." A fat substance composed of fatty acids of high molecular weight would certainly be a more rational addition to the oats than the butter with its valerianic, butyric, and caproic acids, the mother substances of the acetone bodies.

A good deal has been written during the last few years about the oat diet in diabetes. Most of it is of little or no value because it is either based upon insufficient or superficial observation or it is a rehash of v. Noorden's own or inspired statements. A number of theories have been advanced to explain its particular advantages in diabetes, for it was thought in the beginning that it exhibited specific properties which other cereals did not possess. Blum, however, showed last year that there exists no characteristic difference between oats and wheaten flour so far as their value in the economy of the diabetic is concerned. Magnus-Levy[2] even declares that he has not found any marked discrepancy between the two cereals in the milder types of diabetes.

It is not my intention to dwell on this occasion upon the various hypotheses which have been advanced to explain the alleged superiority of oats over all other carbohydrates in the antidiabetic regimen. I merely wish to draw attention to one point connected with the oat ingestion which, it is my opinion, accounts for its mysterious beneficial qualities. In the first instance, v. Noorden does not speak of oatmeal at all, and whenever we find the word "oatmeal" in connection with the specific oat cure it is simply due to negligence of the translator. v. Noorden invariably refers to "Hafergrütze" and not to "Hafermehl," that is, he means groats or grits and not oatmeal. Certain brands of so-called oatmeal on the market may indeed more or less resemble groats, denoting hulled and crushed oats, or grits, signifying the hulled or granulated cereal, but the fact must not be lost sight of that groats or grits is one thing and oatmeal, which is the meal of oats, another. Oats are very rich in cellulose, but while from 7 to 9 or even 10 per cent. of this material is contained in the dried cereal, it occurs in only one-third of this amount in the finest oatmeal. Granted even that the expression "oatmeal," as popularly employed, comprises not only the meal of oats, but also other oat preparations as groats and grits, we find that the oat foods fit for human consumption contain on the average 3.5 per cent. of cellulose. This is just seven times as much as is found in ordinary rice and forty times as much as in rice flour.

It is this high cellulose content of the oats to which must be ascribed an eventual decline of the glycosuric symptom. In this respect the oats do not behave differently from any other food rich in cellulose. The integument of the oats, composed to the greater part of cellulose, firmly adheres to the kernel of the seed and can never be completely separated from it. For this reason the oat carbohydrate offers more or less resistance to the influence of the digestive juices, remains in the intestinal tract for a comparatively long time, and is but slowly and incompletely absorbed, while one portion undergoes certain fermentative changes and another portion, but little altered, finds its way directly into the feces. Again, large amounts of groats, as advocated by v. Noorden, exhaust the activity of the special organs concerned in the elaboration and absorption of the nutritive principles[3]; as a rule, the quantity of nutriment ready for absorption becomes smaller after a day or two as evidenced by the increased fecal matter, and digestive disturbances are liable to occur soon after the beginning of the oat regimen. It is a self-deception of a clinician when he assumes that the impaired economy in grave diabetes is able to derive more nourishment from the carbohydrate of oats than from that of other cereals; he soon will be disillusionized when he observes the bulky and frequent stools of the oat diet with their large content of cellulose and unabsorbed starch.

We know from clinical experience that the ingestion of one single type of carbohydrate may at times be followed by a temporary improvement of certain cases of grave and far-advanced diabetes. In other words, if in a severe case of diabetes the carbohydrate intake is limited to one specific cereal it may be better tolerated by the patient than if a number of carbohydrates be given at the same time. An eventual improvement accruing from the ingestion of a single type carbohydrate is not enduring by any means; it makes itself noticeable by an increase of the patient's strength and weight, by a decrease of the glycosuria, and a decline or disappearance of the excretion of acetone bodies.

I have employed the common rice, *Oryza sativa*, in the treatment of diabetes, more particularly for the suppression of diabetic acetonuria, for some years; systematic studies of rice with a view to de-

Explanatory Note concerning the Acetone Bodies: 0=absence; 1=small quantity; 2=medium quantity; 3=large quantity.

termine its value as a single-type carbohydrate in the antidiabetic dietary were, however, not undertaken by me until about sixteen months ago. During this period I had occasion to employ rice in nineteen cases of moderately severe and grave cases of diabetes, and in a much larger number of milder types of the affection.

In the following I delineate some of the characteristics of rice, which, as is commonly known, is one of the most valuable and largely cultivated cereals, furnishing the principal means of subsistence of nearly one-third of mankind. The composition of rice is as follows:

Nitrogenous matter........	8	per cent.
Fatty matter.............	1	" "
Carbohydrates	78	" "
Cellulose	0.5	" "
Mineral matter...........	0.9	" "

Compared with other grains rice is poor in protein, fats, and mineral matters. It is preeminently a farinaceous food; alone it cannot be considered a complete aliment unless it be taken in amounts entirely too large for a civilized digestive tract. It must hence be combined with nitrogenous and fatty substances and certain salts, probably of potassium and phosphorus, but at any rate with such mineral matter as is ordinarily furnished by fresh green vegetables.*

The principal characteristic of rice is not so much its very large proportion of starch, but the small-

*The "polishing" of the rice, *i.e.* the removal of the inner cuticle, deprives the grain of an important nutritive component, an organic base which is completely precipitated by phosphotungstic acid and by silver nitrate and baryta (Funk: "The Chemical Nature of the Substance Which Cures Polyneuritis in Birds Induced by a Diet of Polished Rice," *Jour. Physiol.*, 1911, p. 395.)

ness of the individual starch granules which, according to Pavy, form exceedingly minute, irregularly shaped, angular particles. The starch granule of rice is more readily digestible than the starch granule of any other cereal; it is quickly converted by the digestive juices, and practically entirely utilized by the normal individual. The very small amount of cellulose carried by rice does not impede the latter's absorption; in fact, the microscopic examination of the feces hardly ever reveals the presence of some rice-cellulose, which means that the latter itself must have been converted and prepared for absorption. On account of the meager or entirely absent residue in the colon following the intake of rice, it is the least irritating of any cereal. In truth, rice is better borne by a sensitive or diseased intestine than any other solid food.

In the beginning I employed rice only in such cases of diabetes with which was associated some form of renal disease. As rice contains but the sixth part of potassium that is found in the cereals of the northern zone, its ingestion is followed by a diminished desire of the organism for sodium chloride. For this reason the kidneys are relieved of unnecessary excretory work.

Rice may, of course, be partaken of by the individual with mild diabetes in suitable amounts and any form, provided it be prepared without sugar; as a matter of fact, I have made my tolerance determinations for over a year with rice exclusively. Rice furnishes a better standard than bread on account of its stable content of starch; the starch content of bread may and does change with every fresh baking. A rice dish must be especially prepared for each meal with a designated quantity of rice; when the patient has finished it he cannot readily obtain a new supply. On the other hand, the loaf of bread is always within easy reach; the diabetic is only too apt to yield to temptation and to overstep the dietary boundaries set for him. Again, many diabetics, even those affected with the lighter forms, suffer from gastrointestinal disturbances and starch indigestion; for these there is but one carbohydrate, with the possible exception of milk, namely, rice.

A description of the determination of carbohydrate tolerance by rice and the details of a rice diet in the general run of cases of diabetes I reserve for a subsequent article. On this occasion I wish to bring in tabular form the abbreviated records of nineteen cases of moderately severe or grave diabetes while they were on rice as the exclusive carbohydrate, and to summarize the results of my observations concerning the advantages of rice over other cereals when utilized as a single-type carbohydrate in the management of the severer forms of the diabetice process.

From a study of the foregoing the following conclusions may be drawn:

1.—Rice, *i.e.* the "polished" product of commerce, furnishes substantially nothing to the organism besides an easy digestible starch. Given in suitable amounts this starch is practically all absorbable and ready to serve as a calorifacient.

2.—The commercial cereal is therefore peculiarly adapted to supply carbohydrates without any portein or mineral admixture of consequence.

3.—This deficiency of protein and mineral substances makes rice an indifferent food so far as the formation of toxic protein products and useless or impossible pancreatic, cardiac, and renal activities are concerned.

4.—The mineral and protein deficiency of rice facilitates the reduction of salts and the calculation of absorbable albumin necessary at every stage of the diabetic affection. (The elaboration of proteins from cereals and leguminous seeds by the healthy organism is mostly incomplete; it is impossible, or nearly so, in every case of advanced diabetes.)

5.—Rice, being nearly entirely absorbable, only a comparatively small quantity of it is needed by the diabetic organism; it is not the purpose of the rice to supply the total food requirement as does v. Noorden's standard oat-diet; the cereal may be incorporated with any properly adjusted protein-fat combination.

6.—Contrary to the oat diet, rice as a single form of carbohydrate and in suitable combination may be employed by the diabetic for more protracted periods; it may be prepared in a number of different ways and forms that prevent monotony and always furnish a palatable dish for the patient.

7.—Sixty grams of the absorbable starch granule of rice generally produce the antiacetonemic effect of 250 grams of the but partly absorbable oats in the standard admixture.

8.—Pronounced cases of acidosis are frequently suppressed by the ingestion of 100 grams of rice.

9.—The amount of rice requisite to depress the acetonuria does not necessarily increase the intensity of the glycosuria. In a large number of cases the glycosuria will even temporarily decline in a marked degree.

10.—The modus operandi of rice is different from that of cereals rich in cellulose. Practically all the rice is absorbed and a certain amount is assimilated by the diabetic (this is evinced by the frequent increase in weight and vigor of the patient and the diminished glycosuria and acidosis), while material rich in cellulose, no matter how much albumin and fat may have been added to it, furnishes in effect nothing more than a starvation diet.

THE OZENA INVESTIGATION IN THE UNITED STATES.*

BY EMIL MAYER, M.D.,

NEW YORK,

CHAIRMAN OF THE COMMITTEE.

AT the meeting of the Second International Laryngological Congress held in Berlin in 1911 it was unanimously resolved that a collective investigation of a statistical nature should be held on ozena and that this investigation should embrace the whole civilized world. A general committee, composed of Professor Grabauer, Professor Rosenberg, and Prof. A. Alexander, all of Berlin, was appointed to institute the same and report its findings at the next International Laryngological Congress in Copenhagen in 1914.

*Presented to the Thirty-fourth Annual Congress of the American Laryngological Association at Atlantic City, May 11, 1912.

This committee at once undertook the herculean task of appointing a chairman for each of the various countries, appealing for the financial aid such an investigation requires, notifying the profession at large of their existence and purpose as also the general public through the press, and finally requesting permission of their government to make the needed examination of school children and inmates of homes, asylums, reformatories, and prisons.

At the request of this committee and at the earnest solicitation of one of our members, the writer agreed to assume charge of the investigation for the United States, so far as our complete lack of means for this purpose would permit. This latter statement was quite essential as the idea seemed to have gone forth that we had but to mention the character of the disease which we wished to investigate, when ample funds from some of our philanthropic multimillionaires would not only be forthcoming for our own needs, but some might even drift the way of the general committee. With a clear knowledge then on their part, of an absence of any funds or our ability to gather the same, the appointment was accepted. The chairman at once formed an executive committee after conferring with the officers of our three large laryngological associations. This executive committee consists of Dr. Joseph W. Gleitsmann, Dr. Robert C. Myles, Dr. Harmon Smith, representing the American Laryngological Association; Dr. Thomas J. Harris, Dr. Wolff Freudenthal, Dr. H. Holbrook Curtis, representing the American Laryngological, Rhinological, and Otological Society, and Dr. Sidney Yankauer representing the American Academy of Ophthalmology and Oto-Laryngology.

The first meeting of this committee was held on March 9 and it was resolved that for the purpose of this investigation the term "ozena" is meant to indicate a disease of the nasal interior, beginning, as a rule, in childhood, which is characterized by degeneration of the nasal mucous membrane and bony atrophy without ulceration, and which in its further course gives rise to a disagreeable odor perceptible at a distance. A second classification was made to be known as "ozena suspects," that is, those having the same conditions without odor where some other member of the family has the same condition.

From the lists of membership of our American Associations this committee selected the names of those who were to be invited to assume charge of the investigation for the various States of the Union, and up to the present time the following men have accepted and their names appear with the name of the State for which they act as chairman: Dr. J. H. Allen, Portland, Me.; Dr. H. L. Swain, New Haven, Conn.; Dr. W. B. Johnson, Paterson, N. J.; Dr. G. B. Wood, Philadelphia, Pa.; Dr. C. W. Richardson, Washington, D. C.; Dr. S. R. Rosenheim, Baltimore, Md.; Dr. D. A. Kuyk, Richmond, Va.; Dr. W. B. Goff, Clarksburg, W. Va.; Dr. H. H. Briggs, Asheville, N. C.; Dr. E. F. Parker, Charleston, S. C.; Dr. Dunbar Roy, Atlanta, Ga.; Dr. Richmond McKinney, Memphis, Tenn.; Dr. Otto Joachim, New Orleans, La.; Dr. J. O. McReynolds, Dallas, Texas; Dr. H. B. Hitz, Milwaukee, Wis.; Dr. W. L. Ballinger, Chicago, Ill.; Dr. J. F. Barnhill, Indianapolis, Ind.; Dr. H. B. Lemere, Omaha, Neb.; Dr. L. W. Dean, Iowa City, Ia.; Dr. James E. Logan, Kansas City, Mo.; Dr. Robert Levy, Denver, Col.; Dr. J. N. Ingersoll, Cleveland, Ohio; Dr. B. R. Shurly, Detroit, Mich.; Dr. J. B. Parsons, Sioux Falls, S. D.; Dr. A. M. MacWhinnie, Seattle, Wash.; Dr. C. A. Thigpen, Montgomery, Ala.; Dr. John McCoy, New York City, N. Y.; Dr. John A. Donovan, Butte, Mont.; Dr. Hill Hastings, Los Angeles, Cal.; Dr. Frederick C. Cobb, Boston, Mass.

Each chairman is privileged to appoint as many assistants as he desires; is to inform the profession of the purposes of the investigation, to secure the examination of school children, inmates of asylums, homes, and public institutions, to supervise the collection of the histories of cases thus obtained, and in some appropriate way to have the general public notified of the investigation and its purport.

For the prompt acceptance of the onerous duties, the committee expresses its thanks and its gratification at the feeling of loyalty shown. The chairman was also authorized to confer with the Surgeon-General of the Public Health and Marine Hospital Service in order to secure the valuable cooperation of that body. The reply of the Surgeon-General states that "it is the purpose of the bureau to keep in touch with and to assist in so far as practicable in those investigations and measures relating to public health subjects. Limitations of our force and the stress of other work connected with investigations which must be carried on have to be borne in mind in considering any new movements, but I should be pleased to meet with you should my duties take me to New York in the near future." Replying to this, the chairman sent a letter to the Surgeon-General asking for such valuable assistance as his department could give in making this investigation and promising him the cooperation of the chairmen of the various States already appointed by this committee. No answer to this has, as yet, been received, but in view of the fact that it is part of the duty of the Public Health and Marine-Hospital Service to take up such investigations, the writer feels that we may in some way still be able to secure the needed cooperation.

The General Committee in Berlin has, in addition to securing permission from the authorities to examine all children in the schools, established an ozena clinic in the larger cities so that once a week cases of ozena assemble at this chosen place and several rhinologists agree to be present to confirm the diagnosis and note the development of these cases.

We are to ascertain the number of cases of ozena existing in the United States, whether ozena occurs in the native born or among foreigners, and the relative frequency of the same, also whether it is at all common among the negroes. It has been deemed advisable to have a rather complete history taken of ozena occurring in children and for this purpose a history blank has been prepared by the General Committee, as follows:

1. Full name. Sex. Religion. Age. Date of birth. Residence. City and country. School. Class. Place of birth. Nationality. How long in the United States. (If foreign) Birthplace of parents. Occupation.

2. History. How long does the nose condition exist? Was there any ophthalmia? When? Diseased conditions directly after birth? Dis-

cases of childhood, especially infectious diseases? Was the child breast or bottle fed? General condition of the residence, size, cleanliness, etc.? Nutritive conditions of the family and child, clothing, care of body and teeth?

3. General bodily conditions. General appearance, size, development, form of chest. Conditions of the circulation, respiration (if tuberculosis is suspected), nervous system. Condition of bones (rachitis, tuberculosis of bones). Skin, eczema, etc. Constitutional conditions, especially syphilis. Glandular infiltration, otitis, etc. Enlarged thyroids. Examination of the urine, blood, secretion of the nose. Wassermann reaction.

4. Local conditions. Examination of the nose, both sides, space, appearance of turbinates, of the mucous membrane of the septum, sensibility of the nasal mucosa, sense of smell, crusts, intensity of the odor before and after removal of crusts. External nose, appearance of the skin, superior maxilla, hard palate, teeth, pharynx, appearance of the mucous membrane, pharyngeal and lingual tonsils. Naso-pharynx, condition of the mucous membrane, adenoid, larynx and trachea. Photograph, full and profile, measurements of the skull, length of the septum.

5. Complications on the part of the lachrymal canal and the middle ear, accessory sinuses. Special examinations, transillumination. Roentgen rays photograph.

6. Hereditary or infectious. Patient is the (fourth, fifth, etc.) child, with -- brothers and sisters, of whom — are living. Patient is an only child. Diseases and causes of death of parents or brothers and sisters. Have children occupied the same bed and up to what time?

If death should occur in an ozena subject autopsy is to be held.

With the cooperation of the rhinologists who have so graciously accepted, and that of the Public Health and Marine-Hospital Service of our Government, which we hope to interest in our behalf, the writer earnestly hopes that the final report made two years hence from the United States will in no way be behind that of other countries.

40 East Forty-first Street.

MEDICAL STUDIES OF THE ALCOHOLIC PROBLEM.

By T. D. CROTHERS, M.D.,
HARTFORD, CONN.,
SUPERINTENDENT WALNUT LODGE HOSPITAL.

Every study of the causes of degenerations and diseases indicates that the use of alcohol is very common as an exciting and predisposing factor. Like syphilis its injurious effects are persistent and cumulative, breaking out in new and most unexpected ways. Thus an attack of excessive drinking in early life, followed by abstinence or a so-called moderate use of spirits extending over years, seems to leave some entailment and degeneration that is traceable in the present conditions calling for relief. There is clearly a relation of cause and effect that extends back, often obscure, at other times clear and traceable. Forms of neuroses and psychoneuroses with epilepsies and degrees of dementia, perversions, lapses, and marked deviations from health, seem to originate in the use of alcohol. Nutrient disturbances and derangement of the circulatory organs have a similar origin.

Modern authors assert with great emphasis that both alcohol and syphilis are the most prominent causes of a great variety of diseases and degenerations that appear later in life. They are very often associated, and a study of their effects explain conditions that are obscure. Modern laboratory research of the effects of alcohol on cell and tissue bring striking confirmation to these clinical observations. The chemical, pathological, and psychological action of alcohol on protoplasm and tissue reveal startling changes which in all probability extend to all parts of the body and attain a degree of permanence. The anesthetic action of alcohol not only lowers the activity of cell and tissue, but perverts it, and whether restoration ever occurs in the fullest sense is uncertain. Control experiments on animals show erosion and corrosion and other changes from the use of alcohol that are permanent. Assuming that the action is the same in the human body, much of the obscurity of symptoms which follow the use of spirits is cleared up. Chemical studies show that alcohol not only breaks down cell and tissue, but encourages the formation of toxins that in themselves are destructive and produce conditions of degeneration largely unknown and yet to be studied.

One conclusion drawn from a great mass of literature, based on laboratory and clinical observations, is that alcohol is a protoplasmic poison, the effects of which are persistent and cumulative, and that alcohol may rouse latent degenerations, stimulate new growths, and increase germ diseases and morbid germ activity. Previous theories that alcohol possesses food, tonic, and stimulant properties are unsupported by modern studies, and these delusive effects are found to be due to its anesthetic and narcotic action. Outside of tradition and personal opinions, the one fact that alcohol is a poison in any form, as manifested by its action on the sensory centers, is established beyond question. Examination of the causes of the evil influences and degenerations, both psychical and physical, which confront civilization of to-day, indicates fields of prevention and possibilities of stamping out the above conditions permanently by removing the causes. Typhoid fever, yellow fever, consumption, diphtheria, smallpox, and many other diseases are in this manner controlled and prevented with startling certainty. In view of these facts, why should the evils from alcohol be tolerated when they can be eradicated by the practical use of means and measures? This fact has grown into a public consciousness and is evident in the tremendous efforts of laymen and reformers to suppress and break up the evils which follow from the use of alcohol.

The assertion that alcohol and its injurious effects far exceed those of any epidemic or contagious disease known is sustained by evidence that cannot be disputed, evidence that is available in almost every family, town, and city of the country. These are evils that appeal to every consideration of health, life, and prosperity, yet, strange to say, notwithstanding the tremendous efforts to understand and control this evil, the theory of moral causation of vice, the theories of weak will and vicious neglect, are in reality the basis of all these efforts. The members of the medical profession, to whom the subject rightly belongs, and who of all others are most competent to study its causes and remedies, practically take no part in the various efforts to understand the means of prevention. The great leaders in medicine over a century ago affirmed that the alcoholic problem was one of disease and not a

question of morals and ethics. In 1870 a small society of medical men was organized in New York City, who declared that alcohol was a poison and inebriety was a disease and curable. This was the first organized society of physicians in the world to take up the study of alcohol. It was called the American Society for the Study of Inebriety. Twenty years later another society was organized called the American Medical Temperance Association, having about the same purpose and plan with the exception of making alcohol the central object of study and educating the public concerning it. In 1903 both of these societies united under the name of The American Society for the Study of Alcohol and Other Narcotics. In 1870 it issued a journal as its organ which has been published up to the present time. In 1884 an English society was formed, called the British Society for the Study of Inebriety. From that time a number of societies, having the same purpose and object and composed entirely of physicians, have been organized in France, Germany, and Switzerland. These societies hold frequent meetings for the discussion of alcohol and its effects and the means of prevention, and educating the public. Within the last ten years these societies have increased, and there are now over a dozen medical organizations in the world with this object. So far they have ranged into two classes. The American and the British Society have taken up the study of the conditions and causes which provoke and precede the use of alcohol and the questions of heredity and predisposing factors that culminate in the excessive craze for spirits and drugs. The German and French Societies, representing a second class, seem to confine their studies to alcohol and its physiological and pathological effects on cell and tissue. The distinct purpose which they have is to convince the public of the danger of alcohol as a beverage and also as a medicine. A society in London called the Medical Temperance Association, which grew out of the researches of the late Dr. Richardson, has presented some very startling sociological and hygienic studies on the effects of alcohol.

Some of the German societies give very exhaustive studies from laboratory works on the chemical and physiological action of alcohol. For originality and accuracy of research they have done most valuable work along this line and have practically changed the conception and traditional theories of the past. This work has attracted an immense amount of attention and has furnished a basis of a great variety of literature which reformers and philanthropists press on public attention with energetic enthusiasm. Research work on alcohol in laboratories is carried on in several great medical centers of Europe, with startling results which after a time come into the medical literature and are accepted. The American and English societies, representing the psychoses and neuroses of the subject, have published some very startling papers calling attention to the inherited defects and degenerations and close association of inebriety with the various insanities. In this country *The Journal of Inebriety* has presented many original papers along these lines, and stimulated the production of several volumes both in this country and Europe which give particular prominence to the disease of alcoholism. Heredity has been the subject of several volumes and studies that are still going on. The American Society from the first gave particular prominence to institutional care and study of inebriates. Discussions of remedies and appliances have gone on for years, every now and then culminating in some experimental institution. Narcotics have come in for an equal share of study and the literature along this line, from this and the English Society, has become practically epoch-making. There has been no endorsement of specifics or claims of extraordinary discoveries, but a steady evolutionary growth of the facts and their practical significance, showing the insanity of inebriety, the neuroses, and psychoses associated, and how far it is possible to control them.

On the Continent the studies of alcohol have absorbed every other consideration, and these societies have become the center of reformers and enthusiastic philanthropists who press their conclusions on public sentiment, educating physicians to total abstinence and to become teachers of the ill effects of spirits. Many of these societies call themselves antialcoholic or total abstinence societies and seem to have mixed motives, not only for themselves, but for the public. In this country the American Society's work opened a field for a great army of quacks and gold-curers who took up the idea of disease and declared they had discovered a remedy for it, and materialized and commercialized the idea as far as they could make it go. Out of all this confusion and empiricism there has come a clearer conception and decided advance in public sentiment. The fact has taken root and assumed the conviction that the work of the quacks showed the possibility of medical help and prevention from more exact means and measures. If reformers and quacks with mistaken theories and dishonest motives could accomplish so much, what could not be attained from a study of the subject as a mental science problem? In England the teachings of the American Society materialized in a law for the control of inebriates and a government department for the organization and management of institutions for the care of inebriates the same as in insane asylums. This has been going on steadily for many years, and the reports year after year show how vast the subject is, and what difficulties there are in its practical cure and prevention. Both the English and American societies have urged the question of disease and hospital care and treatment. In this country the growth of this fact is evident from the increasing number of inebriates that are sent to hospitals for the insane and sanatoriums and places where personal care and restraint can be had. In England there are twenty-four licensed institutions under government control and as many more private homes and sanatoriums for the same work on a smaller scale. In this country there are two state institutions for the care of inebriates and ten or more private or corporate institutions, organized under state laws, dependent on the income of patients and private charity, and over thirty sanatoriums where inebriates are received and treated as mentally unsound. The number of empiric institutions claiming to have some secret drugs at one time was very large, but they have grown less and less. All the large hospitals are providing wards for the care of the alcoholic, and outside of all theory or personal opinion there has grown up a consciousness that the inebriate is sick mentally and physically and needs exact care and treatment other than the pledge or moral remedy. These two distinct efforts to study the alcoholic problem are producing a revolution, not only in public sentiment among the laymen, but in scientific circles and among physicians.

A recognition of this and the work of the American Society in the publication of its transactions as a public document, known as Senate Document No. 48, is the highest tribute to its work. This shows that the work done by the American society has taken equal rank with the startling laboratory researches on alcohol in Europe. The American society, after years of continuous effort, has come at last to be recognized, and while its numbers are few, the work it has done has in some measure pointed out vast fields yet to be occupied and given help and assistance to many persons who are trying to understand something of the problem. Studies and observations of alcohol, inebriety, and the conditions which lead up to it do not require a hospital or extensive laboratory. They can be carried on in every town and city of the country, every medical man can become a pioneer and observe, tabulate, and make note of the great underlying facts which culminate in alcoholism and inebriety. Of the 120,000 physicians in the United States not 10 per cent. consider the alcoholic problem other than a moral one, and leave the great questions to clergymen, reformers, and enthusiastic women. While a much larger percentage are active temperance men in practice and theory, they look out upon the agitations of reformers and church efforts to check the evils of alcohol as outside of the great medical fields of study. Many very active physicians who would like to do all they could to increase the sentiment of total abstinence and raise the standard of living, are made to understand by the alcoholic interests that any efforts on their part to join the great reform movements will react on their personal work. Hence they become indifferent or give only negative help. There is a revolution in the air. Reformers, philanthropists, and clergymen are urging with intense energy the dangers and the evils which grow out of the use of alcohol as a beverage and its destructive effects in all conditions and relations of life. Reformers are coming into every town and city of the country and are trying to build up public sentiment and arouse a feeling among laymen to take part in trying to break up an evil that exceeds any of the epidemics known to science. Curiously enough, physicians who should lead and direct and be most active are not seen or heard of in these efforts. The alcoholic problem has passed beyond the stage of theory and tradition. It is a distinct physical and hygienic evil, pervading all society and homes and breaking out here and there in the most distressing way. The saloon and its patrons are subjects of pathological interest, and the supposed value of alcohol as a food, stimulant, or tonic is based on traditions and theories that all scientific studies contradict.

The great white plague of consumption is insignificant in its prevalence and effects when compared to alcohol and its influences. The injuries and diseases, with distinct entailments of crime, pauperism, neuroses, psychoses, insanity, and a vast tide of evils, clearly traceable to this one most prominent cause, is simply appalling. There are no ethics or morals in a study of these facts. It is not sentiment or theory; it is causes and results, clear and tangible. The inebriate and the alcoholic in the home, on the street, in the saloon, and everywhere is a menace to those about him. He is suicidal. He has crossed the border line of sanity and is poisoned both physically and mentally. He needs medical care, treatment, direction, and control, and this is a new field of practice which may be carried on in the office, in the home, and in the sanatorium. Physicians of all others by training, practice, and study are the natural leaders from whom help may be expected. They are competent to determine the causes and to point out means of prevention that shall lead to restoration and cure. Every temperance revival carried on by reformers and clergymen is a reflection on the physicians of that neighborhood who have failed to study the facts and their meaning, and failed to teach the hygienic significance and the destructive influence of the use of spirits as a beverage. Society demands that they should call attention to the source of typhoid fever, smallpox, and other contagious diseases, and be active in their prevention, before a great epidemic breaks out. Society demands the same of physicians in regard to every other evil that is active in destroying the health, vigor, and interests of the community. They are the persons who should be leaders and teachers, and not reformers and philanthropists who are without knowledge of the causes and can only judge of the effects. The American Society for the Study of Alcohol and Other Narcotics is an organized effort to create interest among physicians to take up this question and study it as a scientific one, not for the promotion of theories or dogmas as to what alcohol is and is not, or what inebriety is, but simply what is the meaning of the facts and what are the relations of alcohol, directly or indirectly, to the tide of evils that follow and are associated with our civilization and progress of the present. Why should an army of enthusiastic persons keep up an incessant agitation that is practically a revolution founded on an ethical and moral theory of causes which they seek to remedy by education and conversion? These questions must be answered practically, and when the physician seeks an answer in his own community, from facts that are tangible and real, he can then become a leader and enter upon a new field of practice of almost unlimited possibilities.

The work is begun, and we in this country have led all others in the study of the inebriate, and with the increasing number of foreign medical men who make alcohol the special object of their work, are opening a new field of cure and prevention, the possibilities of which are beyond all imagination.

PHARYNGEAL ABSCESS.

By BRYAN DeF. SHEEDY, M.D.,

NEW YORK.

ADJUNCT PROFESSOR OF RHINOLOGY AND LARYNGOLOGY, FORDHAM UNIVERSITY MEDICAL COLLEGE; INSTRUCTOR IN DISEASES OF THE UPPER RESPIRATORY TRACT, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; CONSULTING OTOLARYNGOLOGIST ST. JOSEPH'S HOSPITAL; MEMBER OF THE LOCAL COUNTY AND STATE MEDICAL SOCIETIES; MEMBER OF THE AMERICAN MEDICAL ASSOCIATION, ETC.

In discussing inflammation of the pharynx and pharyngeal structures, I believe sufficient emphasis is not placed upon that form of inflammation terminating in abscess. Most of the books referring to pharyngeal abscess define the condition as an infection of the glands located in the connective tissue between the spinal column and the anterior surface of the pharynx. The anatomists tell us that there are a few lymphatic glands normally located in the tissues of the pharyngeal wall at a level with the second and third cervical vertebræ and that pharyngeal abscesses are due to extension of inflammation from the mucous surfaces to these glands. They state, however, that these glands usually atrophy and disappear before the fifth year of life.

Reasoning from their standpoint, therefore, pharyngeal abscess does not occur after the fifth year of childhood. Those who are familiar with throat diseases know that abscesses of the pharyngeal wall occur almost as frequently in adults as in children.

If the breaking down of the retropharyngeal glands referred to is the sole cause of retropharyngeal abscesses then we must consider this condition purely one of childhood. The case that I am about to report occurred in a child three and a half years of age, though I believe that the abscess in this case had nothing whatever to do with the glands in question. Abscesses of the pharyngeal wall are due to the same causes as abscesses occurring in any other part of the body. Therefore, I know of no reason why this condition should be said to be limited to child life. Abscesses of the pharyngeal wall in adults are due to many causes, and I would specially mention, (1) infection escaping from the middle ear into the tissues forming the pharyngeal wall, (2) necrosis and caries of the spinal vertebra, (3) abscesses of the sphenoidal sinus, (4) traumatism of the structures of the pharynx through the swallowing of false teeth, falling upon canes, sticks, or tin horns that are held in the mouth, (5) thrombi or emboli associated with septicemic conditions, (6) tuberculosis, (7) syphilis, (8) disease of the bone other than those above mentioned, are frequently the cause of abscess in this location.

When the abscess occurs in a child under the age of three years the diagnosis is often very obscure and difficult. When the abscess develops in adults there is as a rule little trouble in making a diagnosis. Pain is an early symptom in most cases, and therefore the attention of the practitioner is at once directed to the seat of the difficulty. Associated with the pain we usually have rise of temperature and rapid pulse. In occasional cases there is absence of pain, but if there is much swelling the interference with respiration will attract our attention to the location of the disease. In young children altered voice will frequently call attention to the throat conditions. In others recurring attacks of croup, enlargement of the lymphatic glands in the neck, restlessness and interference with normal respiration, and if the pus comes from disease of the bones of the spinal column stiff-neck symptoms will manifest themselves.

With any of the above symptoms the pharynx should always be carefully examined, and if a globular swelling is found behind the tonsils on either side of the pharynx or in the median line the diagnosis as a rule is easy. The attendant, however, should always examine with the finger, lest the globular swelling be the projecting body of a vertebra. In making a thorough examination in children it is good practice, if one is at all suspicious of pharyngeal abscess, to place the child under ether, and if pus is discovered to open the abscess with the one narcosis.

Those unfamiliar with the prognosis and treatment of abscess of the pharyngeal wall should be very careful and guarded in giving an opinion as to the probable outcome of the case. In one case in my knowledge, the patient, an adult, was treated for many months for chronic pneumonia while the autopsy showed that a pharyngeal abscess had burrowed down and opened into the right pleural cavity. As these pus accumulations may be due to serious disease in adjoining structures the very nature of the original cause of the pus may preclude a favorable prognosis. Then, again, if the abscess occurs in a young child with marked obstruction a guarded prognosis should be given on account of an edema of the glottis that may suddenly arise and take the patient off or the bursting of the abscess may suffocate the little patient before proper treatment can be instituted. The danger of suffocation due to the pouring of the large amount of pus (which is generally found in these abscesses) into the larynx should be borne in mind when treatment is taken under consideration. Many operators give guarded opinions on account of the frequency of pneumonia following the opening of these abscesses in children and some of the best European surgeons have gone so far as to say that the death rate from this cause alone is sufficient to make the external operation advisable. There is but one course to be pursued in the line of treatment, and that is to open the abscess. The only question that one should consider is whether or not one should open the abscess through the mouth or by way of the external route, making an opening behind the angle of the jaw as recommended by some surgeons. From an experience of many years I strongly recommend that the abscesses be opened through the mouth, and during this procedure protect the patient from the danger of suffocation through the presence of a pad of gauze on a sponge holder placed over the larynx when the incision is made and at the same time have an assistant or two assistants hold the patient perpendicularly with the head down so that gravity will favor the discharge of pus through the nose or over the roof of the mouth. In this way there is little probability of the pus being drawn into the lungs through inspiration. The argument may be made that the discharge of a large quantity of pus through the nasal passageways of a child will probably infect the sinuses and make further trouble, but if we bear in mind that the sinuses are very little, if at all, developed in these young children, this danger is not as real as it at first appears.

The case that I wish to report was in a little patient, three and a half years old, the only child of parents, both of whom were healthy, and the child herself more than ordinarily well nourished. The family being connected with a society that furnishes medical treatment to the whole family for ten cents a week, called upon the society physician, six or eight weeks before I saw the little patient, for treatment, and during this six or eight weeks the patient was under the care of the society physician being treated for a cold in the head. The child was very restless at night with considerable fever (just how much could not be told, as a thermometer had not been employed), had three or four attacks of croup during this time and complained much of ear symptoms. The little patient not recovering, but evidently losing weight and strength, the mother visited two other physicians, one of whom made a diagnosis of adenoids and enlarged tonsils, the other stating that the child had a coryza and would be all right in time. After two weeks of this treatment the patient was brought to the Fordham University Medical College, where she came under the care of my clinic. At this time there was a discharge from the right ear as well as a mucopurulent discharge from both nostrils, and the upper lip was irritated from the discharges. The patient had a temperature of 103.5°, was irritable, and had the appearance of being very sick. The mother reported that the child had not slept well for several weeks, took very little food, and had, without intermission, a peculiar rasping,

reflex cough. On examination there was marked swelling of the glands on the right side of the neck behind and below the angle of the jaw, and the cellular tissue of the right side of the neck below and in front of the mastoid region was much swollen and very sensitive. The child carried its head as if suffering from a stiff neck. There was no swelling over the mastoid or the mastoid antrum, nor did the ear project out from the side of the head, as is often seen in periostitis of the temporal bone associated with middle-ear abscess. Examination of the throat showed the tonsils very little, if at all, enlarged, though one of the students diagnosed a very much enlarged right tonsil, which afterward turned out to be not an enlargement of the tonsil, but a large globular swelling behind the right tonsil, forcing the tonsil forward and half way to the median line. After inserting a mouth gag we elevated the feet of the child almost to a perpendicular position, examined carefully with the finger and found that the mass was soft; a diagnosis of retropharyngeal abscess was made. At the same time and before the patient was replaced to the reclining position we made a large opening in the mass parallel with the long axis of the pharynx, first having protected the larynx by a pad of gauze, when from two to four ounces of whitish liquid pus escaped through the nose and over the roof of the mouth. After the patient had been kept in a position with the head very much lower than the feet for about an hour, the throat was mopped out with a gauze sponge, and the child was allowed to return home. There was no tendency of the cavity to refill, and the discharge from the ear ceased within a week from the time the abscess in the throat was opened. Swelling of the neck and glands wholly disappeared in a very short time so that in two weeks from the time the abscess was opened the patient had recovered a good share of her former health and would seem to be on a permanent road to recovery.

I believe that in this case the original cause of this abscess was an infection of the middle ear following an attack of influenza.

THE USE OF CULTURES OF STAPHYLOCOCCUS PYOGENES AUREUS IN A CURIOUS OUTBREAK OF DIPHTHERIA.

By GEO. E. LAKE,

FIRST LIEUT., MEDICAL CORPS, U. S. ARMY.

During the winter of 1911-12 there occurred at Ft. Sam Houston, Texas, a rather curious outbreak of diphtheria, the peculiar features of which were: (1) The mildness of the cases, many hardly showing any symptoms at all; (2) The fact that no children were attacked; (3) The circumstance that nearly all of the cases were sporadic, contact with a preexisting case being traceable in but few of the cases.

The 37 cases observed represented 19 different organizations, besides 3 officers and the wife of one of these, making an actual total of 22 separate establishments attacked. Of these the Hospital Corps showed the largest number (5) and the Infantry guardhouse next (4), which quite naturally follows from the unavoidable conditions of more or less close contact, the Hospital Corps men with the diphtheria cases in the course of their work, and the prisoners with their infected comrades before their condition was discovered. One organization gave 3 cases, five gave 2 cases each, and the other fourteen 1 each. In several instances where more than one case came from the same organization there was no history of contact between the various cases. The fact that the city of San Antonio, near which the fort is situated, and to which officers and men resort in large numbers, contained many cases of diphtheria during this time is a reasonable explanation of the source of the infection.

Of the 37 cases reported only 12 showed marked clinical symptoms of the disease, the remaining 25 having little more than a more or less severe sore throat, without exudate and accompanied by little fever, but harboring the Klebs-Löffler bacillus. The stay in the hospital of the 12 who had marked clinical symptoms averaged about the same as that of those who had not.

Three cases were complicated by Vincent's angina, and all of these proved to be intractable carriers, clearing up only after prolonged treatment. In 4 cases syphilis was present, but appeared to have no influence upon the course of the disease. Two cases developed a severe, parenchymatous, non-suppurative tonsillitis, with considerable swelling and discomfort, which yielded promptly to treatment and seemed not to influence the progress of the diphtheria.

Of the 37 cases heretofore mentioned only 31 were completed when the writer was ordered away from Ft. Sam Houston, and the part of the report which follows deals with the 31 completed cases only. The treatment instituted at the beginning of the outbreak was antitoxin, followed by gargling the throats with hydrogen peroxide and meeting such symptoms as arose. The average dose of antitoxin given was 2,774 units; the largest having been 8,000, and the smallest 1,000 units.

The routine test for releasing patients from quarantine was the absence of Klebs-Löffler bacilli in the swabbings from their throats for three successive days. The average amount of time spent on sick report by these 31 patients was 21.5 days, the longest stay having been 43 days and the shortest 7. This latter patient was one of the medical officers at the post.

In the issue of the *New York Medical Journal* for December 23, 1911, there appeared an article advocating the use of cultures of *Staphylococcus pyogenes aureus* as an application to the throats of diphtheria carriers (which many of these patients now were). Determining to try this treatment I procured a laboratory culture of this organism and also isolated a fresh culture from a boil. Both of these cultures were used in the course of the treatment and little or no difference in their effects could be noted.

Treatment was begun on January 16, 1912, with two patients, so as to observe the effects, and as none of these were untoward the number treated was increased next day to five and more were added to the list from time to time. Eighteen of the patients either had cleared up and been returned to duty before the staphylococcus treatment was begun, or cleared so promptly that it was deemed unnecessary to use it. These 18 patients spent 344 days in quarantine and constitute "Class A."

Eight patients were in quarantine for some time before the staphylococcus was used and then received the treatment. These eight patients spent 170 days in hospital before and 74 days after receiving the treatment, and are "Class B."

Five patients received the treatment as soon as they were fully convalescent and spent 70 days in hospital, constituting "Class C."

The average number of days spent in hospital from admission to discharge by these three classes was as follows:

Class A . . 18 cases . . average 19.1 days in quarantine.
Class B . . 8 cases . . " 30.5 " "
Class C . . 5 cases . . " 15.8 " "

Thus, those who were treated with the staphylococcus from the subsidence of acute symptoms left the hospital, on an average, in 3.3 days (17.2 per cent.) less time than those who did not receive it.

The cases in "Class B" do not bear on the question, when considered as a whole, because many of them had been in the hospital a long time as intractable bacillus carriers, before the staphylococcus was used.

The 13 patients treated with the staphylococcus (5 in "Class C" and 8 in "Class B"), who went to duty, spent 73 days in hospital after this treatment was begun; an average of 5.6 days.

The treatment was carried out by thoroughly swabbing the throats of the patients once a day with cultures of *Staphylococcus pyogenes aureus*. These were varied a good deal for purposes of experiment. Bouillon cultures from 6 hours to 5 days old; young broth cultures, reinforced with two or three normal loopfuls of agar cultures; suspensions in broth of agar cultures from 1 to 7 days old; all these were tried, but the best results apparently were obtained with bouillon cultures from 48 to 72 hours old, grown at incubator temperature.

The growth of the staphylococcus in the throats of the patients was very irregular and unsatisfactory, only four cases showing a strong, luxuriant growth, although the implanted organisms were more or less in evidence, at one time or another, in 11 out of the 13 throats treated. A good growth of staphylococci was present, spontaneously, in the throats of two of the patients who cleared up promptly without special treatment.

Although these few cases offer no proof, one way or another, they seem sufficiently suggestive to warrant the more extended trial of the procedure.

Fort Sheridan, Ill.

THE ELIMINATION OF LOCKJAW.

By DOWLING BENJAMIN, M.D.

Camden, N. J.

The mortality in lockjaw is very high. In fact, the disease, when fully developed, is commonly fatal. Tetanus antitoxin will immunize, if introduced hypodermically before the disease develops or at the time of the injury; but as it is obviously impractical to have everybody take hypodermic injections of antitoxin after every little scratch or wound, the physician is usually called upon to treat the case after it has manifested itself by the symptoms. Then it is generally too late. Prevention is the only satisfactory "cure."

During the past four years 22 cases of lockjaw were treated at the Cooper Hospital by the staff. These cases all received large and frequent injections of tetanus antitoxin (916 injections was the total number). Of these 22 cases of tetanus two recovered and 20 died; which shows that the mortality of this disease is high, even under the best treatment by skilled men.

I am prepared to proclaim that lockjaw, due to puncture and injuries, *can be entirely eliminated* from the whole of [illegible] or surgeon's practice, and his death-rate, [illegible], from this disease, reduced to nothing. I [illegible] may be claimed that this is a most radical and [illegible] statement; one that no physician ever dares to make before; but it is excusable if it is the *truth*. And it is important, not only to the profession but to humanity in general. So I wish to offer some proofs which I think will justify the assertion, on the unassailable ground that what has been done can be done. In support of the above claim I offer the experience of 33 years of practice. It was also a large practice, including about 10,000 injuries of all kinds, among them rusty-nail and other punctures of feet and hands, in private and hospital practice which I have attended; yet I have never had lockjaw develop in one of my patients in all my life. This was accomplished in a locality where lockjaw is endemic—20 cases having been reported in one year.

Treatment.—Sterilize the field of injury, especially the deep edges of the wound. Large and open wounds are irrigated. The vast majority of cases of lockjaw, however, develop from punctural wounds, and there is where the great opportunity for the special treatment comes in. Insert a few drops of alcoholic solution of cocaine. Have on hand variously sized screws, as shown in the drawing. Any instrument maker can prepare them. The threads should be at an angle of about 25 degrees to the axis of the screw, and thin. A set of screws should range from the size of a small probe to 5/16 of an inch in diameter, so as to be ready for all sized wounds, such as nails, pitchfork tines, dog teeth, and so on. In the absence of these special instruments, however, one can often use an ordinary aluminum applicator, which has threads on; or one can procure from any hardware store ordinary screws, which answer very well for many cases.

Dip the sterilized screw into an antiseptic solution, say, 2 or 3 per cent. lysol. The liquid is held by the spiral gutter. The screw should be of a size to follow the track of the wound easily. If the skin is hard (like the sole of the foot) and the wound entrance is tightly contracted, it may be nicked with the point of a knife. As the screw is being inserted it is kept turning but held back, so that by the time it has reached the bottom it has been turned enough to have carried it more than twice as far. It is now given a few more turns. In this way foreign substances and microbes are lifted (screwed) out. The instrument is then *pulled* out and washed in an antiseptic; then dipped in tincture of iodine, if not a large puncture, and then forced down to the bottom of the wound and given a few turns backward. Then the screw is dipped into carbolized oil (1 minim of carbolic acid to 14 of pure olive oil) and pushed gradually to the bottom of the wound, turning backward, then unscrewed out. These antiseptics have the property of permeating the surrounding tissues. Dress the wound in the usual antiseptic manner. No germs will live in that wound.

Even when you have immunized with antitoxin, this local treatment should be used in all punctured and Fourth of July wounds, for the good reason that it not only prevents lockjaw by killing the bacilli, but is equally efficacious against strepto-

cocci (blood poison and erysipelas) and staphylococci (abscess and inflammation). My personal experience has shown this to be a fact.

215 Cooper Street.

TRAUMATIC CYST OF THE PANCREAS.

By ARCHIBALD E. ISAACS, M.D.,

NEW YORK,

SURGEON, BETH ISRAEL HOSPITAL.

On January 26, 1911, this young man, then 17 years of age, was admitted to the Beth Israel Hospital with the diagnosis of empyema of the gall-bladder. His history was that he had been well up to six weeks before his admission; at that time he received a severe injury to his abdomen by running against the side of a horizontal bar while exercising in a gymnasium. His statement regarding his sensations at the time is that he lost his breath for a few minutes, broke into a profuse cold sweat, and vomited about twenty minutes after the accident. He was then taken to the Roosevelt Hospital where he suffered severe abdominal pains for some days. The pains then gradually improved until he was discharged, feeling comparatively well, after a stay of ten days.

In the five weeks after having left the hospital he had had three attacks of severe pain. The first two lasted somewhat over a day each, and the third longer. The pains were in the upper abdomen and not accompanied by fever or vomiting. The third attack began five days before his admission to the Beth Israel Hospital and was more severe than the others. The pain was referred to the right hypochondrium and to the back, in the region of the right scapula. After his second attack he had felt a hard mass in his right hypochondriac region, which was not tender during the interval but became extremely so with this attack. There was nausea, but no vomiting, chills, fever, or jaundice. He had had no bowel evacuation in three days. He had lost twelve pounds since his illness began.

On examination there was tenderness and rigidity in the right upper quadrant, with the sensation, on palpation, of a deep mass which could not be mapped out with any degree of definiteness on account of the rigidity. The rest of the abdomen was comparatively free. The temperature on admission was 100½°, and the pulse between 80 and 90. Blood examination showed 90 per cent. hemoglobin, and a leucocytosis of 13,400 with 85 per cent. of polynuclears. The urine examination was negative, and there were no respiratory, cardiac, or urinary symptoms.

Without having arrived at any definite diagnosis, laparotomy was done on January 28. Through a right rectus incision, from near the costal margin to below the level of the umbilicus, the transverse colon presented, and a large, hard mass could be felt posterior to it. On raising the colon an area of adhesions was found between the under surface of the mesocolon and this retroperitoneal mass. Separation of these adhesions released a small amount of bloody serous fluid, and exposed an angry and almost gangrenous looking surface with areas of fat necrosis on it. The mass beneath this was presumably within the layers of the transverse mesocolon, and incision into it opened into a cavity from which quite a large amount of clear fluid discharged. The finger introduced into the cavity showed the mass to consist of this cyst, occupying the region of the pancreas, and of a boggy infiltration about it. About four ounces of clear colorless fluid were discharged which left a deposit of crystals on the surface of the gauze pads into which it soaked. By a mishap the specimen of fluid, saved for laboratory examination, was lost.

Further exploration showed a normal gall-bladder, and the foramen of Winslow open. The duodenum was pulled down and partially kinked by some well organized bands stretching from it to the transverse colon. These were separated. The appendix was in a state of chronic inflammation. It was also kinked by bands and the distal portion was distended and so adherent that decapsulation was required to remove it. While there was no probable connection between the duodenal and appendiceal conditions, and the pancreatitis, it is interesting to note that the former must have existed for some time without having caused any symptoms.

A cigarette drain was passed into the cyst cavity and the abdomen closed, in layers, except for the small drain opening. There was not much reaction after operation in so far as the temperature and pulse indicated. But there was severe pain, in paroxysms, sometimes with vomiting, requiring occasional hypodermics for relief. After two weeks the pain subsided. The drain was removed in the second week. The discharge kept on for another week. The patient left the hospital, with the sinus closed, 24 days after operation, and has been well since.

1325 Madison Avenue.

*Case presented before the Surgical Section, New York Academy of Medicine, March 1, 1912.

Arsenical Pharmacotherapy.—A. Valenti states that the many organic compounds of arsenic have been frequently employed of late years. Differences have been noted, aside from the local action, between the action of these organic compounds and that of the mineral compounds of arsenic. The metallic arsenic compounds are easily dissociable, with a rapid liberation of the arsenic ions and greater toxicity. The organic compounds are less easily dissociated and hence less poisonous, although not giving the same certainty of absorption into the blood. Each organism has its own individual susceptibility to arsenic and must be separately tested as to idiosyncrasy. We are still ignorant of the intimate action of arsenic. Salvarsan readily liberates its arsenic, which is long found in the urine of patients treated by this drug. The quantity of the solution used and the dose are most important; the differences in the animals experimented on are also of importance; the fact that one cannot get accurate knowledge of the combustion that goes on within the body, and of the lesions which exist in persons under treatment renders accurate observations of its use difficult. It is affirmed that mineral arsenic is a moderator of organic oxidation in relation to repair, and of exaggerated catabolism of nutritive material, while the organic compounds seem to have a more direct action on the hematopoietic organs, stimulating the erythrocytic and leucocytic activities, and increasing the function of the organ in reference to defense. For increasing the number of corpuscles and the hemoglobin of the blood the organic preparations of arsenic are most valuable. Other authors maintain that small doses of mineral arsenic lessen organic oxidation, while in larger doses the destruction of albuminous substances is stimulated, which destruction causes the symptoms of chronic poisoning. At the same time these doses act beneficially on the gastrointestinal circulation, favoring hyperemia and epithelial activity. In the more chronic diseases accompanied by cachexia arsenic is of most value.—*Il Policlinico.*

New York, June 29, 1912.

BIOLOGICAL INTERPRETATIONS OF PATHOLOGICAL PHENOMENA.

IT is remarkable that during the ascendancy of the evolutionary theory, this fundamental doctrine has been so slightly utilized in the interpretation of the phenomena of disease. The revelations of cellular pathology, supplemented by the brilliant discoveries of bacteriology, have apparently diverted attention from those factors in the production of disease which are of wider scope and deeper significance than even the offending microorganisms and the cellular derangements.

In an illuminating thesis on the relations of biology to pathology Hastings Gilford (*British Medical Journal*, June 8, 1912) points out that there are a large number of diseases to which have been applied, without basis of fact, the terms belonging strictly to diseases of bacterial origin. The words "intoxication" and "toxemia" are still loosely employed in describing the etiology of such diseases as cirrhosis of the liver, leucemia, Graves' disease, progressive muscular atrophy, osteomalacia, and cancer. In these and many other morbid conditions, although toxins may play a subordinate rôle, the essence of the disease process has nothing to do with bacteria or toxins. There is available a wealth of material upon which the pathologist can draw in attempting to unravel the mysteries that confront him: this material consists of the facts of variation, heredity, adaptation, correlation, reversion, and recapitulation, together with the facts of comparative anatomy, anthropology, and paleontology.

There is an increasing tendency to regard many phenomena of disease as simple variations. According to Bateson there are two kinds of biological variations: numerical, as in polydactylism, and substantive, or those in which there is a change in constitution. Substantive variations are subdivided into two kinds: (1) fluctuations or continuous variations, which are less pronounced, are not transmitted by heredity, and are subject to the influence of the environment; and (2) mutations, sports, or discontinuous variations, which spring into existence with a leap, are transmitted by heredity, and are not dependent upon environmental changes, either within or without the organism. In the latter group Gilford places such diseases as sporadic cretinism, chondrodystrophy, idiopathic pernicious anemia, idiopathic microcephalus, muscular dystrophy, hypertrophic cirrhosis of the liver, osteitis deformans, and Friedreich's ataxia. "They are biological mutations rendered pathological by being carried to extremes." In the group of continuous or minor variations are placed such diseases as endemic cretinism, rickets, atrophic cirrhosis of the liver, etc., which can be traced to definite internal or external causes.

A conception which throws a flood of light into many of the obscure corners of pathology is that which regards morbid variation as either progressive or regressive. The overgrowth of the thyroid in Graves' disease is an instance of the former, and the arrested development of the brain in microcephalus is an example of the latter. Both variations represent extremes, and are pathological not because they are extremes, but because they do not harmonize with the physiological level of the organism.

The "mneme" theory of Semon is cited as an ingenious explanation of the significance of variations. According to this theory the facts of heredity and variation are translated into terms of memory. The germ cell in its development recapitulates the history of the race, just as the brain cell treasures up and afterwards unfolds the previous experiences of the individual. As so well expressed by Gilford, "racial, like ordinary, memory is not infallible. The registration of impressions received in the remote past, when animal evolution was beginning, are very imperfect, so that only the dim outlines of great and widespread changes are repeated. But as the construction of the body approaches completion impressions are reproduced with ever-increasing fidelity. Impressions may be blurred in one case and not in another, and occasionally actual lapses occur, so that important evolutionary events are forgotten. On the other hand, impressions may stand out far too conspicuously, to the derangement of the general effect. It is after this fashion that variations, normal and pathological, arise. An act of racial forgetfulness, if of extreme degree, is a regressive major variation. The memory of a great racial disaster or depression may be so subdued by lapse of time as to remain latent, but the associations furnished by a depressing environment are capable of awakening those long dormant impulses; the memory of the ancient environment is revived by a modern environment of a similar tendency, and the two together give rise to a regressive minor variation."

In discussing the proximate causes of reversion to a primitive type of structure, Darwin noted that any marked change in the habits of life apparently "favors a tendency, inherent or latent in the species, to return to the primitive state." In thus stating a definite cause for the phenomenon of atavism, Darwin foreshadowed the hypothesis more elaborately unfolded by Semon, and furnished the key which may in the future serve to unlock many a mystery of pathology. There is sufficient basis for the belief that not only the germinal cells, as in the mnemonic theory of Semon, but also the highly differentiated somatic cells of the body treasure up the remote ancestral traits of the primitive protoplasmic units. This conception would adequately explain at least

one important phenomenon of cancer, namely, the tendency on the part of the body cells, under the influence of external irritants, to revert to the primordial condition of early embryonic life, by taking on an excessive proliferative activity.

MORBIFIC DUST.

Some time ago D. D. Jackson of Brooklyn investigated a specimen of city dust to ascertain what germs were present; the bacteria responsible for tuberculosis, pneumonia, influenza, and other infections were found. But other constituents were also noteworthy, such as plaster, iron-rust, stone dust, cement from building operations, dirt from excavations, ashes, house-sweepings, dried garbage blown from barrels and cans, chimney soot, cinder and other material from industrial plants, excrement of horses, dogs, and other animals, etc. How pathogenic a dirty atmosphere may be is impressed upon those who have seen the series of nutrient plates which were exposed by Street Commissioner Woodbury some years ago, in the metropolis. These series were in pairs. One of a pair represented atmospheric conditions in densely crowded neighborhoods, where the sanitary conditions were comparatively poor; and such a plate would be found, upon exposure, teeming with bacteria, moulds, fungi, and every kind of impurity deleterious to health. Its companion plate, exposed in a cleanly and salubrious part of town, under precisely identical scientific conditions, would be almost wholly free of impurities.

There is perhaps an impression that dust is inimical to health only by reason of its content in pathogenic bacteria; but there are other than bacterial properties in dust which are disease-engendering. There is noxious dust in many occupations—dust, the particles of which are irregular and jagged, will irritate the pulmonary mucous membranes, and so predispose these delicate tissues to microbic attack. Thus does the tissue become a congenial nidus of infection. The inhalation of germ-free dust will also induce inflammation, such as pneumoconiosis. Or the dust will be noxious by reason of its chemical properties; thus results industrial poisoning among workers in lead, arsenic, zinc, phosphorus, and mercury. And organic compounds, like anilin, may so contaminate the atmosphere as to jeopardize the health of the workingman.

Nor is the respiratory tract the only pathway by which noxious dust invades the organism. Prof. K. B. Lehmann of Würzburg and his associates, with a view to preventive and palliative measures to be applied in industries, have sought more precise information regarding the ways by which dust permeates the body, as well as the actual quantities which represent dangerous or insanitary limits. These investigators have demonstrated that most inspired dust finds its way into the stomach, not into the lungs. Most of the dust which enters the upper respiratory tract is caught by the moist mucous membranes of the nose and throat; and the dust-laden secretion is then swallowed. Insoluble particles are eliminated in the process of digestion; but soluble dust is absorbed in such amount that chronic intoxications, the like of which are so painfully frequent among workingmen, inevitably follow. This scientific datum of Lehmann is one among innumerable findings that are constantly being made nowadays by sanitary scientists; and for which, to their honor be it noted, many employers of labor are grateful. Much more than this, the enlightened employer does not stop with appreciation. He is prompted by a wholesome admixture of humane and business considerations to make his establishment hygienic. We do not now nearly so often as formerly see shops badly ventilated; the removal of dust from machines inadequate; overcrowding; the air saturated with variegated exhalations; the employee eating at his own machine, his grimy hands fingering his food. On the contrary most factory laws—which are oftentimes most willingly complied with—now provide for the essential sanitation. The importance of personal hygiene is impressed upon employees; and rules are formulated and made stringent to this end. In some places baths—even shower baths—are in evidence.

In occupations involving exposure to poisonous gases or to metallic mineral or animal dust and effluvia, many excellent and effective contrivances have been installed; in this regard there has been a veritable revolution. Dust and vapors are thus kept away from the operators' nostrils and mouths. Sufficient air space is provided. There is proper ventilation and illumination. The floors are clean; and general cleanliness has become a matter of course; this, too, is revolutionary. Most of all, spittoons are provided and kept antiseptic; so that no one need now be guilty of promiscuous spitting. Why, indeed, spit at all; and what need should there be of spittoons?

Rural Water Supplies.

As regards many conditions of life, the country is considerably more insanitary than the city. True it is, that in rural districts extreme old age is not infrequently reached and, superficially regarded, country life may appear to be more healthy by far than urban life. But when one looks carefully below the surface, it will soon be perceived that all is not so fair as outward appearances might lead one to suppose. In a very important respect, country districts fail when compared to urban districts and this is with regard to their water supplies. Henry Kenwood Chadwick, professor of hygiene in the University of London, draws attention in the *Medical Press and Circular*, May 29, 1912, to this point. Many villages in the country are mainly, if not entirely, supplied with drinking water obtained from shallow wells; and this underground water, which may convey pollution from a considerable area, is often drawn but a few yards from a leaky cesspool or privy pit, or from a surface which is liable to considerable pollution. Further, it is the exception to find a shallow draw- or pump-well impermeable; nor is the well mouth generally sufficiently protected from surface waters. The result is that with household slops and rubbish and fecal matter often disposed on land within a few feet of the well, or worse still with leaky cesspools and privy pits in close proximity and often within the drainage area of the well, the dangerously polluted ground water can be seen to

pass through the brickwork. Some of the shallow wells cease to yield during a summer drought. Country dwellers of the poor class have no means of storing sufficient water, nor can they afford the expenditure necessary to ensure such a supply. The picture drawn by the English authority of the water supplies of many English rural districts is very like that of an American countryside. Proper sanitation is lacking, as a rule, and especially are the water supplies inadequate or polluted or both. The old oaken bucket is too often the means of spreading disease and death, and the picturesque country house or cottage clothed in creeper or shrouded by ivy is frequently a whited sepulcher, the home of typhoid fever. This is the season of the year when a warning as to the insanitary conditions which so often characterize country life is strictly in place, for it is no exaggeration to say that as many diseases and complaints are contracted when one is on a vacation seeking health as are developed during the eight or nine months when one moils and toils in the much maligned city. Kenwood suggests that not only do rural sanitary authorities in England need to be stirred up, but that the Government should be asked to make a grant in aid of village sanitation. In the United States there is probably quite as much necessity for improved country sanitation as in Europe. The Federal Government can, of course, do nothing in the matter, but the State health boards have authority, and there are not a few places in every State in which it would be well were the local authorities called to account for their apathy in regard to sanitary reforms.

Fatality from Thorium Emanation.

The old dictum as to the extreme difficulty or impossibilty of influencing morbid tissues without simultaneously affecting sound cells predisposed to other diseases was well illustrated at a recent session of the Berlin Medical Society (*Muenchener medizinische Wochenschrift*, May 21). On this occasion Professor Orth exhibited the organs of a woman who had been treated for chronic rheumatism with thorium emanations. She had received 15,000,000 Maché units in all. Death had resulted from induced hemorrhagic diathesis, affecting chiefly the gastroenteric tract. The same affection was produced experimentally in animals. Orth warned against large doses of thorium emanations. In discussion he added that he had seen one of severe hemorrhagic nephritis follow the use of the same remedy. Kraus had once seen albuminuria supervene after 5,000,000 units had been given. The death naturally caused a sensation and in the *Berliner klinische Wochenschrift* of May 13 Gudzent, who gave the treatment, reports the entire case history, in which he seeks to show that death may not have been due to thorium. Equally large doses of the latter have been given over and over without prejudice to the patients. Similar fatalities are attributed to all new remedies (tuberculin, salvarsan, etc.). Professor His, who is in charge of the clinic at which the treatment was given, announced in the same number of the above journal that he was away at the time of the accident but regarded the treatment, including the dosage used, as in entire accord with two years' experience with thorium. These cases are bound to occur and show the lower limits of lethal dosage.

News of the Week.

Wholesale Vaccination.—More than 1,500 persons in the northwest part of Philadelphia were subjected to compulsory vaccination on June 20 because of the prevalence of smallpox in Manayunk and the surrounding districts. About sixty families barricaded their houses and refused to allow the police to enter. As a result they have all been placed under strict quarantine.

Reports of Births.—Commissioner Lederle of the New York Department of Health has called attention to the fact that the number of births recorded in New York during the first five months of 1912 was 50,082, or 170 less than during the same period of 1911. This would indicate a decrease of 1.10 per 1,000 of population. It is not believed, however, that this decline in the statistics is due to natural causes. A comparison of the births and deaths for the month of May showed, for example, that there were seventeen children under three months of age who died during the month whose births had not been recorded. As one out of every five children dies during the first three months, and as this method of ascertaining the births not reported applies only to those who have died, it is evident that the number of births not reported in May must have been far in excess of seventeen. It would seem probable that in many cases physicians have failed to report births, and the Department of Health states that this state of affairs will not be allowed to continue and that negligence will be prosecuted to the full extent of the law.

New Milk Depots.—During the summer months ten milk stations in addition to those already in operation, will be maintained in New York by Mr. Nathan Straus. The new stations are located in the parks and on the recreation piers. This makes a total of eighteen depots supported by Mr. Straus in this city, in addition to those maintained by the Board of Health.

Cripples Graduate.—For the first time in the history of the New York public schools a class of crippled children, consisting of ten boys and one girl, was graduated last week from Public School No. 2, at 155 Henry street. This school has an annex for crippled children with an attendance of about 200.

Helpful Moving Pictures.—The New York Department of Health in conjunction with the Committee on the Prevention of Tuberculosis gave the first open-air moving picture show of the season in Mount Morris Park last Saturday. During the summer the pictures will be exhibited in many of the parks throughout the city. The films are largely designed to illustrate methods of combating tuberculosis.

Diphtheria Epidemic.—An epidemic of diphtheria in Woodbridge, N. J., recently, which made it necessary to close practically all of the schools and churches, was traced to a milkman who continued to supply his customers after the disease had appeared at his farm.

Leper Republic.—The Philippine Government is endeavoring to solve the problem of the management of affairs in the leper colony on the Island of Culion by the establishment of a republic among the lepers, and on June 18 Michael Whalen, the only American on the island, was elected chief executive.

Water Supply Contaminated.—Test of the city

water in Newark, N. J., recently showed the presence in considerable quantities of the *B. coli communis*, and immediately after the discovery the supply was cut off. It has been decided that the reservoir shall be drained—there are some 679 billion gallons of water in storage—and the basin thoroughly cleaned.

Plague in Porto Rico.—Twelve cases of bubonic plague with five deaths were reported in the district of San Juan, Porto Rico, between June 14 and 19, and extreme measures are being taken to prevent an epidemic in the island. Measures have also been taken to prevent the entrance of the disease into the Port of New York, and the Health Officer of the Port has issued an order that after July 1 all ships from the Tropics shall be thoroughly fumigated before entering the harbor, unless it is certified that proper disinfection has been carried out at the port of departure.

Sex Hygiene.—After months of argument, the Board of Education of Orange, N. J., has come to the conclusion that sex hygiene should be taught in the public schools. By a unanimous vote on June 11 the Board decided that girls of fourteen years of age should receive instruction from competent teachers. Some effort was made along these lines several months ago, but so many protests were entered that a special committee was appointed to report on the propriety of the subject as a part of the school curriculum.

Loomis Sanatorium.—The dedication and formal opening of the Olivia Cottage for self-supporting men and women, the gift of Mrs. Russell Sage, and of the new laboratory and research building, the gift of Mrs. Clarence M. Hyde, in memory of her father, Benjamin Talbot Hyde, took place on June 22. Addresses were made by Dr. Theodore C. Janeway, Dr. Livingston Farrand, and Dr. Herbert M. King.

Street Accidents.—Thirty-three persons were killed on the railroad and street car lines in New York City during the month of May, according to the report of the Public Service Commission, an increase of 5 over May, 1911. The total number of accidents during the month was 6,492. The total number of persons injured outside of the fatal cases, however, was 164, a decrease of 78 as compared with last May.

Accused of Buying a Stolen Dog for Experimental Purposes.—The University of Chicago has decided to fight, as a test case, the charge of receiving stolen goods brought against the keeper of animals in the Department of Physiology in the university. A woman resident of Chicago had the keeper arrested, declaring that her dog, a Scotch collie valued at $14, had been stolen, and was later found in a cage at the university where it had been used for experimental purposes. The judge before whom the case was brought agreed to issue a warrant for larceny, unless the case was settled in a few days out of court.

Dr. H. H. Rusby, dean of the College of Pharmacy of Columbia University, New York, has resigned his office, and intends shortly to establish a pharmacognostical laboratory in the city.

Birthday Honors.—The list of honors issued on King George's birthday recently included the name of Mr. John Bland-Sutton, who was created a knight.

Dr. Philip B. Hawk has been elected Professor of Medical Chemistry and Toxicology in Jefferson Medical College, in succession to Dr. James W. Holland, resigned. Dr. Hawk was graduated with the degree of A.B. from Wesleyan University in the class of 1898 and received the degree of M.S. from Yale University in 1901 and of Ph.D. from Columbia University in 1903. He was assistant to Professor Atwater, at Wesleyan for two years, later a student in physiological chemistry in the Sheffield Scientific School at Yale for two years, instructor in physiological chemistry at the College of Physicians and Surgeons, Columbia University, for two years, demonstrator of medical chemistry in the University of Pennsylvania for four years, and professor of physiological chemistry in the University of Illinois for five years.

Dr. M. Neustaedter has been appointed instructor in neurology in the New York University and Bellevue Hospital Medical College.

Honorary Degrees.—Harvard University at its 247th annual commencement on June 22, bestowed the honorary degree of Doctor of Science on Dr. Frederick Forchheimer, professor of medicine in the University of Cincinnati and president of the Association of American Physicians, and on Dr. Frederick Cheever Shattuck, professor of clinical medicine in the Harvard Medical School, and the degree of Master of Arts on Dr. George Francis Stokes, Surgeon-General of the United States Navy.

The honorary degree of Doctor of Science was conferred by Middlebury College, Vermont, on Dr. C. Ford Langworthy, in charge of investigations on nutrition in the United States Department of Agriculture.

At the 156th commencement of the University of Pennsylvania on June 19, Dr. Louis A. Duhring, emeritus professor of dermatology, and Dr. James Tyson, emeritus professor of medicine, in the Medical Department of the University, received the honorary degree of Doctor of Laws.

Dr. Harvey W. Wiley received the degree of Doctor of Science from Lafayette College, Easton, Pa., on June 19.

Dr. Theodore Caldwell Janeway, professor of medicine in the College of Physicians and Surgeons, New York, was one of the few honored by Yale University at the commencement exercises on June 19, receiving the honorary degree of Master of Arts.

At the eighty-first annual commencement of Wesleyan University at Middletown, Conn., held on June 19, the degree of Doctor of Laws was conferred upon Dr. Amos J. Givens of Stamford, Conn.

College Commencements.—At the 156th annual commencement of the University of Pennsylvania, held June 20, the degree of Doctor of Medicine was conferred on 124 graduates and that of Doctor of Public Hygiene on 7. The orator was Dr. Joseph Swan of Swarthmore College. A portrait of the late Dr. Joseph Leidy was presented by Dr. George A. Peirsol on behalf of the donors.

At the annual commencement of Yale University on June 19 the degree of Doctor of Medicine was conferred on thirty-two graduates of the medical school.

Charitable Bequests.—By the will of the late Elizabeth Gome of Philadelphia the sum of $500 was bequeathed to each of the following institutions: Presbyterian Hospital, Presbyterian Orphanage, American Oncologic Hospital, and Home for Female Consumptives at Chestnut Hill.

By the will of the late Maria Mellon of Philadel-

phia the sum of $5,000 is bequeathed to the Presbyterian Hospital for the establishment and maintenance of a free bed in memory of the father of the testator, Mark Mellon.

By the will of the late Charles C. Hunsberger of Philadelphia his residuary estate is bequeathed in equal parts to the Methodist Home for the Aged and the Methodist Hospital.

By the will of the late Benjamin Bauer of Philadelphia, the sum of $2,500 is bequeathed each to the Jewish Hospital, the Jewish Maternity Home, and the Mt. Sinai Hospital for the establishment of free beds.

Rockefeller Institute.—The Board of Scientific Directors of the Rockefeller Institute for Medical Research, New York, has announced the following promotions and appointments: Dr. Alexis Carrel (Experimental Surgery) has been promoted to the rank of Member of the Institute. The following associates have been made associate members for a term of three years: Peyton Rous (Pathology and Bacteriology), Donald Dexter Van Slyke (Chemistry), Walter Abraham Jacobs (Chemistry), and Frank Watts Bancroft (Experimental Biology). The following assistants have been made associates: Paul Franklin Clark (Pathology and Bacteriology), Richard Vanderhorst Lamar (Pathology and Bacteriology), and Hardolph Wastenays (Experimental Biology). The following new appointments are announced: Harold Lindsay Amoss, assistant in Pathology; Clarence J. West, assistant in Chemistry; Wolfgang Ewald, fellow in Experimental Biology; Homer Fordyce Swift, chief resident physician; Francis Richard Fraser, and Frederic Moir Hanes, assistant resident physicians and assistants in medicine.

Chicago Medical Women's Club.—At the meeting held on June 12, the following officers were elected: *President*, Dr. Effie L. Lobdell; *Vice-Presidents*, Dr. Julia C. Strawn and Dr. Nora Sonle Davenport; *Secretary*, Dr. Sadie B. Adair; *Treasurer*, Dr. Agnes Mikkelsen.

Massachusetts State Medical Society.—At the annual meeting held in Boston on June 11 and 12, the officers for the ensuing year were elected as follows: *President*, Dr. Walter P. Bowers, Clinton; *Vice-President*, Dr. Francis W. Goss, Roxbury; *Secretary*, Dr. Walter L. Burrage, Boston; *Treasurer*, Dr. H. M. Buck, Boston. At the closing banquet on June 12 President Lowell of Harvard University and President McLaurin of the Massachusetts Institute of Technology addressed the society. Speeches were also made by Prof. David L. Edsall of the Harvard Medical School and by Dr. W. G. Thompson.

Maine State Medical Society.—After a very successful session in Portland the 60th annual convention was brought to a close on June 13 with the election of the following officers: *President*, Dr. Ralph H. Marsh, Guilford; *Vice-Presidents*, Dr. Theodore E. Hardy, North Vassalboro, and Dr. Joseph M. O'Connor, Biddeford; *Secretary*, Dr. Willis Bean Moulton, Portland; *Treasurer*, Dr. Edwin W. Gehring, Portland.

Obituary Notes.—Dr. Milton M. Rowley of Berkeley, Cal., a graduate of the Northwestern University Medical School, Chicago, in 1887, died at his home on June 4, aged 61 years.

Dr. George Buckingham Smith of New York, a graduate of the Hahnemann Medical College and Hospital, Philadelphia, in 1863, died at his home on June 8, aged 72 years.

Dr. Louis M. Early of Columbus, Ohio, a graduate of the Jefferson Medical College in 1881, died at his home in June from cancer, caused by exposure to the x rays during the course of experimentation, aged 52 years.

Dr. George H. Strowbridge of Portland, Oregon, a graduate of the University of Oregon, Medical Department, in 1897, a surgeon in the United States Army during the Spanish-American War, died suddenly at his home of apoplexy on May 31, aged 45 years.

Dr. H. Ross Coover of Harrisburg, Pennsylvania, a graduate of the Jefferson Medical College, Philadelphia, in 1880, a member of the Pennsylvania State and Dauphin County Medical Societies, and of the Harrisburg Board of Health, and coroner of Dauphin County, died at his home on June 3, aged 52 years.

Dr. Hext M. Perry of Greenville, South Carolina, a graduate of the Jefferson Medical College, Philadelphia, in 1872, died at his home after a long illness on June 9, aged 61 years.

Dr. John Robert Muse of Lexington, Tennessee, a graduate of the University of Tennessee, Medical Department, in 1878, and a member of the Tennessee State and Henderson County Medical Societies, died at his home on May 30, aged 67 years.

Dr. Albert Milton Williamson of Cincinnati, Ohio, a graduate of the Medical College of Ohio, Cincinnati, in 1871, died at his home in Hyde Park, on June 13, aged 68 years.

Dr. Henry M. Hitchcock of Greenwich, Conn., a graduate of the College of Physicians and Surgeons, New York, in 1861, died at his home of blood poisoning on June 19, aged 72 years.

Dr. Mortimer Howard Farmer, until recently a practising physician of Virden, Ill., a graduate of the University of Nebraska, College of Medicine, in 1885, died at his home in Springfield on June 9, aged 49 years.

Dr. Thomas W. Topham of Brooklyn, N. Y., a graduate of the College of Physicians and Surgeons of Indiana, Indianapolis, in 1880, died suddenly in an elevated railroad station in Brooklyn on June 15.

Dr. Edmund Carleton of New York, a graduate of the New York Homeopathic Medical College and Hospital in 1871, a member of the County Homeopathic Medical Society, consulting physician to the Metropolitan and Hahnemann Hospitals, emeritus professor of homeopathic philosophy in his alma mater, and a veteran of the Civil War, during the course of which he was the bearer of many important dispatches between the front and Washington, died at his home on June 15, aged 72 years.

Dr. Eberhard William Dittrich of New York, a graduate of the Bellevue Hospital Medical College, New York, in 1894, a member of the American Medical Association, the New York State and County Medical Societies, the New York Academy of Medicine, the Greater New York Medical Association, the Society of Medical Jurisprudence, and the Manhattan Dermatological Society; chief of clinic in the department of dermatology of the New York Post-Graduate Hospital, physician to the Northwestern Dispensary, Department of Dermatology, and dermatologist to the German Odd Fellows' Home, and Orphan Asylum, died at his home of heart disease on June 16, aged 51 years.

Dr. James V. Cornish of Quincy, Ill., a graduate of Rush Medical College, Chicago, in 1881, died in Jacksonville on June 16, aged 62 years.

MEDICAL COUNCIL MEETING—SURGERY OF ANEURYSMS COMMITTEE ON PATENT MEDICINES—INSURANCE COMMISSIONERS—B. M. A. SENDS DEPUTATION; ANNUAL MEETING; SCHEMES FOR PUBLIC SERVICE—OBITUARY.

LONDON, June 7, 1912.

SIR Donald MacAlister presided at the opening of the ninety-fifth session of the General Medical Council on Tuesday. In his address, having officially welcomed the new members and referred to the death of Lord Lister, whose memory the Council cherished as once a member, he passed on to speak of the Insurance Act. Several of the Council's amendments had, he said, been adopted in principle by the Government, but it remained to be seen whether the powers of the Commissioners sufficed to solve the questions in which the profession was interested. With the assistance of advisory committees, the Commissioners were preparing regulations for the administration of the medical benefits, and it might be that to appoint a special committee would be the best step for the Council to take to safeguard the interests for which they were responsible. In response to an official invitation from the Select Committee of the House of Commons on Patent Medicines he had named Dr. Tirard and Dr. Langley Browne as suitable witnesses to be called. Respecting the Dominion Medical Act, he had been informed that it was adopted by each of the Provinces of Canada, and if this proved to be the case the way was open for interprovincial reciprocity and the establishment of a Medical Register for the Dominion as a whole. No doubt these results would be followed by the application of the second part of the act. By the entrance of Canada into the Federal relation the ultimate establishment of British or imperial registration would be effected. Among other points referred to was the suggestion that if the Home Rule Bill should be passed the power of altering the Medical and Dentists Acts would be reserved to the Imperial Parliament. The new issue of the B. P., the president stated, was approaching, and it would be more adapted to the varied requirements of the whole Empire than its predecessors. He also announced a volume prepared by the solicitor to the Council, giving the cases which have been tried in the superior courts involving questions of interpretation of the Medical and Dentists Acts. Some changes as to registration of students and the curriculum were also mentioned.

The Council then appointed a committee of thirteen to consider the possible effects of the National Insurance Act on medical education and examination in relation to the efficient practice of medicine, surgery, and midwifery, to make representations thereon to the authorities concerned and report from time to time to the Council. Sir Charles Ball moved that the control of legislation on the Medical and Dentists Acts should, as had been suggested in the president's address, be reserved to the Imperial Parliament and this was agreed to *nem. con.*, it being shown that if no alteration was made in the bill it would become possible, if it were passed, for the Irish legislature to abolish all reciprocity of practice and put Ireland from a medical standpoint in the position of a colony or a foreign country. The executive committee's report was received and approved and other committees appointed and formal business transacted.

On Wednesday the Council considered the case of Dr. Wallace who had been summoned on the charge of being associated with the Sandow Institute. He was defended by counsel, but after a patient hearing it was decided that his name should be erased from the Medical Register.

Yesterday the Council had before it the report of the education committee on the standard of the preliminary examination of students in general knowledge. It is proposed after 1913 to raise the pass standard from 40 to 50 per cent. in each of the subjects, to abolish the principle of compensation, and, in order to reduce the prevalence of cramming to arrange that two sittings instead of one shall be allowed to candidates. It was proposed to enter the report on the minutes with a view of its being considered by those interested. After some discussion the Council adjourned that further consideration might be given to the subject.

Endoaneurysmorrhaphy—that is the pretty word coined by those who think it shocking to employ an English phrase to express one of the surgical procedures devised by Matas for dealing with aneurysm. His "obliterative method," which some of us think as expressive a term and as easy to pronounce, was advocated in the discussion at the Royal Society of Medicine by Mr. Gilbert Barling, who said it was applicable to any form of aneurysm but had been largely limited to the fusiform. The method is, after controlling the circulation above and below, to open the sac, close the orifices of the vessels entering it by means of sutures, and also the walls of the sac. Thus the aneurysm is obliterated. Mr. Barling said this operation had been performed sixteen times in the British isles. The advantages claimed for it are that the vasa vasorum are not so likely to be injured as by ligature, the danger to the main vein is much less than it is by proximal ligature or excision, and the collateral circulation is not so liable to disturbance. Nevertheless Mr. Barling has to report that gangrene followed in three cases, though all three survived after amputation. One case was lost from sepsis. It would appear that the chief danger is gangrene and that it is contraindicated when the circulation is seriously involved. In the discussion other methods were considered and the reputation of the surgical section well sustained by the eminent surgeons who spoke, but one would have liked to meet a larger number. The interest of aneurysm is unfailing notwithstanding that it is generally believed to be less frequent than formerly.

High Commissioner McNeal, attached to the office of the commonwealth has given evidence to the Select Committee on Select Medicines. He said importation into Australia might be prohibited on account of incorrect trade description of any goods. But the commonwealth parliament did not exercise jurisdiction over patent medicines manufactured in Australia. The customs restrictions had not been imposed for trade protective purposes but in the interests of the public health. In reply to a question he said it would not be permissible to import into Australia a medicine labeled "an unparalleled remedy" or "it never fails." Further questioned he replied that in many cases medicines from various countries had been excluded until their labels and printed descriptive matter had been amended.

The assistant director of public prosecutions has also given evidence. He said the public prosecutor took action only when he was instructed by

the attorney-general or home secretary. There was difficulty in obtaining evidence, people who bought things for certain complaints being unwilling to come forward. Moreover it was necessary to prove not only that the description was false but that the defendant knew it to be false.

To-day a deputation of the B. M. A. is to be received by the Insurance Commissioners. It is rumored that the association hopes to bring matters to a head by requesting a categorical answer to the question whether the commissioners will or will not concede the demands made on behalf of the profession and embodied in the "cardinal points" of which we have heard so much.

The B. M. A. is putting two schemes for a Public Medical Service before the profession—one for payment on a capitative system, the other per attendance. As the annual meeting comes on next month we may expect to hear something about them and the opinions they may give rise to. The meeting is this year to be at Liverpool.

Sir W. Thornley Stoker, Bart., died on Saturday night, June 1, aged 67. He was educated at Queens College and the Royal College of Surgeons, Ireland, taking an M.D. at the Royal University in 1860, becoming Fellow of the College in 1873. He was President in 1903-4 and in 1904-5. In the latter period he was also President of the Royal Academy of Medicine, Ireland, and again in 1905-6. He was consulting surgeon to the Richmond, Whitworth, and Handwiche Hospitals, formerly to the City of Dublin Hospital, an ex-governor of the R. Hibernian Military School and to the Academy, the National Gallery, and held many other posts of importance in Dublin. As a teacher of anatomy and surgery at the College and University he long held a high position. He was knighted in 1895 and made a baronet last year. He was left a widower in 1910 and there is no heir to the baronetcy. With his important surgical work your readers are well acquainted for he was in the forefront of his profession for many years.

The death is announced at the age of 77 of Dr. Henry Whitaker, late President of the Ulster Medical Society, who was superintendent medical officer of the city of Belfast for about twenty years. Late (Whitaker) lecturer on Sanitary Science, Queen's College.

Dr. Walter D. Fry, B.C.L., M.A., and M.B., Oxon., 1895, who was also a barrister of the Inner Temple, died suddenly on the 13th inst. He was elected last year coroner for a Yorkshire district.

Dr. Butler-Hogan, M.D., D.P.H., L.L.D., who was Medical Health Officer for Tottenham, died there on the 27th ult. at the early age of 47. He contributed various papers connected with sanitation to the journals. He was director of the bacteriological institution at Tottenham.

OUR CANADIAN LETTER.

(From Our Regular Correspondent.)

MEETING OF THE ONTARIO MEDICAL ASSOCIATION IN TORONTO.

Toronto, June 5, 1912.

The address of the president, Dr. Herbert A. Bruce of Toronto, contained matter of much interest to members of the medical profession of the United States. In the first place he discussed at considerable length the situation of the profession in Ontario with regard to osteopaths and the future policy of the medical council of Ontario toward such practitioners. Osteopaths in Ontario, as in the States, are numerous and aggressive and are using their utmost endeavors to be placed on an equal legal footing with fully qualified medical men. Bruce holds that a man has a right to practise any pathy he wishes, provided he has obtained a sufficient knowledge of the anatomy of the human body, its physiology, and the disease processes to which it is liable. Thus, those wishing to practise osteopathy should be compelled to pass an entrance examination equal to that of any practitioner of medicine, and in addition should pass a primary and final examination, which would include all the essential subjects, including their own method of therapeutics.

On the division of fees the speaker expressed himself in very decided terms. He said there could be no question that it was a pernicious system, fundamentally opposed to the ethical traditions of the profession and could not be advocated by any honorable man. It represented a form of collusion between the consultant and the general practitioner which was compromising and demoralizing to both parties, in that it was invariably practised without the knowledge of the patient, and was at the same time disadvantageous to the latter.

Dr. Alexis Carrel of the Rockefeller Institute gave an illustrated lecture on experimental researches in the surgery of the blood-vessels and the transplantation of tissues and organs. He narrated at length experiments undertaken by him in the direction of transplanting organs and tissues and held the close attention of his audience throughout the lecture.

Perhaps the most engrossing address given was that by Dr. George W. Crile of Cleveland, who took as his subject anoci-association. The following is a summary of Crile's address: All brain cells are not equally affected by inhalation anesthesia, certain cells remain awake, the subconscious mind remains active. These awake cells resist anesthesia and are injured to a greater or lesser degree by the trauma of the operation, and not only by trauma but by the effects of fear of the operation. These effects are manifested by changes in the pulse, respiration, and blood-pressure. Exposed portions of the body are supplied with a shock-resisting mechanism in the form of nociceptors in the nerve endings, but the brain has none of these; an operator may probe the brain and the patient will feel no pain. But physical injury to any sensitive part of the body having no nociceptors causes a discharge of nervous energy leading to exhaustion and shock. Equally may such a condition result to the patient through what he sees and hears. If a patient is in grave doubt whether or not he can survive an operation, if he has an entire lack of confidence in the hospital or in the ability of his surgeon, he makes a bad subject for operation and may be said to possess "a low threshold to stimuli." If under these conditions he is anesthetized and operated upon, the effect of any physical injury in that state will be augmented, and throughout the entire anesthesia and the entire operation the incidence of fear will be manifested in the pulse and the blood-pressure. Such patients stand operations poorly. This exhaustion is due to the driving of the motor mechanism as a whole, and the motor stimulation results from two great causes: the first is the stimulation of the nociceptors of the body—physical injury, and the second, stimulation through the special senses. But whatever the causes the stimulus is

always through the awakening of associated memory. All action must be from philogenetic association. Harmful associations are called noci-associations, but if an operation is planned so that all harmful associations are prevented this state of the patient is called anoci-association, a state of the brain in which there is no discharge of nervous energy. How can the principles of anoci-association be carried out? First, the surgeon must be thoroughly competent, and the patient must be confident of the fact. All the surroundings must be so controlled by the operating surgeon that he can truthfully tell his patient that the operation will be distinctly safer than the disease from which he is suffering, that the operation will be so conducted as to be devoid of painful or dramatic incidents, that the patient will have no unpleasant experiences to reflect upon afterwards. The patient may be further protected from the harmful influences of fear by the administration of morphine, or of morphine and scopolamine. The anesthetic should preferably be administered by a woman because somehow the world has more confidence in the ultimate good intentions of a woman than it has in those of a man. Anoci-association induced by the preliminary exhibition of nitrous oxide. When the patient is under the anesthetic, anoci-association is carried further by so conducting the operation that the brain itself may be entirely isolated from the field of operation by the careful infiltration of the entire field of operation with a solution of novocaine 1-400. Further, the operator must use the minimum amount of traction and the maximum of accuracy and gentleness. In this manner the operation, however extensive, may be performed without materially driving the motor mechanism. At the close of the operation the patient may be given an injection of quinine and urea hydrochlorate. The after pains and the postoperative nerve exhaustion will be thereby very materially decreased in the case of abdominal operations, it is pleasant to note that the distressing gas pains are almost wholly avoided. In this way we arrive at a shockless operation. The practice of anoci-association has markedly reduced the mortality following operation and the patients more often recovered from the disease affecting them. Anoci-association has taken from surgery much of its stigma of harshness, and to an almost incredible degree preserves the nervous system of the patient.

As pointed out before, the main feature of the meeting was that most of the time was given up to clinical demonstrations. On May 22 clinics were held at the Medical Building of Toronto University, in medicine, surgery, ear, eye, nose, and throat, x-ray, and pathology. Among the cases shown in the medical section was one of leprosy. On May 23 clinics were held at the General, St. Michael's, Grace, and Western Hospitals and at the Asylum in Queen street, where interesting cases of various kinds, medical, surgical, gynecological, and mental were shown by the members of the staff. Dr. G. W. Ross gave in his laboratory at the General Hospital a description of the principles and technique of vaccine therapy. A woman suffering from osteoarthritis of the finger joints, who had been successfully treated by mixed vaccines, was presented. Dr. Graham Chambers showed a case of bradycardia exhibiting the Stokes-Adams syndrome, and a case of Hodgkin's disease associated with tuberculosis.

The following officers were elected for the coming year: *President*, Dr. Charles MacGillivray, Port Hope; *First Vice-President*, Dr. A. T. Shillington, Ottawa; *Second Vice-President*, Dr. Taylor, Goderich; *Third Vice-President*, Dr. W. T. Park, Woodstock; *Fourth Vice-President*, Dr. I. H. Hare, Cobalt; *Secretary*, Dr. F. A. Clarkson, Toronto; *Treasurer*, Dr. J. H. Elliott, Toronto.

Dr. Herbert Bruce, the president for the year, gave a garden party at his residence on May 22, at which the Duke of Connaught was present. The annual banquet of the association was held on the evening of May 22, at which a good deal of speech-making took place. On the whole the meeting just held was the most successful in the annals of the Ontario Medical Association.

OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

BACILLARY DYSENTERY — THE PLAGUE — MANILA WATER SUPPLY—MILK FOR CHILDREN—DEATH OF DR. FREER.

MANILA, P. I., April 25, 1912.

JUDGING by the official reports for the ten years preceding 1910, the Philippines were comparatively free from bacillary dysentery. Whether this disease was actually absent, or whether it was confused with the cholera which was more or less constantly present during that period, is not known, but at all events, during the past two years, frequent outbreaks of typical Shiga bacillary dysentery have been encountered from time to time. Several hundred deaths occurred at Barotac, in the Province of Iloilo, the direct cause being that the river, from which the inhabitants obtained their water supply, became infected immediately above the town. During 1910 there was a severe outbreak at Batangas, Batangas Province. The disease was especially severe at the Army post of Camp McGrath. The laboratory investigation of this outbreak resulted in the isolation of the Shiga organism. It was later ascertained that a large proportion of the cases were no doubt due to the water becoming infected from which the ice for the post was made. The persons who were using distilled water seemed to suffer more severely than those who did not; the explanation for this became apparent when it was ascertained that these were also the persons who were the principal users of ice. This year, soon after the Government bureaus were transferred to Baguio, outbreaks of diarrhea were reported. An investigation showed that approximately ten per cent. of the employees were affected. At first there was a disposition to attribute the diarrhea to the altitude and the lower temperature which prevails in Baguio, but a sanitary survey made of the town showed that bloody stools in unprotected places were very common, and that no adequate arrangement existed for the disposal of human excreta. Owing to a severe pest of flies which prevailed, and due to the careless habits of domestic servants in not properly cleansing their hands, the factors were present for rapidly spreading this disease. It was also later discovered that it was customary for some of the servants to wash the table utensils of many of the Filipino employees in the discharges from the septic vaults. Upon correcting these conditions, an immediate reduction in the number of cases took place. Arrangements were immediately made for the burning of all horse manure, and between three and four weeks after this was actually

accomplished, there was a great reduction in the number of flies, and there is every prospect now that they will soon disappear almost entirely. In this particular outbreak, public confidence in sanitary measures was considerably shaken, because it was believed that bacillary dysentery was largely spread by water, and as the greatest precautions had already been taken by all residents to drink only boiled or distilled water, it was difficult at first to assign a satisfactory reason to the outbreak of dysentery, and considerable uneasiness resulted. As soon as excreta was properly disposed of, however, the improvement was very marked, and now the disease has disappeared entirely.

No further cases of plague have been encountered on vessels coming from foreign ports, but in view of the fact that three vessels arrived within such a short period with cases of pneumonic plague on board, the Philippine authorities have imposed additional quarantine restrictions with the view to reducing the danger of the introduction of this disease. In addition to placing a seven-day quarantine against steerage passengers from Hongkong, similar quarantine has now been imposed against Amoy. On account of the large number of vessels which arrive from Saigon with rice, and since there is plague present at that port, it has been deemed advisable to insist upon the fumigation of all vessels with sulphur at Saigon, before loading cargo.

Additional precautions have also been taken with regard to wharf regulations at Manila and the other ports of entry, and steps taken to reduce the number of rats that are present, along the waterfront, and particularly in the grain warehouses.

The Manila water situation still continues to become more acute. It is now not only a question of using polluted water, but, on account of the continued drought, serious difficulty is being encountered in supplying the city with sufficient water of any kind. During the past week this difficulty was accentuated by one of the pumps of the Santolan Pumping Station becoming disabled. At the present writing, unless the rains soon come, an actual water famine will have to be faced in the city of Manila. The sprinkling of streets, lawns, and the use of water for other garden purposes, has been prohibited, and an effort is being made to reduce the consumption of water as far as possible. Copper sulphate, in the proportion of one to three million is being used in the city water supply. It is yet too early to know what effect this is having toward reducing the bacterial count, and particularly the elimination of pathogenic organisms. In addition to the foregoing, the Bureau of Health has given instructions that placards be printed and handbills be distributed in English, Spanish and Tagalog, warning the people to boil the water before using it. Arrangements are also being made with the local newspapers for "liners" to be printed in every column of every edition, in every newspaper in the city of Manila.

The Society for the Protection of Infants (Gota de Leche) has just completed a number of buildings, located near Pasay, on the outskirts of Manila, for the purpose of conducting a dairy farm, in order to furnish the Gota de Leche with the necessary amount of fresh milk. The plot of ground consists of about five acres, and has six modern cow-sheds with cement floors, water installation, and septic tank for the disposal of excreta. Mr. Nathan Straus has recently donated a complete sterilizing equipment and an additional quantity of bottles and other necessary materials for the distribution of milk. This equipment is similar to that which Mr. Straus installed at Washington, D. C.

Dr. Paul C. Freer, director of the Bureau of Science, died at Baguio on April 17th. The direct cause of his death was due to general peritonitis, but he had long been a victim of arteriosclerosis, and it was the advanced stage of this disease that no doubt was responsible for his death. Dr. Freer came to the Philippine Islands as the superintendent of the Government Laboratories, in 1901, and was later made director of the Bureau of Science. He was dean, and one of the founders, of the Philippine Medical School. It is directly due to his efforts that the Bureau of Science has become an institution which is known throughout the civilized world for high-grade research work, and has been a great factor in aiding in the solution of many of the problems connected with tropical medicine.

1. **The New Hospitals of Harvard Medical School.**—J. C. Warren states that new hospitals are springing up in every direction on the grounds about Harvard Medical School, and a great scheme seems to have reached its fruition. These hospitals include the Peter Bent Brigham Hospital, the Huntington Memorial Hospital, the Infants' Hospital, the Children's Hospital, the Psychopathic Hospital, and additions to the Free Hospital for Women. All these institutions when grouped together will represent a plant valued at $15,000,000.

2. **The Peter Bent Brigham Hospital.**—H. B. Howard mentions among the many admirable features of this institution which is now in process of construction on grounds adjacent to those of Harvard Medical School, the five ward buildings which are upon a higher level than the rest of the institution so that the garden of the patients will be better drained. Each ward is made for forty patients and is surrounded by terraces so that the beds can be easily rolled out upon them, and the patients upon these terraces can be in the shade or in the sun, as is desired. Part of this typical ward building is one story high, part two stories, and part three stories, the highest being the northerly part of the building. This arrangement is to keep one ward building from shadowing another.

5. **The New Children's Hospital.**—R. W. Lovett, in describing this addition to Harvard's hospital scheme states that there are two peculiar requirements in a children's hospital dealing with surgical and orthopedic cases: first, facilities for outdoor treatment must form an integral part of the institution, and, second, the arrangement must be such as to minimize the danger of the spread of infectious diseases in the wards. Again and again it has been experienced that a ward of twenty beds would have to be closed because of the occurrence of one case of measles or scarlet fever, and in addition to the unnecessary

illnesses contracted in this way, the work of children's hospitals has been very seriously impaired by the large ward unit. Therefore the small ward unit furnishes the solution of the difficulty. Each pavilion in the new Children's Hospital is to contain twenty beds, and these beds are to be divided into two units of ten each at different ends of the pavilion, the children of the two units never coming in contact. One or two ward units will always be kept vacant, so that if an infection occurs the ward has simply to be quarantined until emptied and then disinfected.

11. **Skin Grafts and Organic Dyestuffs in the Hastening of Wound Healing.**—J. S. Davis, in concluding his article on this subject states that although skin grafting is being utilized each year more and more, nevertheless its value is not yet fully appreciated, and many cases are dressed week after week and allowed to heal by granulation which could be closed by grafting a much shorter time, and eliminate, to a large extent, the chance of future cicatricial contraction. The organic dyestuffs used for the purpose of hastening wound healing are the following: the sodium salt of diazo-azobenzene-disulphonic acid Beta naphthol (commercial name, Biebrich Scarlet Red); benzene-azobenzene-azo Beta naphthol (commercial name, Soudan III); toluene-azotoluene-azo Beta naphthol (commercial name, Oil Scarlet); the sodium salt of xyleneazo Beta naphthol monosulphonic acid (commercial name Scarlet G. R.). The technique of applying these dyestuffs is as follows: Every effort should be made to bring the wound into a healthy condition as soon as possible. Anoint the skin surrounding the defect with some bland ointment up to about 1 centimeter of the wound edge, as this prevents possible irritation. Then spread the scarlet red or amido-azotoluol ointment in a thin layer on perforated old linen, and apply to the wound, either along the edges or over the whole surface. A light dressing of sterile gauze secured by a bandage completes the procedure. The strength of the scarlet red and amido-azotoluol ointment ordinarily used is 8 per cent. in a vaseline or vaseline and lanolin base, and it should be alternated every twenty-four to forty-eight hours with some bland ointment. By applying a weak ointment, say 4 per cent, it can be used over longer periods. Scarlet red and amido-azotoluol will not heal every granulating wound, but in the majority of cases, when applied with the proper technique, they will cause epithelial stimulation in the edges of the most sluggish wounds and give a rapid healing which is stable and resistent, and which has the macroscopic and microscopic appearance of the normal skin. There is no tendency to subsequent contraction, and the skin becomes movable on the underlying tissues in a reasonable time. Any one of these characteristics would make the use of these substances well worth trying.

1. **Sex Issues from the Freudian Standpoint.**—By J. J. Putnam. (See MEDICAL RECORD, May 11, 1912, page 918.)

2. **Phases of Prostatic Disease.**—L. Bolton Bangs reports a series of cases illustrating these phases. One of these is prostatic hyperemia causing the symptoms of pain or aching in the perineum, frequent urination, and diminution of sexual vigor. In many of these cases which are frequently found in bicyclists and horseback riders, there are besides the prostatic lesion minor traumatisms of the bulbous urethra which intesify the effect upon the patient's nervous system and prolong his malady. Long continued abuse or overexcitation of the sexual apparatus, especially during adolescence, produces a chronic hyperemia which, in turn, induces a sexual irritability of the presiding brain areas. If, as is frequently the case, in addition to the habit of masturbation (and even if the latter has been overcome), there is association with a person of the opposite sex who permits dallying, even if coitus is not indulged in, an excessive dilatation of the bloodvessels of the prostate takes place. As this indulgence is generally too frequently repeated, the bloodvessels remain continuously dilated and a condition of nerve exhaustion with mental depression, together with other abnormal symptoms, becomes manifest. In cases of this nature the author has proposed prostatic massage as a therapeutic measure. Another phase of prostatic disease which is worthy of consideration is that, when the organ enlarges it forms a dam, behind which urine is retained, thus forming a culture chamber, in which various forms of bacteria germinate. Even if the obstruction to the outflow of urine is of a very moderate or minor degree, relief of symptoms and restoration of the urine to a normal condition will be impossible without the removal of the obstruction.

3. **Uses of Combined Organic Extracts.**—F. R. Starkey has tested the therapeutic value of the combined use of thyroparathyroid, pituitary, ovarian, and testicular extracts. He concludes that the polyglandular substance has a marked stimulating effect, and that in acute asthenic conditions with low blood pressure and suboxidation it activates the vital process and thus tides the patient over the most critical stages of the disease, while increasing the efficiency of his autoprotective resources. The same polyglandular solution seems also to be almost a specific for neurasthenia. It has a marked stimulating effect on mental, nervous, and muscular activity as well as on general metabolism and oxidation. It augments powerfully the contractile power of the cardiovascular system, and is, therefore, contraindicated in cases of high blood pressure. Finally, it increases the action of other drugs, arsenic, mercury, iodides, and salicylates in particular, and their curative efficiency.

7. **The Effect of Infundibulin on Mammary Secretion.**—J. C. Scott reports the history of a case in which severe labor was followed in five days by a severe postpartum hemorrhage, the milk secretion improving within three or four hours after the hemorrhage, at which time infundibulin was administered. The marked improvement in the quantity and quality of the milk is attributed to no other factor than to infundibulin.

5. **Blood Cultures in Pneumonia.**—H. W. Lyall presents an analysis of a series of cases of pneumonia which were characterized by a low total death-rate, and in which blood cultures were positive in only 40 per

cent. The total number of cases was 42, of which 17, or 40.5 per cent., were positive and 25, or 59.5 per cent., were negative. The total mortality was 11, or 26.19 per cent.; 5 patients who died were alcoholics. The positive cases showed a mortality of 8, or 53.5 per cent., among which were 4 alcoholics. The negative cases showed a mortality of 3, or 8 per cent., one patient who died was an alcoholic. On account of the incidence of alcoholism it is difficult to draw any definite conclusions as to the relation between positive findings and prognosis. All cases at the time of or after crisis or lysis gave uniformly negative results.

7. **Myasthenia.**—D. Riesman reports a case of this condition occurring in a man who was suddenly seized with profound weakness involving apparently all the voluntary muscles, causing no psychic, sensory, or sphincteric disturbances, but marked by bradycardia, subnormal temperature, and bradypnea. A facial palsy ensued ten days after the onset of the myasthenia. Recovery was complete in about two months. Two other cases somewhat similar which recently came under the author's observation and an experience of his own while a medical student are also reported. In all these cases there was a physical weakness amounting to actual prostration, a feeling of coldness, a subnormal temperature, and in two cases slow pulse and low blood pressure. Recovery was prompt in all, though the feeling of impending death was quite acute during the attack. Riesman finds the easiest explanation of these cases in the assumption of some disturbance of the internal secretions causing changes in the sympathetic system and voluntary muscles. The chief controller of these two systems is the adrenal or, better, the chromaffin system. The functions of this system are manifold and complicated, but the two that particularly concern one in this connection are the angiotonic, controlling vascular tone and blood-pressure, and the antitoxic through which the fatigue products of muscular activity are neutralized.

8. **The Chicago Epidemic of Streptococcus Sore Throat.**—J. A. Capps and J. L. Miller report the incidence of a recent epidemic of streptococcus sore throat in Chicago. It was conservatively estimated that over 10,000 persons in Chicago were victims of epidemic sore throat. Of the total of 622 cases that were investigated, 530, or 87 per cent., were users of milk from a certain dairy—Dairy X. Of nineteen fatal cases investigated, fifteen, or 79 per cent., were users of this milk. A comparison of the prevalence of sore throat among consumers of X milk with that of consumers of milk from another dairy in the same neighborhood showed that the morbidity ratio was fourteen times as great among the former as among the latter. This ratio prevailed in three widely separated districts of the city. An epidemic of mastitis, involving 46 per cent. of the cows supplying milk to the Dairy X occurred during the winter months. Sore throat of the epidemic type was prevalent among the farmers and milkers supplying Dairy X. Often bovine mastitis and human sore throat prevailed on the same farm at the same time. A virulent streptococcus was isolated from the milk of a cow with chronic mastitis and from the throat of a girl on the same farm, who had been ill with sore throat and arthritis. The pasteurization records reveal a remarkable degree of failure to maintain a proper temperature. The days on which the most striking failures of pasteurization occurred shortly preceded the great outbreaks of sore throat. The remedy is to be found in more careful inspection of cows and milkers, and, most important of all, in efficient pasteurization.

The Lancet.

June 8, 1912.

1. **Acute Infective Processes Due to the Streptococcus.**—W. Girling Ball states that for practical purposes it is convenient to place the various diseases caused by streptococcus under one of two headings: (1) a local group, in which it is not possible to recover the infecting agent from the blood stream by the ordinary methods of cultivation; or (2) a septicemic group, in which an investigation of this nature yields a positive result. The treatment adopted has first consisted in the use of the ordinary surgical methods. The use of vaccines and sera has only come in as an adjuvant to the treatment, in some cases as a routine, in others where the surgical methods have failed to bring about the desired result. The ground on which the author bases his claims of vaccine-therapy are as follows: (1) the favorable effect it has on the course of the temperature chart; (2) the prevention of recurrences in conditions in which they are common; (3) the improvement in the signs of the local disease, and (4) the change for the better in the general condition of the patient. The following method of treatment is suggested: After an accurate clinical diagnosis, and after having dealt with the lesion surgically, serum should be given at the earliest possible moment, either locally as a dressing, intravenously, subcutaneously, or by the rectum. Following the use of the serum, or in combination with it, a vaccine should be injected as soon as it has been prepared. As a general rule, an autogenous agent is preferable, but it may be replaced by one prepared from a mixture of streptococci of the same type which are known to commonly cause the type of lesion from which the technique used has failed to isolate it. Moreover, stock vaccines may be used during the preparation of the autogenous agent. The more acute and the more generalized the lesion the smaller should be the dose introduced. Having obtained no effect as the result of the smaller dose it should be increased gradually until such is reached which will produce the desired reaction. On the other hand, if a harmful effect is observed, then a smaller dose is indicated, or even vaccine-therapy contraindicated.

2. **Clinical Notes on Blood Plates.**—E. M. Brockbank concludes as the result of a prolonged series of observations that the bodies met with in blood smears which have been fixed and stained in the ordinary way, and known as blood plates, all arise from the interior of red corpuscles, many of which manifestly burst as the blood plate material escapes from them.

3. **Rheumatic Form of Ulcerative Endocarditis.**—C. E. Coombs states that the hearts from seven cases of streptococcal ulcerative endocarditis have been subjected to a thorough histological examination. The findings in all the cases were substantially identical, in spite of wide clinical differences in their virulence and in their relation to previous rheumatism. No histological evidence of a directly rheumatic origin was forthcoming, even in those cases in which the rheumatic factor was most in evidence clinically.

1. **Chronic Diarrhea in the Adult.**—R. Hutchison points out that diarrhea is a symptom and not a disease. The chief varieties of chronic diarrhea met with in practice are classified and described as follows: (1) Gastrogenic diarrhea. This is a form due to imperfect digestion in the stomach, which in turn is caused by an insufficient secretion of gastric juice often amounting to complete achylia. (2) Pancreatic diarrhea. This is a form of diarrhea attributed to pancreatic insufficiency, either from blocking of the pancreatic duct, from chronic pancreatitis, or from a functional pancreatic achylia. (3) Fermentative diarrhea, caused by an imperfect digestion of starch. (4) Enteritis. This is a form of diarrhea that is distinctly rare in the adult. Its most frequent causes are alcoholism, cirrhosis of the liver, and pulmonary tuberculosis. (5) Colonic diarrhea. This is the most common form of chronic diarrhea, and its three commonest causes are malignant disease, catharrhal colitis, and ulcerative colitis. Malignant disease is frequently overlooked, for the diarrhea caused by it is not characteristic. Catarrh of the colon is one of the commonest causes of chronic diarrhea. The diarrhea in these cases is often of the explosive "morning" type. In cases of ulcerative colitis, whether dysenteric or non-dysenteric in origin, the stools tend to have more of the true colonic character than in any other form of diarrhea, blood and mucus being usually present, while tenesmus is not infrequently complained of. (6) Nervous diarrhea. In this form the disorder appears to result from an exaggerated irritability of the nerve mechanism which controls peristalsis. There are two types of this variety. In one type, to which the term "post-prandial" or "lienteric" diarrhea has been applied, the action of the bowels tends to take place immediately after or even during meals. In the other type the diarrhea is brought on by emotional impressions.

2. **The Relation of Biology to Pathology.**—By Hastings Gilford. (See page 1231.)

3. **Ulcerous Lesions of the Tongue.**—J. H. Evans states that the "simple ulcer" is recent in appearance and of obvious causation—for example, a sharp tooth, local trauma, or glossitis and is characterized by the absence of neuralgic pain, the absence of peripheral induration, and, though tumefaction may not be evident to the naked eye, a certain amount of local edema is distinctly seen by means of a lens; further, there is possibly an absence of lymphatic enlargement and an absence of foul deposit on the neighboring teeth. The tuberculous ulcer, situated generally on the dorsum or at the tip of the tongue, is readily recognized as a pallid solitary sore, often of considerable depth with sharply cut edges, and an indolent base usually devoid of induration, and almost invariably associated with pulmonary or laryngeal tuberculosis in young adults. Though actinomycosis is not common in the human subject it should be borne in mind (1) that its most frequent avenue of entrance is the mouth; (2) that the only positive diagnostic evidence is the presence of the actinomyces; (3) that the occurence of this disease is diagnosed absolutely by its yellow granules visible to the naked eye and greasy to the touch, which, when placed under the microscope, reveal the distinctive character of the growth. Lingual papillitis—a frequent associate of gastric disturbance, and often found in syphilitics—is predominated by a burning pain in the anterior two-thirds of the tongue, increased by any food except the most bland diet. Scarcely any lesion can be detected by the unaided eye, but the lens will bring into view a varying number of minute red spots, as though they were truncated bases of hypertrophied papillæ with exposed nerve endings in the minute painful ulcer. Syphilis of the tongue is probably the most common of all diseases of the tongue, being found as the following ulcerous lesions: 1. Superficial: primary infective focus or chancre—rare; fissures and ulcers on the dorsum of the tongue—irritable and sensitive to the touch; ulcerous indentations around the edge of the tongue; sessile warty growths—often multiple; patches of faint leucomata; and denser patches of leucoplakia. 2. Deep: indurated masses—gummata—which form in the substance of the tongue, with an upheaval of the surface, and on breaking down leave a crateriform excavation with little or no peripheral induration, but with its deep base covered by a dirty grayish-yellow secretion. Cancer of the tongue is of frequent occurrence in males over the age of 40 who may be addicted to alcohol or tobacco, who frequently partake of irritating condiments, or who practise any of the different habits of chewing. Any long-continued wart, hard lump, or unhealed ulcer on the tongue or gums is liable to become the seat of cancer. Close attention to the cleanliness of the mouth and the brushing of the teeth is advisable. There is no more frequent precursor or accompaniment of cancer of the tongue than syphilis.

Münchener medizinische Wochenschrift.

June 4, 1912.

The Berlin Diphtheria Epidemic of 1910-11.—Blühdorn, of the Division of Infectious Diseases of the Rudolf Virchow Hospital, Berlin, refers to the severity of diphtheria in Berlin during the past two years and the opportunity thereby furnished for testing serotherapy. The severity did not lie in the mortality, which was but 11 per cent. in 203 cases, but in the number of patients who required tracheotomy and who presented sequelæ. Many adults were attacked. Generally speaking, the first two days of the disease were severe, and patients seemed very ill. This severity was doubtless responsible for the development of the complications and sequelæ. As usual, the patients came largely from the lowest social strata. Under these circumstances the effects of the serum in arresting so severe a disease were all that could have been expected. In 151 patients, all severely attacked, who were injected at the beginning of the disease, but 4 died, less than 3 per cent. In many cases very large serum doses were not only begun, but repeated. The point of interest was that with such a prompt response to specific treatment complications were not averted to the same extent. The sequelæ consisted largely of paralyses of the usual post-diphtheritic types, including cardiac weakness, paralysis of velum palati, ophthalmoplegias, vocal cord paralyses, etc. Of complications proper there were laryngeal diphtherias, myocarditis, and nephritis. When a deadly disease like diphtheria has its mortality cut down fourfold we must expect the survivors to present accidents which were formerly present in a more restricted number.

Inferior Tracheotomy in Diphtheria and Postdiphtheria.—Loede of the Hamburg-Eppendorf Hospital describes this resource in detail, with numerous photographs of children so treated. For cosmetic purposes the cutaneous incision is short and transverse. The transverse incision was counseled by Frank about two years ago for superior tracheotomy. That today tracheotomies are being elaborated in epidemics of diphtheria with not even a mention of intubation as a competitive procedure is a document to the provincial element in medicine. The author gives a table of 150 tracheotomies in diphtheria with a mortality of about 50 per cent., which coincides with the original death rate whenever this resource was employed. Evidently when a patient is in such straits as to require tracheotomy his chance of survival is no better than it was fifty years ago. Naturally the proportion of diphtheria patients requiring this intervention is much smaller, although in certain epidemics it is not inconsiderable

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

THE PHYSICAL EXAMINATION.

NON-ORGANIC MURMURS.—Every murmur heard over the heart does not point to disease of the valves or the orifices of the heart. Murmurs may therefore be classed as organic and non-organic, the latter class being commonly known as "functional." It is frequently difficult to differentiate one from the other, and whenever the examiner does not feel sure as to the true nature of the sound, he should not hesitate to re-examine the heart on another day, especially if the applicant is nervous or has been through some unusual mental or muscular exercise just before the interview.

The company should always be given the benefit of the doubt when there is any indecision in the diagnosis. This is especially true in the so-called functional murmurs at the base, which have shown a very high degree of mortality. If any injustice is inflicted on the applicant by pronouncing a functional murmur to be organic, this may easily be rectified later; but if a murmur reported as functional turns out to be organic, an impaired risk has been put on the books and the policy will be beyond recall.

When the examiner is convinced after an extra careful examination that the accidental sound is not significant of any pathological lesion or abnormal condition, he should omit all reference to it in his report. The medical officers at the home office will surely feel that if the murmur is important enough to report, they will have to reject the risk or request the examiner to make a further investigation. The examiner is relied upon not only to be exceedingly painstaking in his medical examination in these cases, but also to carefully ascertain the size of the heart and the condition of the blood vessels.

Functional Murmurs.—The true "functional" murmurs are apt to be associated with anemia or with some special attack upon the resources of the body such as physical overstrain or fever. They usually disappear when the underlying forces are removed. They are almost always systolic in time, and usually heard with maximum intensity in the pulmonic area, especially at the end of inspiration. They are rarely transmitted beyond the pericardiac region. There is no evidence of enlargement or significant accentuation of the 2nd sounds at the base. It is often difficult to decide whether these murmurs are organic or non-organic, but as they are caused by other disturbances which, even though temporary, make the risk undesirable at the time, the examiners task becomes the simple one of recommending postponement.

Murmurs During Rapid Action.—Faint systolic murmurs are heard at times when the heart action is unusually rapid. These sounds are apt to disappear during the latter part of the examination or when the applicant assumes the recumbent position. They are possibly due to insufficient time during the rapid action for perfect closure of the valves—a temporary insufficiency. If such a murmur does not clear up during the first examination, it will usually have disappeared before a second interview after the applicant has had an opportunity to recover from general nervousness or excitement.

Dynamic Murmurs.—These sounds are occasionally produced at the base by a forcible distortion of the chest wall, such as may occur during the excessive contraction of the muscles in certain unnatural postures or during efforts at extreme forced expiration or inspiration of the lungs. The same sounds may also be the result of heavy pressure by the stethoscope on exceptionally flexible chest walls.

Cardio-Respiratory Murmurs.—This form of non-organic murmur is the one most frequently heard. These murmurs have no pathological significance unless caused by extensive adhesions between the pericardium and pleura, but are often troublesome to the examiner. They are usually caused, probably, by the forcible displacement of air in a portion of the free margin of the lung overlapping the heart. If the murmurs are accompanied by friction sounds denoting adhesions they should be reported, but if the examiners are convinced that they arise purely from the impact of the heart with the lungs they should be ignored.

These murmurs are systolic in time in the vast majority of the cases, and are confined to a limited area. Their quality varies from that of a soft, breezy, blowing murmur to one closely simulating a friction sound, but as a rule it is soft and resembles that of the ordinary respiratory murmur.

The murmurs will have some or all of the following marked characteristics, which render valuable assistance in diagnosis:

1. There is well marked alteration in intensity by crescendo and diminuendo variations during inspiration and expiration.

2. They become obliterated as a rule while the applicants hold their chests for a few seconds, either in a position of forced inspiration or forced expiration or when they simply arrest respiration. A true cardiac murmur cannot be made to disappear.

3. They are usually heard more distinctly at the end of inspiration, whereas true cardiac murmurs become more faint at that particular time.

4. They are usually heard over a limited area and seldom transmitted to the left axilla or to the back.

5. They are not associated with hypertrophy or accentuation of the second sound.

6. They may be greatly modified by pressure exerted on the thoracic wall in the vicinity of the murmur, both as to intensity and quality. Organic murmurs are but little, if any, influenced by this procedure.

7. The position of the applicant will often assist the examiner. Almost all the cardiac murmurs are affected to a greater or less degree by the position of the body through the change in the blood-pressure in the region of the heart. Some organic systolic murmurs which are almost inaudible during the sitting or standing attitude, may easily be heard when the applicant lies down. The cardio-respiratory murmur will often disappear in the supine position.

ACCENTUATION OF HEART SOUNDS.—Accentuation of both sounds is not uncommon in health when the action of the heart is forcible on account of nervousness. The accentuation will often disappear during the examination, but if it does not and no serious disturbance capable of producing it can be discovered, the applicant should be given the opportunity of undergoing a re-examination before the final decision, when the sounds may be found normal. In such cases, the accentuation is of no moment and may be omitted from the report, but only after the examiner has looked carefully for more serious causes. When the accentuation is re-

ported, the examiner should state explicitly whether or not he has made an extra effort to ascertain the cause and if he has any suspicion that the changed sound is significant of serious trouble. If the officials at the home office are not informed that a careful investigation has been made, they will invariably ask for it when the mere fact that the applicant has an accentuation is reported.

Pathological accentuations are met with when there is increase of blood-pressure in the systemic or pulmonary circulation. Whenever, therefore, an accentuation of the first or second sounds is marked or persistent, the examiner should make a most rigid examination for the detection of arteriosclerosis, Brights, mitral disease or cardiac hypertrophy.

Reduplication.—It is not uncommon to hear an occasional reduplication of the first and second sounds in healthy subjects. When the reduplication is marked or persists, however, there is probably some increase in blood-pressure in the systemic or pulmonary circulation, or changes in the walls of the heart, which must be carefully investigated. The suggestions and precautions offered in the previous section on Accentuation, are equally applicable in these cases.

Life Insurance for Medical Men.—Although the endowment policy has many attractions, there is still nothing superior to the ordinary life policy for the physician. This is no longer old-fashioned, but is modern, because of its elasticity and the many options granted to the insured. By paying a very little more the annual payments on this policy can be limited in number from the start; they can be reduced and finally extinguished at or about the pension age by the operation of the bonus, or single extra payments can be made at any convenient times for the same purpose. The ultimate cost of an ordinary life policy can be ascertained at the outset, as in an endowment insurance. On the other hand, it may be argued that the superiority of the endowment insurance lies in the fact that the sum insured is payable during lifetime. True, the holder of an endowment policy handles his capital if he survives, but unless he is prepared to spend it, only the income resulting from its investment is available. In this respect his position is not overwhelmingly superior to the life policy holder whose capital is securely locked up for the benefit of his dependents, and whose policy, once the premiums are extinguished, also produces an income in the shape of bonuses which can be drawn in cash. While the life policy yields less to the insured in his old age it has provided a far greater measure of protection during the most important and most hazardous years of working life, and in this way has more adequately met the wants of the professional man dependent upon his earned income. Officials of insurance offices more often than not take the line of least resistance, and if the public show a preference for an endowment policy, an endowment policy will be supplied. A life insurance contract is made up of two important parts—protection and savings, that is, accumulation of premiums. In one form of policy the protection element is emphasized; in another the savings element predominates, and it is only possible to increase the savings payable in old age by taking away from the protection benefit. Let the prospective insured carefully consider which is of greater importance—the successful accumulation of a sum of money payable at the end of a period which may or may not be survived, or immediate adequate protection against premature death, for herein lies the answer to the question, which is the most suitable policy for medical men? If responsibilities have been incurred, then the necessity of life insurance must be more pressing in the early years before savings have been accumulated or legacies inherited. The requirements of old age, always an unknown quantity, can be and often are provided for by the exercise of thrift during the later stages of life. The demands for the protection of life insurance are, on the contrary, never more urgent than when they first become manifest. In the majority of cases, therefore, the first requirement is a whole-life policy, the amount of protection under which will be from 25 to 50 per cent. more than that secured under the endowment policy. Suffice it to say that, while the endowment policy is a modern product, and in some respects very attractive, the whole-life policy has stood the test of time, and has been so improved in its form as to supply nearly all the wants which called the endowment policy into being.—*British Medical Journal*, April 6, 1912.

The Local Medical Examiner, the Medical Director, the Insurance Company, and the Public Health.—There is little doubt that the local medical examiner for an insurance company is a most important factor in the examination of applicants for insurance. Indeed, it is more or less essential to the company that the local examiner should be well qualified for the task from all points of view. M. M. Smith, Dallas, Texas, in a paper read before the Section on State Medicine and Public Hygiene, State Medical Association of Texas, at Amarillo, on May 11, 1912, discussed the matter. He pointed out that the local examiner should not only be well fitted professionally but that he should possess such firmness of character that he will report exactly what he finds, irrespective of either friendship for the applicant or the influence of the agent.

The medical directors of insurance companies are naturally presumed to be men learned in every particular line of medicine. Their duties as medical directors call for practical experience in medicine and surgery. It is the duty of the medical director to advise the insurance company whether to insure or not to insure an applicant; consequently, the responsibility resting upon him is much greater than the average person would imagine. He is supposed to have an all-seeing eye and to be possessed of more than ordinary intuition. The responsibility of the medical director, even with the assistance of competent local examiners, is very great. At times it appears that the business end of insurance companies expects too much at his hands, especially when an early entrant dies; but as a rule, he is given all the assistance and support needed from the other officials of the company. Reference is made to the great aid that insurance companies are giving in the endeavor successfully to solve many problems bearing on public health, as for instance, by the establishment, through the recommendations of their medical directors and others, of sanatoria for the care and treatment of tuberculosis. The value of tabulated statistics is emphasized and especially of those dealing with the circulatory system. Many cases have occurred which have gone a long way to show the value of taking the blood pressure in applicants or private patients over forty years of age.—*Texas State Journal of Medicine*, May, 1912.

Society Reports.

AMERICAN MEDICAL ASSOCIATION.

Sixty-third Annual Meeting, Held at Atlantic City, N. J., June 3, 4, 5, 6, and 7, 1912.

Special Report to the MEDICAL RECORD.

(Concluded from page 1167)

SECTION ON SURGERY.

Tuesday, June 4. First Day.

Afternoon Session.

The Hospital Problem.—Dr. THOMAS W. HUNTINGTON of San Francisco read this paper. He stated that the greater number of hospitals had not contributed as much to the general knowledge as their opportunities afforded; and therefore he suggested that the House of Delegates should appropriate funds to make an examination of all civil hospitals, and to report the results to the American Medical Association.

The Results of Operations, Especially Abdominal, Performed on the Principle of Anoci-Association.—Dr. GEORGE W. CRILE of Cleveland read this paper. He drew attention to the large stores of potential energy contained in the body, and to the fact that this energy was released and made manifest through associative memory or stimulations. These associations (stimuli) might be beneficial, when they would be called "bene-associations," or they might be harmful or noxious, when they would be called "noci-associations." He further stated that as surgical operations were performed to-day, they usually caused noci-associations; but that by special technique operations could be performed without the noci-associations, but with a neutral condition designated "anoci-association." Operations with special technique had been performed with remarkable results in the case of abdominal operations, of operations for Graves' disease, and of handicapped patients especially. The general operative mortality had also been reduced and the postoperative impairment had been greatly diminished.

Physiological Basis of Thoracic Operations.—Dr. JOSEPH M. FLINT of New Haven, Conn., read this paper. He spoke of typical thoracic operations that had been performed on dogs. During these operations the animals had been connected with a kymograph, which had given constant records of blood-pressure and respiration. By this means he determined the effect of positive pressure and of intratracheal insufflation with closed and open thorax. The pleura was opened under differential pressure; it was also opened without this differential pressure. The application of the rib spreader and manipulation of or traction on the lung were described. Ligation of the pulmonary lobe was made at the root. Crushing of the phrenic nerve, incision of the pericardium, the hemostasis of Sauerbach, stab wound of the heart, heart suture, packing off of lung with gauze, dissection of the vagi, and acute pneumatic dilatation of the stomach were all described.

Surgery of Chronic Infectious Diseases of the Lung.—Dr. SAMUEL ROBINSON of Boston read this paper. He spoke of the clinical and experimental investigations of problems associated with the treatment of bronchiectasis, chronic pneumonitis, and chronic abscess and tuberculosis of the lung. He stated that there was increasing evidence that the resection of lung tissue was most successful in cases in which previous shrinkage of the diseased portion had been either spontaneously or artificially produced. In cases in which this shrinkage occurred spontaneously, it resulted from hydrothorax, empyema, and pneumothorax. It might be artificially produced by rib resection, artificial nitrogen pneumothorax, or by ligature of the branches of the pulmonary artery. The speaker reported the results of operations for bronchiectasis, including rib resection, lung resection, and the production of artificial pneumothorax. He also gave the conclusions from a series of forty cases of phthisis treated by nitrogen injection. He gave the report, also, of experimental pulmonary arterial ligature and the operative results of twenty-five cases of extensive rib resection in animals. From deductions based on these clinical and experimental results, the speaker pointed out that these results tended to show that the immobilization and shrinkage theories were contributory in the solution of prevailing difficulties.

The Obliteration of Empyemic Cavities.—Dr. E. MOSER VON EBERTS of Montreal read this paper. He gave experimental evidence of the value of intrathoracic tension in the obliteration of pleural cavities. This was shown to apply in the obliteration of empyemic cavities, as well as of lung abscess cavities after closure of or in the absence of bronchial communication. The speaker also described the course of chronic unopened empyema. With reference to the tidal air test, he showed that the measurements of tidal air and complementary air were indices of the rate of obliteration. He also gave the technique of thoracotomy and of the application of negative tension dressing. He discussed the advantages of ambulatory treatment.

Abnormal Involution of the Mammary Gland.—Dr. W. L. ROBMAN of Philadelphia read this paper. He stated that the most frequent period when involution became abnormal in the mammary gland was after the fortieth year of life, though it was not rare in the decennium from thirty to forty. It was most frequent about the time of the menopause, when cancer was common. Abnormal involution was frequently bilateral, while cancer was not frequently bilateral. Abnormal involution was usually painful, but cancer was rarely so in the early stage. The speaker said that the breast varied in size, especially during menstruation, owing to the frequent association of cysts, and that discharge from the nipple was frequently present. Also that in pronounced cases of abnormal involution the superficial veins might be enlarged. He stated that abnormal involution resulted in cancer in at least 25 per cent. of all cases; from which fact it should be considered as a precancerous stage. The operation demanded was radical; its extent could be determined by frozen sections, together with careful microscopic examination of the breast after removal. Partial excision of the gland should never be practised.

Wednesday, June 5—Second Day.

An Aseptic Route to the Pituitary Body through the Orbital Vault.—Dr. L. L. MCARTHUR of Chicago considered the routes now used in getting to the pituitary body and showed that antisepsis could not be secured by using either the nasal or buccal route. By repeated experiments on the cadaver a supraorbital route was selected as one in which asepsis could be secured. In entering by this route the frontal arch, the roof of the orbit, and a corresponding part of the forehead were resected temporarily and the rest of the orbital roof was removed by subperiosteal excision. The frontal lobe was elevated by means of a spoon-shaped brain retractor and the pituitary tumor exposed by incision of the dura between the diverging optic nerves. Dr. McArthur cited three cases in which the operation by this route had been performed with gratifying aseptic condition maintained.

Aphasia and Agraphia in Some of Their Practical Surgical Relations.—Dr. C. K. MILLS of Philadelphia stated that this paper was along the line of accuracy and exactitude in the application of neurological diagnosis to surgical procedure. Anomia, he said, was of a peculiarly determinative and early positive character in growths of the midtemporal region. Partial word-deafness might be present, also inability to name the sensation felt; or there might be word, letter, or number blindness. In color aphasia the ability to match colors might be present, but inability to name the colors matched. Aphasia and agraphia, Dr. Mills explained, could give four or five different conditions in which the flap over Wernicke's zone could be opened in different positions.

Dr. EDWARD MARTIN of Philadelphia said that Dr. Mills had done great work in localization, and that he had but a few words to add to Dr. Mills' paper. He said, "The first question we ask in an operation is, 'Where shall we open?' And when the neurologist tells us to open at a certain spot, knowing that we shall find our growth there and at no other place, it is a great help." He also stated that the Murray cutting instrument fulfilled the requisites of speed and painlessness, and that there was no need to limit the size of the flap. The accurate localization of the neurologist might seem to indicate a smaller flap, but it would be of no especial advantage; and the larger flap enabled the surgeon to control hemorrhage and cut out traumatism, and there was no greater danger of complication than with the smaller flap.

Dr. Mills, in closing, cited two cases of Dr. Martin's which illustrated a point in surgery: In these two cases the tumors had been located in the agraphic region, and in one case paresis was present. The Wassermann and Noguchi tests had been used, and instead of operating, three injections of salvarsan were used in each case, effecting cures in both instances.

Preservation of Tissues and Its Application in Surgery.—Dr. ALEXIS CARREL of New York told of his experiments, conducted six years ago, in the preserving of tissues outside of the organism for the purpose of trans-

planting. The fact, he said, was known 200 years ago that tissues of mammals could be kept for several days in a humid atmosphere, and after transplanting would continue to grow. Experimental studies made by Paul Bert, Harrison, and Laewenhaeck have thrown light on the subject. Dr. Carrel stated that he had extirpated tissue on the 17th day of January and four months later the cells were still reproducing. The only way to determine whether a piece of tissue kept in cold storage was still alive was to place it again under its ordinary condition and see if it manifested life. Pieces put in cold storage for two, four, or six weeks were afterward transplanted into the bodies of dogs; for instance, a piece of the skin of a black dog was extirpated, kept in cold storage, and then transplanted into the body of a white dog. It contained latent life and soon became incorporated into the tissue of the white dog. Blood-vessels, skin, periosteum, spleen, heart, and glands had been preserved in this way; and skin, bone, and cartilage have been kept in large quantities by putting them in tubes with vaseline and placing the tubes in cold storage.

Dr. J. S. Davis of Baltimore said he had been able to preserve skin, bone, tendon, and cartilage by simple methods (placing in an ordinary refrigerator), and successfully transplanted after days and even weeks. This, he said, brought up the feasibility of iso- or heterografts. The opinion had been held that no tissue preserved longer than three weeks could be transplanted successfully, with which Dr. Davis did not agree. On the other hand, the transplantation of a full joint had been reported with excellent results. Dr. Davis did not believe that a mass of tissue as large as the knee joint could be transplanted without the blood and nerve supply being taken care of. Isografts, if obtained and transplanted with proper technique, should give satisfactory results. In the treatment of deformities and the correction of defects, especially of the face, transplantation of fat, cartilage, or bone could be successfully performed and with far better results than the insertion of foreign materials. Dr. Davis cited a case in which a boy of ten years, who through an accident had the lower fourth of the fibula destroyed, had bone transplanted with remarkable results. The lower part of the leg was covered with scar tissue which was opened so as to expose the upper end of the fibula, which was split longitudinally so as to expose one-third of the cartilage and part of the shaft. Bone graft was made, and although transplanted in scar tissue, the epiphyseal cartilage held intact and the bone was still growing. This result was very encouraging, to say the least.

Dr. Carrel, concluding, said that the work was still in the experimental stage. It was known what could be done in skin graft, and more would be known within the next few months about osteoplastic operations.

Cardiospasm.—Dr. H. S. Plummer of Rochester, Minn., stated that out of forty cases of cardiospasm under his observation in 1898 thirty-eight had dilatation of the esophagus. In a group of 136 cases there was a group with diffuse dilatation of the esophagus without anatomical stenosis; no gastric lesions. In another group with cardiospasm there were two with ulcer, two with syphilis, five with carcinoma. Almost without exception these cases were of a neurotic type, and many were hysterical. But diffuse dilatation had not followed cardiospasm.

Dr. Jesse Meyer of St. Louis stated that the esophagoscope and *x*-ray showed no possible anatomic stenosis, and he believed that the cardiospasm in these cases was a primary disturbance and the dilatation a secondary condition. The fact that these patients were relieved through complete relief of the spasm seemed to him to speak for the truth of this theory. The symptoms of dilatation manifested by the patient were the last to occur, and not the first. The first were those of obstruction. The question which arose, said Dr. Meyer, was: "What constitutes a cure?" Possibly in most of them the answer would be: "To bring about clinical or symptomic cure." But in most cases he doubted whether they were ever cured from an anatomical standpoint; that is, sacculation persisted. Dr. Meyer said he had had about fourteen of these cases, and eight of them were under more or less constant observation for periods ranging from one to four years. Three that had been under observation for four years he had seen only a few days previous to leaving St. Louis. He was able to demonstrate in all these cases by means of the *x*-ray that the sacculation remained practically the same size after the patient had been completely relieved of the obstructive symptoms for four years. This was demonstrated by an intragastric thin rubber bag, introduced into the esophagus, and bismuth with sour milk—he could introduce the same amount as before. Dr. Meyer had used, he said, the method of stretching or paralyzing the pericardium, using the size of the dilator and the manifestations of the patient as a guide.

Dr. Einhorn of New York said he had tried stretching at various times for years and finally devised an instrument that could be bent in the esophagus and it proved to be a success. After dilatation his patients could eat as well as anybody. Sometimes he could not reach the cardium.

Dr. Bassler of New York thought that cardiospasm might be a reflex expression of an organic disease of the esophagus, with ulcer at the lower end, or organic disease of the stomach, or ulcer nearby, just as pylorospasm might be the reflex expression of gallstone disease or of chronic appendicitis. Dr. Bassler said that the point he wished to make was: "Be sure no local pathology exists." He stated further that the *x*-ray helped very little until marked stenosis existed in the malignant disease. He said that, after general use of various forms of instruments for dilating, he believed in "forcible, complete dilatation of the cardium—its paralysis, possibly, in suitable cases." This Dr. Bassler considered a satisfaction to both the patient and the doctor.

Dr. Plummer, in closing, stated that most cases were due to spasm at the cardium, yet that it was not demonstrated; and that there was much evidence to contradict this theory. As to methods of dilating, he said we had to rely either on the pressure used or the size of the dilator. He had tried to use various sized dilators and opened them as a guide. He dilated each dilator to full size. Only one skilled in the use of the instrument should make a diagnosis by dilatation in a person over 35 years of age unless the history was of over two years' duration.

Tumors of the Small Intestine.—Dr. W. D. Haggard of Nashville presented this paper, in which he stated that tumors occurred in the small intestine only one-fourteenth as often as in the large intestine; also that cancer of the duodenum was rare, there having been only three in 1,000 cases of the small intestine. The average age at which tumors occurred was 43.9 10 years. Sarcoma occurred more often high in the intestinal tract; but carcinoma was more prone to occur near the cecum; and twice as often in men as in women. Sarcoma generally occurred under fifteen years of age and carcinoma was to be suspected in patients over forty. It was generally fatal, Dr. Haggard said, in the first nine months; metastasis resulted in 75 per cent. of the cases. Of seventy-seven cases of cancer in the intestines operated on between 1890 and 1900 less than 20 per cent. lived longer than six months. Other cases lived from one to nine years. Ileointussusception might occur. Report was made of a large sarcoma of the ileum in a boy of nine. Resection of the small intestine (forty-two inches taken out) resulted in recovery and freedom from recurrence at the end of two years.

Experimental Intestinal Obstruction.—Dr. J. A. Hartwell and Dr. J. P. Hoguet of New York presented this paper. Dr. Hartwell said they had arrived at the cause of death in uncomplicated clinical obstruction through a process of elimination. First, bacteriemia; second, loss of nervous control; and third, the so-called intoxication theory, were considered. He said they had thrown out the nervous cause, with reasons for considering it valueless, and had confined themselves to the study of bacteriology and toxemia. Along this line he stated that stagnated stomach contents were very poisonous if they obtained entrance into the intestinal tract, and death might result from absorption of these substances when the normal toughness of the mucosa had been destroyed. But their experiments with dogs had convinced them that the principal cause of death, without strangulation, was the extreme dehydration of tissues caused by the vomitus. Hence, the great value of injections of normal saline solution subcutaneously, often nearly one-tenth of the body weight per diem. These injections had a diuretic action on the kidneys and diminished dehydration of the tissues, enabling the dogs to live three weeks and longer with clamp applied to the lower duodenum. So, Dr. Hartwell said, they had abandoned their previous theory of poisonous substances entering the mucosa. The vomitus was a diluted mixture of bile and other secretions. Ordinarily dogs with complete obstruction in the lower duodenum lived but two or three days, vomiting in large quantities. If a quantity of saline solution slightly in excess of the vomitus was injected the dogs promptly returned to a state indicating simple starvation, living three weeks or more. The important element, therefore, was loss of water due to vomiting. The symptoms of toxemia were simply due to disintegration of tissues following this water loss.

Dr. ANGUS MCLEAN, of Detroit spoke of his experience with ileus and paralysis of the intestines following operation. He said it was not frequent, occurring in one case out of a thousand. Death was not due to toxemia or bacteriemia. The cause of death was generally loss of fluid, of blood, and of lymph. Ileus in the human being, he said, in which there was a pouring out of vomitus, had an effect on the sympathetic nervous system. What it was due to would be hard to say, but wherever there was a pouring out in such quantity Dr. McLean considered that enterostomy was the thing to do. These patients, he said, looked as though bleeding to death. He stated that he would do this operation with local anesthesia because in his experience almost all cases of ileus were confined to the small intestine. He thought if enterostomy were done promptly it would save about one-half of the unfortunates who now go down to destruction.

Dr. GRAY of Jersey City considered that death sometimes was due to shock and sometimes to toxemia not always to loss of fluid.

Dr. HARTWELL, concluding, said that their object was to eliminate certain points advanced as the cause of death in low obstruction, uncomplicated by strangulation of the intestinal wall, and that bacteriemia was excluded because there was no bacterial infection of the blood. Also, absorption of toxins in the pancreas, duodenum, etc., was excluded because after the death of the dogs no infection was found in these parts.

The Relation of the Duodenum to Surgery of the Stomach.—Dr. J. C. BLOODGOOD of Baltimore presented this paper, in which he stated that dilatation of the duodenum could be divided into three groups. In the first two the obstruction was at the root of the mesentery; in the third group the obstruction was both at the pylorus and at the root of the mesentery, and the contents of the duodenum could not be discharged into the stomach, and in this group, if not relieved immediately, there was physiological death, which was demonstrated by experimental work on animals. In practice the knowledge of these possibilities was important; acute dilatation of the duodenum, Dr. Bloodgood stated, occurred as a complication in the convalescence from certain infectious diseases, such as typhoid fever and pneumonia; also a not infrequent complication after operation. If not relieved it could produce death. He said he had seen death result from acute dilatation of the duodenum, even from secondary dilatation of the stomach after typhoid fever, pneumonia, or acute inflammatory rheumatism; and he thought these deaths could have been prevented by the use of the stomach tube. In the first two groups, acute and chronic, in which the obstruction was at the root of the mesentery, there might be hypersecretion of the stomach, also fluid due to gastric secretion. The important clinical fact to remember, he said, in the convalescence from operations, etc., was the possibility of this complication, and also the fact that vomiting was not always the initial symptom; but where a patient with a good pulse, convalescing from an infectious disease or from an operation, suddenly developed dilatation, examination should be made and a stomach tube passed. The relief would be immediate. Surgeons soon learned in what type to expect dilatation of the duodenum or stomach, and in those cases should pass a stomach tube within the first ten or twelve days as a routine. In trained hands the stomach tube could be passed, said Dr. Bloodgood, with very little discomfort to the patient, and in this way the surgeon could find the complication earlier and could shorten the period of the complication. If cases in which the stomach tube would not relieve, the stomach should be washed out and report made every twelve hours. To differentiate the group in which operative intervention was necessary Dr. Bloodgood said it was his experience that obstruction of the duodenum with secondary dilatation of the stomach was associated with high intestinal obstruction, and although the patient was kept comfortable for a day or two it was not relieved because the obstruction was further down. This was determined sometimes by washing out of the stomach and the administration of castor oil. The stomach tube, he said, was not used enough in medicine or surgery today. Resection of the colon, according to Dr. Bloodgood, was life-saving in the second group of obstructions; and the use of a rubber tube draining the duodenum oral to the point of obstruction was life-saving in the third group.

Dr. DRAPER of Rochester said it could be called a law that dilatation did not occur in any organ except at the point of obstruction. This was certainly true in animals, and he believed it to be true also in the human being. He believed that dilatation remote from the point of obstruction was due to physiological and chemical disturbance.

Gastroptosis and Its Surgical Treatment.—Dr. T. ROVSING of Copenhagen read an exhaustive paper on this disease—its pathology, signification and its surgical treatment. He said he had chosen a subject on which American and Danish surgeons had worked for many years with the same object in view. The symptoms of gastroptosis and coloptosis, he said, were constipation, first and most constant; cardialgia, vomitings, emaciation and a host of nervous symptoms, which were added little by little. He regarded these symptoms as the result of the ptosis, which he established by over 400 cases; others, however, regarded the ptosis as an irrelevant symptom, the diversity of opinion resting on the difference in the conceptions of the pathogeny of enteroptosis. Of the two theories held, the one by Glenard included a mysterious liver disease; and Stiller pronounced enteroptosis a feminine disease par excellence. As to symptomatology, Dr. Rovsing spoke of the wearing of corsets the first or second year after the commencement of puberty, with persistent constipation, weariness, headache, loathing of food, and later, cardialgia. The pathogenesis, in his opinion, was the lacing of the young girl's gracile, easily relaxing and plastic body in corsets, involving the deformation and straightening of the lower thoracic aperture, with shifting of sub-diaphragmatic organs. The pressure, he said, acted on the massive liver, and this again served to dislocate the organs below. Hertz has shown how the corset caused nephroptosis by utilizing the liver as a weight to tilt the right kidney out of its niche. That is why the majority of floating kidneys were on the right side; if the liver was pushed down, the stomach followed suit, and this caused pains on the left side of the epigastrium. Virginal ptosis, he said, was frequently mistaken in diagnosis for—first, ulcus ventriculi; second, colitis; third, nervous disease of the stomach or hysteria; and, more rarely, confused with cancer. Sometimes, it led to "hour-glass stomach." The solution of the long-disputed question of the pathogenesis of the "hour-glass stomach" was to be sought, Dr. Rovsing declared, in the fixation of the creases of the subsided stomach caused by corsets and laces. "It is due simply to adhesions which form themselves with folds of the serosa surfaces, which rest one upon the other." Maternal gastrocoloptosis: This, in women whose abdominal wall, consequent to past pregnancies and confinements, had become distended and relaxed. Everything, in this condition, depended upon the strength of the ligaments, as to whether gastroptosis would result. This, he said, differed from virginal gastroptosis in that the stomachic attacks, cardialgia and vomiting were far weaker, and often, indeed, absent, as the stomach was not jammed or liable to be folded and bent as in the virginal abdomen; so they didn't suffer the pains and nervous sensations which characterized the others. With maternal ptosis, the constipation and all its consequences were the dominant feature. The effect of autointoxication, in time, manifested itself; feeling of fatigue across the loins, constant pain in the left side of the epigastrium. Symptoms improved or vanished on confinement to bed. Treatment: Finally, Dr. Rovsing said, the question was whether the case would lend itself to bandage treatment, or whether it demanded operative procedure. Maternal ptosis might be helped, virginal ptosis was seldom helped by bandaging. The virginal abdominal wall was already strong and elastic, and too strong a pressure was needed to overcome its resistance, and was unendurable to the patient. Even the powerful belts, he said, which he recommended, were impotent with most virginal ptosis, as also with those particularly severe cases of maternal ptosis where the colon transversum had subsided right down into the small bowels and was therefore beyond the range of the belt, being squeezed rather than raised by it. The only help in all those cases, then, was from operative treatment. First, direct gastropexy; or, second, indirect operations which endeavored to raise the stomach either by basting together and shortening the omentum minus, or from below by stitching the omentum majus firmly to the anterior abdominal wall, which raised the stomach and colon. Direct gastropexy, in Dr. Rovsing's experience, had been the safest and best method, notwithstanding the theoretical attraction of the indirect method. Since 1897, when he performed this operation for the first time, until January 1, 1911, Dr. Rovsing had done 163 gastropexies; and information was received from Scandinavian surgeons of 93 operations performed in accordance with his method, making 256 operations, which had been traced and the condition of the patients since operation carefully examined. The mortality with gastropexy proper was only three in the 256 cases, or 1.17 per cent. Of the other eight who died two succumbed to tuberculosis of the lungs, four to bronchopneumonia, and two to ileus. Seventy-six out of the 163 cases Dr. Rovsing operated on were freed of their constipa-

to n of many years' standing, which had proved insensible to any other treatment. The table showing statistics of cases operated on showed that of 256 cases operated on 162, or 63.2 per cent. were completely cured, constipation and all symptoms disappearing; 33, or 12.8 per cent., experienced great improvement; 18, or 7 per cent., were improved; 32, or 12.8 per cent., were slightly improved; 11 died three from the operation, eight from other causes (given above). What still had great influence, according to Dr. Rovsing, on the results of gastropexy, was ptosis of the other abdominal organs, above all the liver and kidneys, which was so frequently present.

The liver subsided and lay across the stomach and its adhesion might not only cause pain, but ileus of the stomach, as in the case of one death reported by Hertel. In no less than 68 of Dr. Rovsing's cases he had to perform hepatopexy simultaneously with gastropexy. His technique, after comparing with that of Duret of Lille, was to make an incision through the skin and muscles to the umbilicus from the processus ensiformis, but he incised the peritoneum only in the lowest half of the wound, and fixed the lesser curvature of the stomach to the untouched part of the peritoneum parietale with three strong threads (Duret used but one) in and out of the stomach, leaving the pars pylorica free. The upper thread was drawn close under the lesser curvature and the two others with an interval of about two centimeters, were placed in such a way that the greater curvature and rather a large piece of the wall above this were left free. With a fine needle the serosa coating between the threads was then clarified in all directions, also the surface of the peritoneum parietale, and eventually that part of the underside of the liver to which he wished the stomach to adhere. The ends of silk were led out through the entire thickness of abdominal wall, the peritoneum joined with catgut, and fascia and skin with aluminum bronze. The silk sutures were tied over a glass plate a little larger than the stomach surface, so the stomach lay flat and close to the abdominal wall without shrinkage or folding. The threads were left four or five weeks, and then easily removed. Dr. Rovsing went on to say that death, in extirpation of the colon, was extremely great in comparison with that resulting from gastropexy. Gastrotomy, he said, was never indicated, as it did not strike at the cause of these cases, which lay in the large intestine.

The Functions of the Large Intestine.—Dr. W. B. Cannon of Boston read this paper, in which he said that many diseases of the blood arose from bacterial putrefaction in the colon. The main functions of the colon, he said, were those of storage and periodic riddance of waste, both mechanical motions. Absorption of water caused the consistency of waste to be more dense, and the contents of the transverse colon were as stiff as the discharge from the rectum. The movements of the proximal colon in the cat were characterized as antiperistaltic, backward toward the cecum, or antistaltic. The antistaltic waves rarely ran for a long time (only four or five minutes) then ceasing. They started at the nearest ring of a constriction; an additional feature being that the condition of their appearance was the pushing of a further mass of material from the small intestine into the colon, and distention of the constriction ring, causing it to pulsate, sending off a wave. Elliott and Barclay Smith made a study of this action in different classes of animals; they stated that in herbivorous animals the sacculation of the proximal colon was associated with kneading movements, each sacculus becoming, in time, the scene of waving oscillations. As to antistalsis in man, the human colon was sacculated as in the herbivorous animals rather than as in the carnivorous. Inferential evidence of antistalsis in the human proximal colon had been drawn from cases of cecal fistula, in which rectal enemas traversed the entire length of the colon and escaped at this point. Antistalsis, in the sense of possible waves, however, had not yet been proven in man, notwithstanding the above evidence; but Dr. Cannon said he was inclined to think it could occur. The tonic ring of prime importance in starting antistalsis was in the colon; the first portion of the large colon might therefore be regarded as a portion in which partial digestion might still be going on. The proximal colon contained normally, he said, a firm mass of material, which was pushed outward by a wave of antistalsis, of which there were in man, two methods: First, a wave onward, by sudden push; second, a small piece the size of a thumb separated from the mass and pushed slowly to and around the splenic flexure, and then down the descending colon. In man the changes during defecation had been studied by the *x*-ray method, and the entire portion of the large colon was found to evacuate at a single act, and free itself through an onward-pushing wave of the waste material accumulating in the distal colon, the pelvic colon rising and elevating the angle. Intraabdominal pressure was caused by the natural movements, the near-relation of the large intestine causing it to receive a tonic or motor impulse from the motor nerves.

Dilatation of the Large Bowel.—Dr. A. D. Bevan of Chicago presented this communication, in which he showed that chronic constipation produced dilatation and edema of the colon, especially of the cecum; colitis from fetal stagnation; pericolitis from adhesions; obstructive symptoms due to these adhesions with resulting colic. Lane's surgical treatment, as removal of the colon, could not be too severely condemned. Lane had, he said, devised an admirable technique for the removal of the colon, but he removed for constipation alone. Cases of movable cecum, with dilatation, he treated surgically by anchoring the cecum. The medical variety of chronic constipation, lacking the severe symptoms of colic, Dr. Bevan stated, was seen frequently, and was best treated naturally by exercise, massage, proper diet, cathartics, and enemas. Those cases of inveterate constipation were usually found in women, and, as a rule, were badly managed and could often be cured by simple means of exercise, massage, and diet. As to the cecum, bismuth in connection with the *x*-ray showed the position and condition of the cecum. If not evacuated in twenty-four hours, requiring thirty-six hours or more, it was said to be pathological. Also, if not in its normal position it was sewed or anchored into place. In dilatation of the cecum or the pouchy, low-lying cecum, the operation should be purely exploratory. After this operation, and the physician had made a definite diagnosis, then the condition could be cured. Surgically following the sequence of events Dr. Bevan said there were constipation, colitis, pericolitis, adhesions, obstructions. These were cases in which radical surgical measures were not only warranted, but demanded, and often curative. Where the adhesions were at the cecum or appendix the condition was generally mistaken for appendicitis, but a thorough understanding of the subject made diagnosis easy. Pericolitis, with obstruction, was best dealt with, Dr. Bevan declared, by dividing the adhesions and so-called membrane by colostomy or anastomosis between the ileum and the sigmoid, rarely by resection of the colon or artificial anus. Operations should not be solely based on the *x*-ray indication, for some of the bismuth lingered a little longer in the cecum than, in the opinion of the operator, it should. He said that surgeons should recognize and investigate with great care the large group of pericolitis cases which did exist; and properly interpret other symptoms due to pathological conditions which could be relieved by proper surgical methods.

Adhesions of the Colon.—Dr. M. L. Harris of Chicago read this paper, dividing the groups as, first, adhesions about the appendix; second, adhesions about the colon; and, third, adhesions about the mouth of the cecum. Incision, he said, should be large enough. In many cases the trouble was in the cecum or ascending colon instead of the appendix, adhesions being on the posterior surface of the cecum and the posterior wall of the ascending colon. Agglutination, he stated, was the cause of some of the adhesions. Membranous pericolitis, or Jackson's membrane, was characterized, Dr. Harris said, by pain and tenderness. Pericolitis occurred in young women, mostly, about 25 years of age. The colon bacillus found in cases of appendicitis played a minor part in this disease instead of being the chief offender as formerly thought. Further investigation was needed, but sufficient was known to warrant the assertion that many of these troubles on the right side of the abdomen were to be found in the flora of this tract.

Colonic Intoxication.—Dr. J. F. Binnie of Kansas City, Mo., considered the symptoms of this condition, which he said were various in different people. Lack of exercise, he said, produced the same symptoms as mild colonic intoxication. He cited the case of a man who continued from the time he left England until he reached Mexico (making the trip before the time of swift-sailing ocean greyhounds) without an evacuation. Such a condition would produce colonic intoxication, or any lack of balance between absorption and purification or elimination. An important general symptom is the staining of certain polymorphonuclear blood-corpuscles by Wright's stain, as observed by Hoxie. In case of inflammation, fever and localized rigidity of the muscles would be symptoms that might associate these inflammatory lesions with intoxication.

Diverticula of the Gastrointestinal Tract and Their Surgical Importance.—Dr. C. H. Mayo of Rochester, Minn., read this communication, in which he stated that diverticula, which might be true or false, congenital or acquired, were often present—the acquired type affecting the gastrointestinal tract. In the esophagus they were

common, he said, and were often overlooked. Rare in the lower third of the esophagus, in which they appeared on investigation only at post-mortem. Operation in two stages, Dr. Mayo said, was preferred for large sacs, and diverticula in the stomach appeared mostly at the apex. From 1902 until 1912, out of thirteen cases coming under Dr. Mayo's observation, ten were operated on and cured. Diverticulum of the intestine, he said, was now recognized as the occasional cause of serious disability and danger, probably a certain number of cancers of the large intestine developing from it. Diverticula were often multiple, something over 400 having been found in one individual. Dr. Mayo further stated that they were found twice as often in men as in women. Clinical symptoms appeared in 60 per cent. of cases, but usually the greater number of diverticula gave no symptoms during life. The appendix might have a diverticulum of its own. Search of the mucosa with a probe, he said, would show diverticula in tumors in the transverse colon. In the large intestine they were similar to hernia, and were due to pressure. Many cases, he said, originated in openings dilated by the passage of vessels into the bowel; congenital local defect in early life might give rise to this result. Diverticulum occurred, according to Dr. Mayo's statistics, one-seventh as often as cancer of the sigmoid, and sometimes cancer was grafted on the diverticulum. Therefore, it should be looked upon as a potent source of cancer.

The Rôle of Movable Kidney in Vascular and Intestinal Stasis.—Dr. K. A. J. MACKENZIE of Portland, Oregon, read this paper, in which he stated it was necessary for the colon to pass in front of and across the right kidney, allowing the extension of the right kidney over the peritoneum, and afforded too great movability to that kidney. Frequent ptosis of the kidney, he said, resulted from trauma. Several organs might be displaced, and ptosis begin below or above; ptosis of the colon might be caused by displacement of the kidney. The kidney, he said, was more frequently the organ of primary displacement than was generally supposed. A feature of ptosis of the kidney was augmented size and weight, which factors Dr. Mackenzie thought should receive consideration. A clinical fact, in hydronephrosis, especially in the female, was that its effect was to cause delay in the transmission of urine from the kidney, thereby augmenting the size and weight of that organ. Pressure on the intrinsic blood supply, he said, doubtless contributed an important element to the causes of ptosis. The progressive drag of the kidney on its own vascular supply, obliquely downward from above on the aorta, and the vena cava, the position of the pedicle being obliquely downward and forward—these caused progressive ptosis of the viscera, and stasis. Vascular disorders, according to Dr. Mackenzie, were further induced by displacement of the left kidney, pending downward and forward, those ptoses bringing about elongation and increase of weight and various associated disorders. Elongation of the intestines was due, he said, to continuous traction upon their ligaments, and their increased weight in part engendered by hypertrophy. Motility of the intestines was not seriously impaired, nor were catarrhal conditions present, which indicated enormous peristaltic activity. The causes of intestinal stasis, Dr. Mackenzie stated, on inspection of the viscera, swerved toward splenic ptosis. Congestion and edema of the mucosa presented reaction of function and blood supply, and vascular stasis brought about intestinal stasis rather than intrinsic intestinal disorder, as generally thought and too often. Operative intervention for the relief of splenoptosis was justified, declared Dr. Mackenzie, if it relieved the condition and did not leave in its wake a condition worse than the original. The stomach should not be entered upward when the other organs were down. Timely operation, he said, would often relieve and prevent extension of the splenoptosis from one viscus to others.

Thursday, June 6—Third Day

Election of Officers.—The officers elected for the ensuing year were as follows: Dr. A. F. Jonas of Omaha, *Chairman;* Dr. W. L. Cousins of Portland, Oregon, *Vice-Chairman;* Dr. Dean Lewis of Chicago, *Secretary;* Dr. W. D. Haggard of Nashville, *Orator on Surgery;* Dr. Le Moyne Wills of Los Angeles, *Delegate to the House.*

Further Experimental and Clinical Work Bearing on the Value of Lane's Bone Plate.—Dr. WILLARD BARTLETT of St. Louis reported a series of experiments on dogs in the use of the Lane plate, especially in infected bone tissue. It took a pressure of but 41 pounds to dislodge the screw from dog bone. The fibula might remain intact and operate in very much the same manner as when the splint was used in the human body. Three series of four dogs were experimented on, with femur fractured and plated, the leg being amputated after death. After removal of the soft parts segments of bones covered by plate were dissected and screws unscrewed. In twelve of thirteen cases plates remained fastened to both fragments, in spite of infection and of the dogs being allowed to run at large. Both fragments were extremely tight. In five plates one or more screws were loose; in one plate, four screws; in three plates, three screws, and in one plate one screw was missing. A Lane plate put on a suppurating wound in the human body in four cases of compound fracture resulted as follows: The first patient recovered so he could walk without difficulty. The second patient had solid union and returned to work. The third case recovered in three months, as did the fourth case, with a low fracture of the tibia. Often anchorage could not be found on cortex. Patients developed no serious reaction, due partly, Dr. Bartlett thought, to the fact that the wounds were flooded with iodine after the screws were applied.

Operative Treatment of Fractures and Dislocations.—Dr. F. J. COTTON of Boston read this paper, stating that in fractures into or near joints the restoration of joint function came foremost, the esthetic object being secondary. Non-union in joints came, he said, from failure of contact, causing lack of formation of clot and callus. Impacted fractures of the anatomical neck were best left alone, bacterial invasion pulling the lower fragment in. The proper thing to do in the great majority of cases was to cut down and reduce and then suture suitably together. Fractures close above the ankle, he said, must be operated on and plated. In fractures involving the joint there was no excuse for plating, correction of the joint as a whole was indicated. Dr. Cotton said he believed thoroughly in operation on joint fractures and said it had been part of his work for eight years past. But surgeons should not keep on with open work, because that had not kept up with other methods. If they could not reduce sufficiently otherwise then it was well to operate and reduce. In joint fractures more than shaft fractures the use of foreign materials was undesirable.

Operative Treatment of Fractures and Dislocations.—Dr. WILLIAM DARRACH of New York presented this communication, in which he referred to the convention, of three years previous, when Dr. Lane said all fractures should be treated by the open method, and declared that the courts would compel surgeons to use this method. Dr. Darrach said he did not agree with Dr. Lane that all or nearly all fractures should be treated by the open method. In the Roosevelt Hospital, he said, they considered that most fractures should be treated by the closed method, but that in certain cases the open method might be employed to advantage. He said there were three classes of these: A, open reduction of recent cases; B, open reduction of old cases; C, cases in which they did not treat to reduce but to correct the deformity resulting from fracture. In the first class, if a satisfactory reduction could not be obtained and maintained by the closed method, the fracture or dislocation should be operated on—no contraindication being present. In transverse fracture of the femur, where the edges engaged, and the patient had a useful and strong limb, why should an operation be performed? Satisfactory reduction might be defined as where increase in the range and degree of deformity by the closed method did not warrant the risk of an operation. "When to operate," Dr. Darrach said, could be answered by saying, "After the body has got its breath; after bleeding has stopped, and good, healthy reaction has set in." Too early operation should be avoided, and the body should be spared a second trauma too soon. Also, too light operations should be avoided. Somewhere between the fifth and fifteenth day, he stated, was the best time to operate; and unless a man was able and willing to carry out the exaggerated technique which Dr. Lane advised, he had no right to operate on a fracture. That, he said, was the only way to obviate the deformities that seemed to hover around bone work. No appliance should be left near the bone, if possible to avoid it; in 57 fractures treated by the open method, no appliance was used in 21 of the cases. Plates were used in only 28 per cent., or 16 fractures. Prompt union, Dr. Darrach declared, came a little more slowly in fractures that had been opened. When plates were used, there should be no strain on them as even a slight pull, if continued, would loosen the screws. In old cases a non-reducing operation should be done, if possible. The technique should be carefully followed out, because with even the open method the operations were not always successful.

The Surgery of Bones and Joints.—Dr. L. W. ELY of Denver contributed this paper, in which he drew attention to the fact that in comparison with other branches

of surgery, the knowledge of diseases of bones and joints and fractures had lagged behind, in pathology, symptomatology, and diagnosis. This, he said, was due to reliance on clinical experience. "We owe little," said Dr. Ely, "to clinical experience; too little to rely upon it." It was hard, he further declared, to overestimate the importance of correct work on bones and joints, for if a joint was dissected unnecessarily, or a limb amputated, the surgeon partially destroyed the patient's usefulness for life. Laboratory examination of 100 specimens of bones and joints, together with histories of cases, gave valuable information, and was thorough because based on careful pathological work. Six tissues were to be studied in diseases of bones and joints: bone tissue proper, marrow, periosteum, cartilage, synovia, and ligament. Bone tissue, he said, was the same wherever found, and varied only in arrangement and amount. It was not, itself, subject to inflammation, but simply responded to the action of its contained marrow. This passive rôle of the bone-tissue was recognized, Dr. Ely said, except at the ends. Then, studying the bone itself, carcinoma often started where the epithelium changed. He said there were two kinds of marrow generally found in bone. If it was recognized that marrow was the essential factor in all bone disease, and it was borne in mind where each kind of marrow was found, the diseases of bone would be recognized. Rapid growth predisposing to infection of bone should be put aside; and study should be made of the marrow at various periods of life and in its vulnerability to infection. Tuberculosis, he said, affected the synovia and lymphatic marrow. He stated that there had been much discussion on the subject of joint cartilage; and that he would not attempt to go into details, but that his personal opinion was that the cartilage was not subject to inflammation or directly to disease; that its role was always a passive one.

The Treatment of Fractures Near to or into Joints.—As Dr. H. M. Sherman of San Francisco was not present, Dr. John B. Murphy of Chicago took up the discussion of this subject, showing a series of photographs taken of cases on which he had operated. He said that 85 to 90 per cent. of the bad results following Colles' fracture were due to defective reduction. More awful even than Colles' fracture was the fracture in the neighborhood of the elbow joint.

An Operation for Pott's Disease of the Spine.—Dr. R. A. Hibbs of New York read this paper, in which he spoke of the value of casts, etc., limiting motion in cases of Pott's disease; but he said they did not secure absolute immobilization of the diseased joints of the vertebræ, and left much still to be desired. In almost every case, he said, the deformity increased to a greater or less extent. Then it was sought to devise a method that would absolutely eliminate motion of the diseased vertebræ, and give promise of radical cure of the disease and removal of the deformity. He stated that the posterior aspects of the vertebræ were left free for fusion of the spinous processes and laminæ, as the disease affected the bodies of the vertebræ alone. Therefore, he had performed an operation in which incision was made over the kyphosis through skin, supraspinous ligament, and periosteum to the tips of the spinous processes. The periosteum was split over the upper and lower border of the spinous processes and laminæ and stripped from them to the base of the transverse processes. Then the spinous processes were transplanted, after partial fracture, to bridge the gap between the vertebræ. The periosteum and split supraspinous ligament were sutured together in the middle, and the diseased vertebræ were anchored above and below to the healthy ones, so that all the structures concerned were preserved in one bone growth, making certain the fusion of the spinous processes and the laminæ of the vertebræ operated on, and eliminating motion between them, insuring rapid cure. Photographs of cases operated on were shown, the operations being successful in that cure of the disease was effected and the deformities greatly reduced.

Afternoon Session.

JOINT MEETING WITH THE SECTION ON MEDICINE

The Internal Secretion of the Pancreas.—Dr. J. H. Pratt of Boston stated that the attempts to obtain an internal secretion from the pancreas had all failed. Experiments spoke strongly against the neurogenic theory. By depancreating the dog, an effect was observed on the sympathetic nervous system. Chemical relation existed, he said, between the thyroid gland and the sexual functions. In his experiments, Dr. Pratt stated that the theory that the pancreas furnished an internal secretion seemed to be supported by cases in which the organ was partially or totally extirpated, also by cases in which extract of pancreas was injected subcutaneously and into the spleen, or in which pancreatic preparation were fed.

The Anatomical and Physiological Effects of Iodine on the Thyroid of Exophthalmic Goiter.—Dr. David Marine of Cleveland presented this paper, in which he stated that he had examined 137 operative and post-mortem specimens of thyroid, and the symptom-complex, as at present diagnosed, was not constant in changes in the thyroid body; the opinion was again returning that the symptom-complex might be present in a gland actively hyperplastic, and in glands consisting of tumors either benign or malignant, or which are atrophied. Ordinary goiters were of long standing and reported in the involution stage. Following the administration of iodine in goiter, there was storage of iodine in the thyroid. It was impossible, he said, to ascertain whether iodine induced the same effects on a hyperplasia of exophthalmic goiter after it induced a reduction in size of the thyroid gland following its use. Out of 160 thyroids, in those known to receive iodine there was definite storage of iodine within the gland and involution of active hyperplasia. Therefore, one could certainly conclude, Dr. Marine said, that physiologically as well as anatomically, there was as yet no known attribute of the thyroid in exophthalmic goiter that might not be associated with the thyroid in any other condition.

The Functional Activities of the Adrenals.—Dr. S. J. Meltzer of New York read this paper, in which he stated that little was known of these bodies; some hundred years ago they were thought to be the organ for secreting black bile. In 1893 Oliver told of the discovery of adrenalin, which, Dr. Meltzer said, should be named adrenin. He further stated that we did not know yet what the adrenals were for. Animals deprived of the adrenals died in a period varying from 12 hours to four days.

Function of the Parathyroid Glands.—Dr. W. G. McCallum of New York presented this communication, in which he said the parathyroid glands lay one on each side of the thyroid gland, and were supplied by the thyroid blood-vessels; ordinarily they were soft, flat, brownish structures, he stated, not difficult to recognize with the naked eye, though they seem but accessory nodules to the thyroid. They were twice discovered; their lodgment near the thyroid gland, and the name parathyroid glands had burdened them with the thought that they were part of the thyroid gland, whereas they were quite as separate, said Dr. McCallum, as the adrenals or the thyroids, or any other organs of internal secretion. Study of them was carried out by extirpation and it was learned that symptoms of atony might arise from other causes than the removal of the parathyroid glands. After the parathyroids were removed from dogs, nothing was evident for the first day or two; but hyperexcitability of the nerves appeared, and increased to a climax, especially striking in the motor nerves, but also seen in the sympathetic and sensory. As the climax was reached there were twitchings of the muscles, tremors of the tongue, etc., until the muscles were thrown into a rigid condition and convulsions. Fever was produced by the violent muscular contraction. The animal might die, or recover through sheer fatigue, but die later from a sort of poisoning in addition to striking muscular symptoms.

Friday, June 7—Fourth Day.

Thrombophlebitis of the Left Leg.—Dr. H. D. Kistler of Butte, Montana, spoke of the etiology of this condition, stating that the main points to be considered were: changes in the blood, changes in the vessel walls, and retardation or stoppage of the blood current. Thrombophlebitis occurred more frequently in the left leg than in all other parts of the body combined, because, he said, of the peculiar relations of veins and arteries on that side, the left external iliac vein at its termination being surrounded by an elastic arterial constricting circle which might very easily arrest the circulation in it.

New Method of Suturing Blood-Vessels.—Dr. J. S. Horsley of Richmond, Va., spoke of the need of a technique of suturing which would permit of successful operations in emergencies, where delicate manipulations were impossible, but where the sutures could be held at the proper angle and at the same tension throughout the operation. The method he described made use of the continuous mattress suture, where even approximation of the intima could be secured, making it particularly successful in the transfusion of blood where the artery was liable to contract because of exposure; a small probe could be inserted (with this method) through a branch of the vein, by means of which the artery could be easily dilated.
